Rang & Dale's Pharmacology Tenth Edition Preface

Section 1. GENERAL PRINCIPLES

---

1. What is pharmacology?

- What is a Drug?
- Origins and Antecedents
- Pharmacology in the 20th and 21st Centuries

2. How drugs act: general principles

- Introduction
- Protein Targets for Drug Binding
- Desensitisation and Tolerance
- Quantitative Aspects of Drug–Receptor Interactions
- The Nature of Drug Effects

3. How drugs act: molecular aspects

- Protein Targets for Drug Action
- Receptor Proteins
- Ion Channels as Drug Targets

Control of Receptor Expression

Receptors and Disease

4. How drugs act: cellular aspects – excitation, contraction and secretion

Regulation of Intracellular Calcium

Excitation

Muscle Contraction

Release of Chemical Mediators

Epithelial Ion Transport

5. How drugs act: biopharmaceuticals and gene therapy

INTRODUCTION

PROTEIN AND PEPTIDE BIOPHARMACEUTICALS

OLIGONUCLEOTIDES

GENE THERAPY

SAFETY AND SOCIETAL ISSUES

THERAPEUTIC APPLICATIONS

FUTURE DIRECTIONS

6. Cell proliferation, apoptosis, repair and regeneration

Cell Proliferation

Angiogenesis

Apoptosis and Cell Removal

Pathophysiological Implications

Therapeutic Prospects

7. Cellular mechanisms: host defence

Introduction

The Innate Immune Response

The Adaptive Immune Response

Systemic Responses in Inflammation

8. Method and measurement in pharmacology

BIOASSAY

ANIMAL MODELS OF DISEASE

PHARMACOLOGICAL STUDIES IN HUMANS

CLINICAL TRIALS

CLINICAL CONSIDERATION OF BENEFIT AND RISK

9. Absorption and distribution of drugs

Introduction

Physical Processes Underlying Drug Disposition

Drug Absorption and Routes of Administration

Distribution of Drugs in the Body

Special Drug Delivery Systems

10. Drug metabolism and elimination

INTRODUCTION

DRUG AND METABOLITE EXCRETION

11. Pharmacokinetics

Introduction: Definition and uses of Pharmacokinetics

Drug Elimination Expressed as Clearance

Single-Compartment Model

More Complicated Kinetic Models

Population Pharmacokinetics

Limitations of Pharmacokinetics

12. Individual variation, pharmacogenomics and personalised medicine

Introduction

Epidemiological Factors and Inter-Individual Variation of Drug Response

Genetic Variation in Drug Responsiveness

Therapeutic Drugs and Clinically Available Pharmacogenomic Tests

Conclusions

Section 2. CHEMICAL MEDIATORS

13. Chemical mediators and the autonomic nervous system

Historical Aspects

The Autonomic Nervous System

Some General Principles of Chemical Transmission

Basic Steps in Neurochemical Transmission: Sites of Drug Action

14. Cholinergic transmission

Muscarinic and Nicotinic Actions of Acetylcholine

Acetylcholine Receptors

Nicotinic Receptors

Physiology of Cholinergic Transmission

Effects of Drugs on Cholinergic Transmission

15. Noradrenergic transmission

Catecholamines

Classification of Adrenoceptors

Physiology of Noradrenergic Transmission

Drugs Acting on Noradrenergic Transmission

16. 5-Hydroxytryptamine and the purines

5-Hydroxytryptamine

Clinical Conditions in Which 5-HT Plays a Role

Purines

Purinergic Receptors

The Purinergic System in Health and Disease

Purines as Neurotransmitters

Summary

17. Local hormones: histamine, lipids, peptides and proteins

Introduction

What is a ‘Mediator’?

Histamine

Eicosanoids

Leukotrienes

Other Important Fatty Acid Derivatives

Platelet-Activating Factor

Sphingosine 1-Phosphate

Protein and Peptide Mediators

Biosynthesis and Regulation of Peptides

Bradykinin

Neuropeptides

Cytokines

Proteins and Peptides that Down-Regulate Inflammation

Concluding Remarks

18. Cannabinoids

Plant-Derived Cannabinoids ('Phytocannabinoids') And Their Pharmacological Effects

Cannabinoid Receptors

Endocannabinoids

Synthetic Cannabinoids

Clinical Applications

19. Nitric oxide and related mediators

Introduction

Biosynthesis of Nitric Oxide and its Control

Degradation and Carriage of Nitric Oxide

Effects of Nitric Oxide

Therapeutic Aspects

Clinical Conditions in Which Nitric Oxide May Play a Part

Related Mediators

Section 3. DRUGS AFFECTING MAJOR ORGAN SYSTEMS

20. The heart

Introduction

Physiology of Cardiac Function

Autonomic Control of the Heart

Cardiac Natriuretic Peptides

Ischaemic Heart Disease

Drugs that Affect Cardiac Function

21. The vascular system

Introduction

Vascular Structure and Function

Control of Vascular Smooth Muscle Tone

Vasoactive Drugs

Clinical Uses of Vasoactive Drugs

22. Atherosclerosis and lipoprotein metabolism

Introduction

Atherogenesis

Lipoprotein Transport

Prevention of Atheromatous Disease

Lipid-Lowering Drugs

Antisense Oligonucleotides

23. Haemostasis and thrombosis

Introduction

Blood Coagulation

Drugs that Act on the Coagulation Cascade

Platelet Adhesion and Activation

Fibrinolysis (Thrombolysis)

24. Haematopoietic system and treatment of anaemia

Introduction

The Haematopoietic System

Types of Anaemia

Haematinic Agents

Haematopoietic Growth Factors

Haemolytic Anaemia

25. Anti-inflammatory and immunosuppressant drugs

Introduction

Cyclo-Oxygenase Inhibitors

Antirheumatoid Drugs

BIOLOGIC DISEASE-MODIFYING ANTIRHEUMATIC DRUGS, ANTICYTOKINE DRUGS AND OTHER

BIOPHARMACEUTICALS

Drugs Used in Gout

Antagonists of Histamine

Possible Future Developments in Anti-Inflammatory Therapy

26. Skin

Introduction

Structure of Skin

Common Diseases of the Skin

Drugs Acting on Skin

Principal Drugs Used in Skin Disorders

Agents Acting by Other Mechanisms

Concluding Remarks

27. The eye

Introduction

Special Pharmacokinetic Considerations in the Eye

Treatment of Inflammation and Infection in the Eye

Control of Intraocular Pressure and Treatment of Glaucoma

Ocular Vasculature and Vascular Endothelial Growth Factor Inhibitors

28. Respiratory system

The Physiology of Respiration

Pulmonary Disease and its Treatment

29. The kidney and urinary system

Introduction

Outline of Renal Function

The Structure and Function of the Nephron

Drugs Acting on the Kidney

Drugs that Alter the pH of the Urine

Drugs that Alter the Excretion of Organic Molecules

Drugs Used in Renal Failure

Drugs Used in Urinary Tract Disorders

30. The gastrointestinal tract

The Innervation and Hormones of the Gastrointestinal Tract

Gastric Secretion

Vomiting

The Motility of the GI Tract

Drugs for Chronic Bowel Disease

Drugs Affecting the Biliary System

Future Directions

31. The control of blood glucose and drug treatment of diabetes mellitus

Introduction

Control of Blood Glucose

Pancreatic Islet Hormones

Diabetes Mellitus

32. Obesity

Introduction

Obesity as a Health Problem

Homeostatic Mechanisms Controlling Energy Balance

The Pathophysiology of Human Obesity

Pharmacological Approaches to the Problem of Obesity

New Approaches to Obesity Therapy

33. The pituitary and the adrenal cortex

The Pituitary Gland

The Adrenal Cortex

New Directions in Glucocorticoid Therapy

34. The thyroid

Synthesis, Storage and Secretion of Thyroid Hormones

Regulation of Thyroid Function

Actions of the Thyroid Hormones

Transport and Metabolism of Thyroid Hormones

Abnormalities of Thyroid Function

Drugs Used in Diseases of the Thyroid

35. The reproductive system

Introduction

Endocrine Control of Reproduction

Drugs Affecting Reproductive Function

Drugs Used for Contraception

The Uterus

Erectile Dysfunction

36. Bone metabolism

Introduction

Bone Structure and Composition

Bone Remodelling

Disorders of Bone

Drugs Used in Bone Disorders

Section 4. NERVOUS SYSTEM

37. Chemical transmission and drug action in the central nervous system

Introduction

Chemical Signalling in the Nervous System

Targets for Drug Action

Drug Action in the Central Nervous System

The Classification of Psychotropic Drugs

38. Amino acid transmitters

Excitatory Amino Acids

Glutamate

γ-AMINOBUTYRIC ACID

Glycine

Concluding Remarks

39. Other transmitters and modulators

Introduction

Noradrenaline

Dopamine

5-Hydroxytryptamine

Acetylcholine

Purines

Histamine

Other CNS Mediators

A Final Message

40. Neurodegenerative diseases

Protein Misfolding and Aggregation in Chronic Neurodegenerative Diseases

Mechanisms of Neuronal Death

Ischaemic Brain Damage

Dementia

Parkinson's Disease

Essential Tremor

Huntington's Disease

Amyotrophic Lateral Sclerosis

Spinal Muscular Atrophy

Multiple Sclerosis

41. General anaesthetic agents

Overview

Introduction

Mechanism of Action of Anaesthetic Drugs

Intravenous Anaesthetic Agents

Inhalation Anaesthetics

Individual Inhalation Anaesthetics

Sedation and Balanced Anaesthesia

42. Headache

Headache

Types of Headaches

Drug Therapy for Headache

Summary

43. Analgesic drugs

Introduction

Neural Mechanisms of Pain

Analgesic Drugs

Chronic Pain

44. Local anaesthetics and other drugs affecting sodium channels

Local Anaesthetics

Other Drugs That Affect Sodium Channels

45. Anxiolytic and hypnotic drugs

The Nature Of Anxiety And Its Treatment

Measurement Of Anxiolytic Activity

Drugs Used To Treat Anxiety

Delayed Anxiolytic Effect Of Drugs Acting Via Serotonergic Mechanisms

Drugs Used To Treat Insomnia (Hypnotic Drugs)

46. Antiepileptic drugs

Overview

Introduction

The Nature of Epilepsy

Antiepileptic Drugs

Muscle Spasm and Muscle Relaxants

47. Antipsychotic drugs

Introduction

The Nature of Schizophrenia

Antipsychotic Drugs

Future Developments

48. Antidepressant drugs

The Nature of Depression

Theories of Depression

Antidepressant Drugs

Clinical Effectiveness of Antidepressant Treatments

Future Antidepressant Drugs

Brain Stimulation Therapies

Drug Treatment of Bipolar Disorder

49. Psychoactive drugs

Introduction

Psychomotor Stimulants

Cognition-Enhancing Drugs

Psychedelic Drugs

Dissociative Drugs

Depressants

Synthetic Cannabinoid Receptor Agonists

50. Drug use and addiction

Drug Use

Harm Reduction

Section 5. DRUGS USED FOR THE TREATMENT OF INFECTIONS AND CANCER

---

51. Basic principles of antimicrobial chemotherapy

- Background
- The Molecular Basis of Chemotherapy
- Resistance to Antibacterial Drugs
- Current Status of Antibiotic Resistance in Bacteria

52. Antibacterial drugs

- INTRODUCTION
- ANTIBACTERIAL AGENTS THAT INTERFERE WITH FOLATE SYNTHESIS OR ACTION
- β-LACTAM ANTIBIOTICS AND OTHER AGENTS THAT INTERFERE WITH BACTERIAL WALL OR MEMBRANE SYNTHESIS
- ANTIMICROBIAL AGENTS AFFECTING BACTERIAL PROTEIN SYNTHESIS
- ANTIMICROBIAL AGENTS AFFECTING TOPOISOMERASE
- MISCELLANEOUS ANTIBACTERIAL AGENTS
- ANTIMYCOBACTERIAL AGENTS

PROSPECTS FOR NEW ANTIBACTERIAL DRUGS

53. Antiviral drugs

Background Information About Viruses

The Host–Virus Interaction

HIV and AIDS

COVID-19

Antiviral Drugs

Combination Therapy For HIV

COVID-19 Pharmacotherapy

Prospects for New Antiviral Drugs

54. Antifungal drugs

Fungi and Fungal Infections

Drugs Used to Treat Fungal Infections

Future Developments

55. Antiprotozoal drugs

Background

Host–Parasite Interactions

Malaria and Antimalarial Drugs

Amoebiasis and Amoebicidal Drugs

Trypanosomiasis and Trypanocidal Drugs

Other Protozoal Infections and Drugs Used to Treat Them

Future Developments

56. Antihelminthic drugs

Helminth Infections

Antihelminthic Drugs

Resistance to Antihelminthic Drugs

Vaccines and Other Novel Approaches

57. Anticancer drugs

Introduction

The Pathogenesis of Cancer

General Principles of Cytotoxic Anticancer Drugs

Anticancer Drugs

Future Developments

Section 6. SPECIAL TOPICS

58. Harmful effects of drugs

- Introduction
- Classification of Adverse Drug Reactions
- Drug Toxicity
- Immunological Reactions to Drugs

59. Lifestyle and drugs in sport

- What are Lifestyle Drugs?
- Classification of Lifestyle Drugs
- Cognitive Enhancers
- Drugs and Sex
- Drugs in Sport
- Regulatory, Societal and Ethical Issues
- Conclusion

60. Drug discovery and development

- Drug Discovery: Background
- The Stages of a Project

Biopharmaceuticals

Commercial Aspects

Future Prospects

A Final Word

In conversation with Humphrey Rang
Interview with Humphrey Rang of *Rang & Dale's Pharmacology* textbook. In discussion with David MacEwan, Humphrey recalls the history and development of the textbook and reflects on his distinguished career.

In conversation with Jim Ritter
Interview with Jim Ritter, author of *Rang & Dale's Pharmacology* textbook. In discussion with David MacEwan, Jim reflects on how the textbook has developed during his time as one of the longest-serving authors.

In conversation with Rod Flower
Interview with Rod Flower, one of the earliest authors of *Rang & Dale's Pharmacology* textbook. In conversation, Rod reflects on changes during his time working on the popular textbook.

In conversation with Graeme Henderson

Interview with Graeme Henderson, author of *Rang & Dale's Pharmacology* textbook. Here, Graeme reflects on how the textbook has developed during his time as its Editor and how *Rang & Dale's Pharmacology* has impacted the teaching of pharmacology and drug use over the years.

In conversation with Yoon Loke

Interview with Yoon Loke, author of *Rang & Dale's Pharmacology* textbook. In dialogue with David MacEwan, Yoon discusses his experiences co-authoring the successful textbook and how it has influenced teaching of pharmacology to medical students.

In conversation with Emma Robinson

Interview with Emma Robinson, one of the most recent co-authors of *Rang & Dale's Pharmacology* textbook. In discussion, Emma discusses her early impressions as co-author of the successful book, and how she tries to incorporate her own teaching method into the textbook.

In conversation with James Fullerton

Interview with James Fullerton, co-author of *Rang & Dale's Pharmacology* textbook. In discussion with David MacEwan, James discusses his impressions of the textbook and how it influences how medical school students learn about drugs, applying that knowledge in the clinic.

Pharmacology in practice: clinical overdose

Topic video with Adam Danashmend, clinical registrar in London. Adam gives his advice on the importance of

pharmacology to doctors, and opioid overdose cases in the clinic.

Pharmacology in practice: role of pharmacology in undergraduate medical education

Dr Mohammad Sarwar describes the clinical use of anaesthetics and pain relief in preoperative, operative and postoperative clinical settings, to inform students of the most appropriate drug combinations used by anaesthesiologists.

Pharmacology in practice: importance of chemistry, drug-receptor interactions and pharmacokinetics to people who use opioids

Rang & Dale author Graeme Henderson describes opioid use and misuse, outlining how agonists and antagonists are used on the street and the pharmacological knowledge underlying their use.

Pharmacology in practice: investigation of the frequency of narcotic misuse

Pharmacology graduate Meurig Shotton describes his project analysing the purity of narcotics and use of cutting-agents in social nonclinical settings, such as music festivals.

Topic: what are drugs and how do they work? Understanding receptor theory better

Rang & Dale author David MacEwan describes drugs, receptors and receptor theory in more depth to help students understand these pharmacology basics.

Topic: enzyme inducers and inhibitor – the logical approach

Rang & Dale author Yoon Loke describes how enzyme inducers and inhibitors have the ability to modify the actions of other drugs taken concurrently.

Inflammation case study

A 58-year-old woman is visiting her doctor to review her arthritis medication, which is no longer effectively controlling the symptoms of the condition.

What are the symptoms of rheumatoid arthritis (RA)?

RA is a chronic inflammatory condition involving swollen, painful and deformed joints, which affects patient activity and mobility. The inflammation is centred particularly on the joints with proliferation of the synovium and erosion of cartilage and bone.

What are the main cell types and inflammatory mediators involved in the progression of the disease?

Differentiation of T-helper 1 (Th1) cells leads to activation of macrophages, which release tumour necrosis factor-α (TNF-α) and interleukin 1 (IL-1), leading to the up-regulation of other inflammatory mediators. Th17 cells release proinflammatory IL-17. Activation of osteoclasts triggers bone erosion and resorption, exacerbating joint damage.

In the initial stages of the disease, patients may be given non-steroidal anti-inflammatory drugs (NSAIDs) to reduce/control the symptoms. Describe the therapeutic

actions of these drugs. How do these relate to their pharmacological actions? Why may these agents only have limited efficacy in controlling the symptoms of RA?

Anti-inflammatory – reduction of cyclo-oxygenase II (COX-2)–mediated prostaglandin (PG) release, resulting in a reduction in vasodilatation and oedema.

Antipyretic – NSAIDs reset the hypothalamic 'thermostat', which is dysregulated by IL-1-mediated PG release.

Analgesic – NSAIDs decrease PG release, which sensitises nociceptors to inflammatory mediators such as bradykinin.

The limited efficacy of the NSAIDs is due to their lack of direct effect on the underlying cause of the disease, which is largely mediated by cytokines/chemokines, leukocyte migration, lysosomal enzyme release and toxic oxygen radical production, rather than PGs.

RA is an autoimmune disease of uncertain aetiology, involving the recognition of self-antigen and inappropriate, chronic activation of the immune system.

Briefly outline the role of the innate and adaptive system in disease recognition, response and progression.

Cells and mediators of the innate immune system account for the inflammatory component of the disease. Movement of neutrophils and monocytes from the blood into the tissues and the release of pro-inflammatory mediators such as IL-1 and TNF are the main drivers of the condition.

Activation of T cells by presentation of self-antigen and secretion of IL-2 leads to a Th1 and cytotoxic T cell (TC)–mediated response, which further enhances macrophage inflammatory activity and causes tissue damage, and a Th2 response leading to B-cell activation and the production of self-reactive antibodies.

Following the failure of NSAIDs to maintain control of the disease symptoms, the patient was prescribed methotrexate. Outline the rationale for the use of this agent in RA.

Methotrexate is a disease-modifying antirheumatic drug that results in improvement of the symptoms and a reduction in disease activity, as measured by a decrease in the number of swollen joints, pain levels and disability. Methotrexate is a folic acid antagonist with cytotoxic (higher dose) and immunosuppressive (lower dose) activity. However, its immunosuppressive effect is unrelated to its effect on folic acid but may well be connected with its ability to block adenosine uptake and hence increase circulating adenosine which has anti-inflammatory actions.

Many patients fail to respond to methotrexate alone and effective control of the condition requires the co-administration of a glucocorticoid or biopharmaceutical agent. Outline the rationale for the use of each of the following in the treatment of RA, with reference to their molecular target and mechanism of action in dampening the immune response.

Prednisolone
Adalimumab

Abatacept
Rituximab

Prednisolone – a glucocorticoid that exerts anti-inflammatory effects through the suppression of IL-2 production and T-cell clonal proliferation. It also decreases the transcription of several inflammatory mediators (e.g. TNF-α and IL-1) through the inhibition of transcription factors nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB) and activator protein-1 (AP-1).

Adalimumab – a humanised monoclonal antibody that neutralises excess TNF-α· to prevent its inflammatory effects.

Abatacept – a fusion protein that downregulates T-cell activation by blocking co-stimulatory activation molecules.

Rituximab – a chimeric antibody that targets and causes lysis, so reducing T-cell activation and antibody production (including reduced rheumatoid factor).

Cardiovascular case study

A 58-year-old man has been rushed into hospital with a suspected myocardial infarction (MI).

What is the cause of the MI?

The occlusion of a coronary artery by a thrombus (in vivo blood clot) resulting in a decrease in oxygen supply and subsequent death of the downstream cardiac tissue.

What, often asymptomatic, condition may have led to the MI? Briefly outline the process by which this may have occurred and the key mediators involved.

Atheromatous disease leading to the rupture of an atheromatous plaque.

Atheromatous disease is predisposed by endothelial dysfunction with decreased nitric oxide (NO) production. Endothelial injury leads to the expression of adhesion molecules and monocyte attachment. Low-density lipoprotein (LDL) cholesterol is transported into the vessel wall and oxidised by monocyte free radicals. The oxyLDL is taken up by macrophage scavenger receptors resulting in cellular activation and release of proinflammatory mediators. Sub-endothelial accumulation of macrophage 'foam cells' and T cells produces fatty streaks.

Cytokine and growth factor release by activated cells and platelets causes deposition of connective tissue components and the formation of a fibrous cap overlaying the plaque. Subsequent plaque rupture can lead to the formation of a thrombus (involving platelet aggregation and thrombin activation of fibrinogen to fibrin), which travels through the arteries to the smaller coronary arterioles where it causes occlusion.

What risk factors may have contributed to this condition?

Modifiable risk factors are hypertension, dyslipidaemia (high LDL:high-density lipoprotein (HDL) ratio), type 2 diabetes and smoking.

How might the MI be clinically diagnosed?

By raised circulating levels of troponin which are indicative of myocardial injury.

If left untreated, what cellular changes would occur and what effect would this have on cardiac function?

Cell death would occur through a combination of necrosis and apoptosis.

Necrosis involves a decrease in ATP and ion pump activity and an increase in intracellular calcium, leading to protease activation and membrane damage. This can lead to dysrhythmias and decreased cardiac efficiency, which may result in complete heart failure and death.

Apoptosis is mediated via tumour necrosis factor-α (TNF-α), interleukin-1-converting enzyme (ICE)–related protease activation,

poly-[ADP-ribose]-polymerase (PARP) inactivation and DNA fragmentation. Apoptosis may be a protective mechanism to sacrifice some myocytes in the hope of preventing necrosis-induced dysrhythmias.

What would be the primary therapeutic aim in the treatment of this patient and how may this be achieved? (Consider both physical and pharmacological approaches and, where relevant, suggest appropriate agents and their pharmacological mechanisms.)

Opening the occluded artery is of key importance to prevent irreversible ischaemic damage.

This can be achieved using angioplasty – a catheter with an inflatable balloon at the tip coated with a glycoprotein IIb/IIIa antagonist to prevent reocclusion. Glycoprotein IIb/IIIa antagonists, such as the hybrid murine–human Fab fragment abciximab, inhibit all stages of platelet aggregation and are given intravenously (IV) as an adjunct to aspirin and heparin therapy in angioplasty.

If necessary, the vessel can be kept open by the fitting of a stent.

Alternatively, thrombolytic, antiplatelet and antithrombotic agents can be used to dissolve the thrombus, open the artery and prevent reocclusion.

Thrombolytic agents, *e.g. streptokinase and alteplase/reteplase.*

Streptokinase, extracted from streptococci cultures, is a plasminogen-activating protein that results in dissolution of the

thrombus, but its use is limited by the presence/formation of antibodies.

Alteplase and reteplase are recombinant tissue plasminogen activators (tPAs) and show some 'clot' selectivity. Reteplase has a longer half-life and can be given as a bolus injection in MI patients for whom angioplasty is not an available or viable option.

***Antiplatelet agents** , e.g. aspirin and clopidogrel.*

Aspirin inhibits platelet aggregation by irreversible acetylation of cyclo-oxygenase I (COX-1) leading to an inhibition of thromboxane (TX)A_2 synthesis. In acute MI, it is started with a single dose to achieve rapid inhibition followed by regular small maintenance doses.

Clopidogrel is an adenosine ($P2Y_{12}$) antagonist, which inhibits ADP-mediated platelet aggregation by irreversible inhibition of the receptor. It is given orally in high loading doses followed by lower dose maintenance therapy. It is a prodrug and is metabolised to the active form in the liver. It has been shown to be slightly more effective than aspirin in preventing ischaemic damage following MI, but is often reserved for aspirin-intolerant patients. Combined treatment has been shown to reduce mortality.

***Anti-thrombotic agents** , e.g. heparin. Heparin is an anticoagulant usually given acutely as an IV bolus injection followed by a constant rate infusion to decrease the chance of further thrombus formation and reocclusion. It functions by binding and increasing the affinity of antithrombin III for thrombin, so inhibiting its coagulant activity.*

What further agents may be prescribed to maintain cardiac function once the patient is stable?

β-Adrenoceptor antagonists, e.g. metoprolol, to reduce cardiac work and therefore the metabolic requirements of the heart.

Angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists can also be beneficial in reducing cardiac work and improve survival.

Prevention of an MI is obviously of greater benefit. What prophylactic agents may be prescribed to patients with identified risk of MI due to symptomatic atherosclerotic disease?

Statins to reduce plasma LDL through the inhibition of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase.

Respiratory case study

A 50-year-old man visits his doctor reporting episodes of shortness of breath, wheezing and a mild cough. This happened once previously a few months ago but the condition resolved and he did not seek advice. However, the symptoms have worsened in the last few weeks and seem to be worse due to the cold weather. Conversations with the patient reveal that he is an occasional smoker but also undertakes regular exercise. He has no previous history of respiratory problems although other family members do suffer from hay fever.

What are the two main possible diagnoses for the patient's condition and how might these be distinguished?

Asthma and chronic obstructive pulmonary disease (COPD).

Asthma is an inflammatory condition in which there is recurrent reversible airways obstruction in response to irritant stimuli. It presents with chronic inflammation of the airways, bronchial hyper-reactivity and variable and reversible airflow limitation. Patients with asthma experience intermittent attacks of wheezing, shortness of breath – with difficulty especially in breathing out, chest tightness and, sometimes, cough. Acute attacks are reversible,

but the underlying pathological disorder can progress in older patients to a chronic state superficially resembling COPD.

The clinical picture of COPD starts with attacks of morning cough during the winter, and progresses to chronic cough with intermittent exacerbations, often initiated by an upper respiratory infection, when the sputum becomes purulent (i.e. yellow or green due to the presence of many pus cells – neutrophils or eosinophils). There is progressive breathlessness. Some patients have a reversible component of airflow obstruction identifiable by an improved forced expiratory volume in 1 second (FEV_1) following a dose of bronchodilator.

The two conditions have several overlapping symptoms and patients can present with elements of both. Complete diagnosis may only be possible following a period of treatment to assess the reversibility of the bronchoconstriction and the intermittent versus progressive nature of the condition.

What initial tests and treatment regime would be prescribed for the patient? What is the mechanism of action of this agent?

Spirometer measurements to assess respiratory capacity in the form of FEV and peak expiratory flow rate (PEFR).

Short-acting bronchodilator, e.g. salbutamol, given by inhalation on an as required basis.

β_2 Agonists cause bronchodilation by binding β_2 adrenoceptors on the bronchial smooth muscle.

The patient returns to the doctor 2 weeks later and reports that whilst the medication has provided some relief, he is still experiencing episodes of wheezing and is requiring the inhaler several times during the day and especially at night.

Relating your answer to the pathophysiology of the condition, why might the patient's symptoms be worse at night?

This reflects the two stages of an asthmatic response – the immediate/early phase due to bronchial smooth muscle spasm caused by the release of acute inflammatory mediators. The night-time exacerbation is likely to be due to the late phase response caused by an influx of eosinophils releasing leukotrienes, interleukins and toxic proteins, which further damage the epithelium leading to exposure of irritant receptors and sensory C fibres. Further release of growth factors can result in smooth muscle hypertrophy and hyperplasia.

In light of the patient's family history of allergy, further tests are carried out to assess the levels of inflammatory mediators. What differences might be observed in patients with allergic/atopic versus non-allergic/non-atopic conditions?

Allergic asthma triggers the production of allergen specific immunoglobulin E (IgE), causing mast cell degranulation and histamine and leukotriene B4 release which exacerbates bronchoconstriction.

What further therapies maybe prescribed for the patient to better control the condition?

Regular inhaled corticosteroid, e.g. beclometasone.

Regular longer-acting β agonist, e.g. salmeterol, given regularly twice a day.

Cysteinyl leukotriene receptor antagonists, e.g. montelukast, used mainly as add-on therapy to inhaled corticosteroids and long-acting β_2 agonists

If allergic, anti-IgE omalizumab, given intravenously (IV).

A combined inhibitor of interleukin (IL)-4 and IL-13 signalling (dupilumab) is prescribed for patients with moderate to severe eosinophilic asthma.

What are the risks to the patient if the condition is not adequately controlled? How would this be treated?

Severe acute asthma – status asthmaticus.

Severe acute reaction requiring hospitalisation – treatment includes high oxygen, inhaled nebulised salbutamol and IV hydrocortisone plus oral prednisone, with other bronchodilator agents as required. Regular monitoring of respiratory output.

What further advice may be offered to the patient?

To stop smoking.

To receive an annual flu vaccination to reduce the likelihood of infection, which will exacerbate asthma.

Food and glucose regulation case study

An elderly lady visited her doctor for a review of her current medical condition and monitoring of the effectiveness of her medication. She reported symptoms of polyuria and polydipsia.

Observing the patient was overweight and following discussions that revealed a sedentary lifestyle with a moderate consumption of alcohol, the doctor carried out various assessments and a blood test.

The findings from these tests revealed:

Height 1.58 m
Weight 80 kg
Blood pressure 160/90 mm Hg
Fasting blood glucose level 14.5 mmol/L
Cholesterol 5.8 mmol/L.

Comment on the findings and suggest the most likely explanation for the patient's symptoms.

Body mass index (BMI) is >30, so the patient is obese, hypertensive, hypercholesterolaemic and hyperglycaemic – these

symptoms presenting together with the polyuria and polydipsia indicate the presence of metabolic syndrome and type 2 diabetes.

What is the current understanding of the underlying genetic and pathophysiological cause of this condition?

Insulin resistance and impaired insulin secretion. Possible concomitant leptin resistance.

Potential genetic factors contributing to predisposition to obesity. It is now thought that genetic components underpin about 40%–50% of the susceptibility or predisposition to obesity in general populations. However, there are subgroups of people with severe obesity where the relative genetic contribution ('heritability') is much higher and exceeds 60%–80%. Most cases of obesity will turn out to be polygenic in nature, involving a complex interaction between multiple sets of genetic sites.

Imbalance of secreted hormones that regulate food intake and satiety, e.g. leptin and ghrelin.

Defects in the hypothalamic neuronal systems responding to any of these signals; defects in the systems controlling energy expenditure (e.g. reduced sympathetic activity), decreased metabolic expenditure of energy or decreased thermogenesis caused by a reduction in β_3 adrenoceptor–mediated tone and/or dysfunction of the proteins that uncouple oxidative phosphorylation.

Describe the pharmacological mechanism by which a rise in blood glucose stimulates insulin secretion.

Glucose enters pancreatic beta cells through Glut2 transporter and is metabolised by glucokinase. This results in a rise in ATP which blocks K_{ATP} channels causing depolarisation. This opens voltage-dependent calcium channels leading to Ca^{2+} influx, triggering insulin secretion.

Outline the signalling pathway and regulatory mechanisms downstream of the insulin receptor.

Insulin binding to its receptor results in the activation of the β subunit tyrosine kinase and recruitment and phosphorylation of insulin receptor substrate signalling proteins. This leads to recruitment of phosphatidylinositol 3 kinase via its SH2 domains leading to the relocation of the Glut-4 transporters from the Golgi apparatus to the plasma membrane. Longer-term effects of insulin involve the Ras-MAP kinase signalling pathway and activation of gene transcription leading to the expression of genes involved in cell growth and metabolism.

Activation of protein phosphatase 1 down-regulates the pathway by dephosphorylation of the receptor and IRS proteins.

How might the condition be modelled in a laboratory animal to enable the investigation of novel treatments?

IRS-2 knockout mice develop overt diabetes, implicating this gene as a candidate for human type 2 diabetes and would therefore be a good model for investigation of potential novel therapeutic agents.

What are the acute and longer-term risks to the patient if the condition remains untreated?

Acute – hyperosmolar hyperglycaemic nonketotic syndrome; ketoacidosis.

Longer term – muscle wasting; vascular effects – macrovascular disease and microangiopathy; diabetic neuropathy; hypertension; renal failure.

What initial non-pharmacological interventions would be advised to reduce these risks?

Reduced diet – weight loss

Decreased alcohol intake

Increased exercise

Supplementation with orlistat to decrease fat metabolism and absorption.

Despite initial success, the following review revealed little change in the patient's readings.

What pharmacological interventions may be prescribed to aid control of the condition and what is the rationale for the use of these agents?

The patient may be prescribed oral hypoglycaemic agents, e.g. biguanides or sulphonylureas. Biguanides result in reduced hepatic gluconeogenesis, increased glucose uptake and utilisation. Sulphonylureas stimulate insulin secretion from β˙cells.

SGLT2 inhibitors, e.g. ***canagliflozin,*** *are licensed for use in type 2 diabetes. These agents promote glucose excretion into the urine, thereby reducing the concentration of circulating glucose.*

The resulting glycosuria is associated with an osmotic diuresis and salt excretion.

Clinical trials have demonstrated the efficacy of glucagon-like peptide 1 (GLP-1) receptor agonists (***liraglutide*** *,* ***semaglutide*** *) in lowering body weight in conjunction with diet and exercise. The early action of GLP-1 is to stimulate insulin secretion and inhibit glucagon, thus providing a means of regulating blood glucose concentrations. However, GLP-1 receptors are found in multiple other sites and their role in tackling obesity appears to be through reduction of appetite, and promotion of satiety centrally at the hypothalamus.*

Specific formulations of ***liraglutide*** *(daily subcutaneous injection) and* ***semaglutide*** *(licensed as a once weekly subcutaneous injection; there is a daily oral formulation in clinical trials) are available. Higher doses of these drugs are required for treatment of obesity than the typical dose ranges used for glucose lowering in type 2 diabetes mellitus.*

Gliptins, e.g. ***sitagliptin*** *, are synthetic drugs that competitively inhibit dipeptidyl peptidase-4 (DPP-4), thereby lowering blood glucose by potentiating endogenous incretins (GLP-1 and GIP), which stimulate insulin secretion.*

Which of these agents may be considered to be the drug of choice for this patient? Justify your answer.

Biguanide–metformin.

Metformin decreases hepatic glucose production directly or indirectly by inhibiting the mitochondrial respiratory chain

complex I. The resulting increase in AMP activates AMP-activated protein kinase (AMPK) which triggers release of GLP-1 stimulating a gut–brain–liver vagal network that regulates hepatic glucose production. Chronic administration of metformin alters recirculation of bile acids and composition of the gut microbiome in type 2, leading to increased GLP-1 secretion in diabetes patients.

Treatment with sulphonylureas carries a greater risk of hypoglycaemia and can cause weight gain and increased risk of cardiovascular adverse effects.

In which patients would this agent be contraindicated?

Patients with renal or hepatic failure, hypoxia, severe pulmonary disease or shock, due to increased risk of lactic acidosis.

Neurodegenerative disease case study

A 72-year-old man visits his doctor accompanied by his wife, who has concerns about his memory and mobility. She reports that he has been forgetting things and appears to be struggling with routine tasks. He also seems to be less mobile, with difficulty getting up from a bed or chair, a shuffling gait when walking and a tendency to falling.

What condition may be causing the cognitive decline? What neurological and microscopic changes may be responsible for this?

Alzheimer's disease (AD) is associated with brain shrinkage and loss of neurons in many brain regions, but especially in the hippocampus and basal forebrain. The loss of cholinergic neurons in the hippocampus and frontal cortex is a feature of the disease, and is thought to underlie the cognitive deficit and loss of short-term memory that occur. Two microscopic features are characteristic of the disease, namely extracellular amyloid plaques, consisting of amorphous extracellular deposits of β-amyloid protein (known as Aβ), and intraneuronal neurofibrillary tangles, comprising filaments of a phosphorylated form of a microtubule-

associated protein (Tau). Both of these deposits are protein aggregates that result from misfolding of native proteins.

The familial nature of the development of this disease has led to the identification of certain predisposing genetic risk factors. Briefly outline the consequence of altered genes on the pathogenesis of the condition.

Genetic mutations in amyloid precursor protein (APP) result in overproduction of the Aβ42 segment by γ˙-secretase cleavage of APP. This fragment shows a greater tendency to form amyloid plaques.

Mutations in other proteins involved in the pathway, such as presenilins, can enhance γ-secretase activity, resulting in more Aβ42.

Aβ also enhances the phosphorylation of Tau through activation of glycogen synthase kinase-3β (GSK-3β) and cyclin-dependent kinase 5 (CDK5).

Mutations in another gene, that encode for the lipid transport protein ApoE4, also predispose to AD and may be involved in tau neurofibrillary tangles, microglia and astrocyte responses and blood–brain barrier disruption.

What condition may be affecting the mobility of the patient? What neurological and molecular changes may be responsible for this?

Parkinson's disease (PD).

Loss of dopaminergic neurones in the substantia nigra and degeneration in the striatum.

PD is also associated with the development of Lewy bodies containing misfolded α-synuclei which impairs vesicular storage of dopamine. This may lead to an increase in cytosolic dopamine, degradation of which produces reactive oxygen species (ROS) and hence neurotoxicity. A mutation associated with PD (parkin) also involves a protein that participates in the intracellular degradation of rogue proteins.

Other gene mutations that have been identified as risk factors for early-onset PD code for proteins involved in mitochondrial function, making cells more susceptible to oxidative stress.

The exact mechanisms linking the neurological loss and molecular changes are unknown but appear to involve excitotoxicity, mitochondrial dysfunction, oxidative stress, inflammation and apoptosis. Briefly outline these processes.

Excitotoxicity *is caused by excess glutamate signalling secondary to calcium overload. Glutamate, even at low doses, is neurotoxic if not adequately controlled. Glutamate release regulates and is regulated by calcium in a complex feedback mechanism.*

Calcium levels are normally kept in check by the mitochondria, endoplasmic reticulum and calcium efflux pumps. However, excess calcium can lead to mitochondrial dysfunction and a positive feedback on glutamate release, further elevating calcium and potentiating neurotoxicity.

Mitochondrial dysfunction *is seen as a major factor in many neurodegenerative diseases and may be due to inherited or*

accumulated mutations in enzymes within the mitochondrial respiratory chain. Damage to mitochondria can trigger apoptosis.

Oxidative stress *is excessive production of cell-damaging reactive oxygen species, which can be due to mitochondrial dysfunction. This can lead to inflammation.*

Inflammation *is often observed in neurodegenerative conditions and is associated with necrotic cell death caused by calcium overload and release of cellular contents into the local environment. Reduction of the inflammatory component of the disease is a secondary goal in current treatment.*

Apoptosis *is a controlled mechanism of cell death that, unlike necrosis, does not result in the release of damaging mediators resulting in inflammation. Apoptosis can be triggered by receptor or mitochondrial pathways and results in the activation of caspases causing DNA fragmentation and proteolytic cleavage. Prevention of neural apoptosis is a target for future therapies.*

What would be the first-line agents of choice for each of the conditions? Explain the rationale for this choice and the limitations of the therapy.

AD – cognitive decline. This is treated with anticholinesterases such as donepezil and rivastigmine aimed at prolonging the duration of action of acetylcholine. However, they have limited efficacy in improving cognitive function and do not halt disease progression. They may be given in combination with an N-methyl-d-aspartate (NMDA) inhibitor, memantine, to reduce excitotoxicity.

PD – affected movement. This is treated with levodopa, often given in combination with carbidopa and entacapone, to increase dopamine levels in the central nervous system (CNS). However, the effectiveness of the therapy decreases as the disease progresses, possibly due to the loss of dopaminergic neurones to convert the levodopa to dopamine.

What is the complication of combining the treatments in this patient?

Muscarinic acetylcholine receptors exert an inhibitory effect on dopaminergic neurones and so the anticholinesterases used to promote cognitive function antagonise the efficacy of the levodopa.

What developing areas of research may offer new therapeutic potential for the treatment of neurodegenerative diseases in the future?

Stem cell–based therapies – harnessing the inherent ability of neuronal progenitors to form new neurones.

Gene therapies aimed at modulating the synthesis of neurotransmitters and neurotrophic factors.

Electrical stimulation of affected brain areas with implanted electrodes (which inhibits ongoing neural activity, equivalent to reversible ablation) is used in severe cases, and has been shown to improve motor dysfunction in PD, but does not improve cognitive and other symptoms and does not stop the neurodegenerative process.

Epilepsy case study

A 14-year-old boy is admitted to hospital following an episode at school during which he was observed to undergo an epileptic seizure. During the seizure, which lasted around 7 minutes, the boy lost consciousness and was observed to undergo violent synchronous jerking.

Whilst at the hospital, the boy suffered another episode. An electroencephalogram (EEG) recording taken during the seizure revealed generalised continuous high-frequency activity followed by a period of intermittent discharge.

What is the most likely classification of this type of epilepsy?

Tonic–clonic (grand mal) seizure.

What is the current proposed hypothesis for the neuronal abnormality that leads to an epileptic episode?

The actual mechanisms are poorly understood but result from facilitation of excitatory transmission or reduction of inhibitory transmission. A rapid depolarisation (paroxysmal depolarising shift) occurs in the initiating neurones, resulting in a burst of

action potentials, and is probably due to exaggerated and prolonged neurotransmitter release.

Effective treatment for the disease is severely limited by the lack of understanding of the aetiology and pathological changes that occur. To enhance our understanding of the disease, many animal models have been established enabling monitoring and detection of neurological changes, as well as enabling the development and screening of novel therapeutic compounds.

Describe two different mechanisms for inducing spontaneous seizures in an animal model.

Drug induced

The administration of penicillin crystals directly to the brain causes focal seizures by interfering with inhibitory transmission.

Pentylenetetrazol, a convulsant drug, provides an effective model for the investigation of absence seizures.

A single injection of kainic acid into the amygdaloid nucleus of a rat precipitates spontaneous seizures.

Electrically induced

These models are used for absence and focal seizures. The kindling model, using low-intensity stimulation, will eventually lead to spontaneous seizures.

A range of therapeutic agents have been developed to counteract the symptoms of epilepsy rather than addressing the underlying cause. Whilst many are effective

in a large percentage of patients, the need to take the drugs continuously means that the management of adverse effects is important to patient quality of life and compliance.

Three commonly used agents are carbamazepine, valproate and vigabatrin.

Compare the mechanism of action of the three agents and rationalise their use in the treatment of epilepsy.

Carbamazepine affects membrane excitability by blocking voltage-dependent sodium channels responsible for the generation of the action potential. They show use dependency and so preferentially block the excitation of cells that are firing repetitively. They show selectivity for sodium channels in the inactivated state preventing their return to the resting state and reducing those available to generate action potentials.

Valproate works by several mechanisms and although individual parameters may be affected less than by other agents, it may be the combination of these that contributes to its overall efficacy. It increases GABA content and is a weak inhibitor of GABA-metabolising enzymes. It may enhance postsynaptic GABA activity and inhibits both sodium and T-type calcium channels.

Vigabatrin, the first 'designer drug' in the epilepsy field, is a vinyl-substituted analogue of GABA that was designed as an irreversible inhibitor of the GABA-metabolising enzyme GABA transaminase. In animal studies, vigabatrin increases the GABA content of the brain and also increases the stimulation-evoked release of GABA, implying that GABA transaminase inhibition can

increase the releasable pool of GABA and effectively enhance inhibitory transmission. In humans, vigabatrin increases the content of GABA in the cerebrospinal fluid.

Which of these agents is likely to be the first drug of choice for treating the patient?

Valproate may be the first drug of choice due to low toxicity and lack of sedation and dizziness. Note, Valproate is contraindicated in women of childbearing age.

Why would it not be appropriate to treat the patient with a combination of valproate and carbamazepine?

Whilst both agents are beneficial in the treatment of tonic–clonic seizures, carbamazepine is a powerful inducer of hepatic microsomal enzymes, and thus accelerates the metabolism of many other drugs, as well as of itself. When starting treatment, the opposite of a 'loading dose' strategy is employed: small initial doses are gradually increased, as when dosing is initiated, metabolising enzymes are not induced and so even low doses may give rise to adverse effects (notably ataxia); as enzyme induction occurs, increasing doses are needed to maintain therapeutic plasma concentrations. In general, it is inadvisable to combine it with other antiepileptic drugs, and interactions with other drugs metabolised by cytochrome P450 (CYP) enzymes are common and clinically important.

Cancer case study

A 68-year-old woman visits her doctor concerned about a lump she has found in her breast. The patient is sent for a scan to ascertain the nature and diagnosis of the condition.

What diagnostic factors distinguish a malignant from a benign growth?

Uncontrolled proliferation – cancer cells do not necessarily proliferate faster than normal cells but they have escaped the regulatory mechanisms that normally control cell division.

Dedifferentiated morphology – loss of intracellular organelles and loss of specialised cellular function.

Invasiveness – ability to overcome contact inhibition, spread into surrounding tissue.

Metastasis – ability to spread around the body and recolonise in secondary sites.

Outline the two main categories of genetic change that predispose to carcinogenesis and their role in the progression of the disease. Give an example of each relevant to the development of breast cancer.

Proto-oncogenes are genes that normally promote cell growth and survival but are highly regulated. They can be converted to

oncogenes by a dominant, gain of function mutation, leading to malignant change – one example relevant to breast cancer is the cytoplasmic tyrosine kinase c-src. The human epidermal growth factor receptor 2 (HER2) can also be overexpressed in breast cancers leading to increased growth of breast cells.

Tumour suppressor genes function to suppress tumour growth by and promote DNA repair or apoptosis to protect the cell. Loss of function or expression of tumour suppressor proteins can lead to the accumulation of mutations. One example relevant to breast cancer is the inheritance of defective copy of the BRCA1 or BRCA2 gene involved in DNA repair.

Outline the mechanism by which metastasis occurs and the tissues in which secondary growths are most likely to occur.

Metastasis occurs by the separation of cells from the primary tumour and their transportation through the tissues and bloodstream, facilitated by the expression of matrix metalloproteinases (MMPs) to digest the extracellular matrix (ECM). Metastasis from mammary tumours is often found in lung, bone and brain due to expression of CXCR4 in these tissues, which binds to receptors on the breast cells and facilitates accumulation at these sites.

Treatment regimens are tailored according to the cancer profile of presenting mutations and responsiveness of tumour cells to specific growth factors.

Commonly used agents in the treatment of breast cancers include:

Cyclophosphamide
Docetaxel
Tamoxifen
Goserelin
Anastrozole
Trastuzumab (Herceptin)

For each agent, outline the rationale for its use and its mechanism of action in reducing tumour growth.

Cyclophosphamide – an alkylating agent that induces DNA strand breaks.

Docetaxel – a plant derivative that blocks microtubule depolymerisation and inhibits Bcl-2.

Tamoxifen – an oestrogen receptor–modulating agent that blocks the oestrogen activation of the receptor.

Goserelin – an analogue of gonadotrophin-releasing hormone, which when administered chronically can inhibit gonadotrophin release. These agents are therefore used to treat advanced breast cancer in premenopausal women

Anastrozole – an aromatase inhibitor that blocks oestrogen production.

Trastuzumab (Herceptin) – a monoclonal antibody that blocks HER2 receptor activation.

What main side effects may the patient experience as a result of the chemotherapy?

What additional therapies may be co-administered to reduce some of these symptoms?

Bone marrow toxicity (myelosuppression)/increased risk of infection

Loss of hair

Damage to GI tract

Nausea and vomiting.

To reduce the nausea and vomiting associated with chemotherapy, patients may be co-administered a 5-hydroxytryptamine (5-HT) $_3$ *antagonist such as ondansetron. Metoclopramide (a dopamine antagonist), often with the glucocorticoid dexamethasone, can also alleviate the nausea.*

To counteract the myelosuppression – myelosuppression limits the use of many anticancer agents. Red cell and platelet transfusions can be used to support the patient, but febrile neutropaenia continues to pose a significant risk. Here, recombinant human granulocyte-colony stimulating factor (rhG-CSF) can be used after cytotoxic chemotherapy to stimulate neutrophil production and shorten the duration of the at-risk period for serious infections. Filgastrim (and its related compounds) can be given by daily injection at the end of each chemotherapy cycle to restore the white cell count.

In conversation with Graeme Henderson
Interview with Graeme Henderson, author of *Rang & Dale's Pharmacology* textbook. In discussion with David MacEwan, Graeme reflects on how the textbook has developed during his time as its Editor and how *Rang & Dale's Pharmacology* has impacted the teaching of pharmacology and drug use over the years.

In conversation with Yoon Loke

Interview with Yoon Loke, author of *Rang & Dale's Pharmacology* textbook. In dialogue with David MacEwan, Yoon discusses his experiences co-authoring the successful textbook and how it has influenced teaching of pharmacology to medical students.

In conversation with Emma Robinson

Interview with Emma Robinson, one of the most recent co-authors of *Rang & Dale's Pharmacology* textbook. In discussion with David MacEwan, Emma discusses her early impressions as co-author of the successful book, and how she tries to incorporate her own teaching method into the textbook.

In conversation with James Fullerton

Interview with James Fullerton, co-author of *Rang & Dale's Pharmacology* textbook. In discussion with David MacEwan, James discusses his impressions of the textbook and how it influences how medical school students learn about drugs, applying that knowledge in the clinic.

Pharmacology in practice: clinical overdose

Topic video with Adam Danashmend, clinical registrar in London. Adam gives his advice on the importance of pharmacology to doctors, and opioid overdose cases in the clinic.

Pharmacology in practice: role of pharmacology in undergraduate medical education

Dr Mohammad Sarwar describes the clinical use of anaesthetics and pain relief in preoperative, operative and

postoperative clinical settings, to inform students of the most appropriate drug combinations used by anaesthesiologists.

Pharmacology in practice: importance of chemistry, drug-receptor interactions and pharmacokinetics to people who use opioids

Rang & Dale author Graeme Henderson describes opioid use and misuse, outlining how agonists and antagonists are used on the street and the pharmacological knowledge underlying their use.

Pharmacology in practice: investigation of the frequency of narcotic misuse

Pharmacology graduate Meurig Shotton describes his project analysing the purity of narcotics and use of cutting-agents in social nonclinical settings, such as music festivals.

Topic: what are drugs and how do they work? Understanding receptor theory better

Rang & Dale author David MacEwan describes drugs, receptors and receptor theory in more depth to help students understand these pharmacology basics.

Topic: enzyme inducers and inhibitor – the logical approach

Rang & Dale author Yoon Loke describes how enzyme inducers and inhibitors have the ability to modify the actions of other drugs taken concurrently.

Rang & Dale's Pharmacology Tenth Edition Preface

> *'Things will have to change in order that they remain the same.' (Prince Don Fabrizio Salina, in Il Gattopardo)*

'*Pharmacology*', first published by Churchill Livingstone in 1987 and dedicated to the memory of Professor HO Schild, was the brainchild of Humphrey Rang. Its predecessor, Schild's '*Applied Pharmacology*', set a standard that the authors tried to maintain. '*Rang & Dale's Pharmacology*', as it is now known, has gone through nine editions and been published in 11 languages since the fifth edition. This present (tenth) edition is the first that has not benefitted from Humphrey's hands-on leadership and, while he remains very much alive and kicking, we have tried in a similar spirit to maintain the standards that he has set over the past 35 years. In this spirit, and in line with the sentiment expressed by Prince Don Fabrizio and quoted above, we have welcomed two younger colleagues Professor Emma Robinson (Bristol) and Dr James Fullerton (Oxford) who have ably assisted us in writing this present edition.

In this edition, as in its predecessors, we set out not just to describe what drugs do but to explain the mechanisms by which they act. This entails analysis of physiological mechanisms and

pathological disturbances at the cellular and molecular level. Pharmacology has its roots in therapeutics as well as in organic chemistry and biotechnology, so we have attempted to make the link between effects at the molecular and cellular level and the range of beneficial and harmful effects that humans experience when drugs are used for therapeutic or other reasons. Many psychoactive drugs are not prescribed as medicines or sold over the counter. Some of these are widely used for pleasure, especially by young people, sometimes with harmful consequences. While our main emphasis is on therapeutic use, psychoactive drugs, drug addiction and tolerance are also covered. Similarly, there is a chapter on drugs used (or abused) in sport and for other lifestyle purposes.

Pharmacology remains a fast-moving field. In 2021 the European Medicines Agency approved 54 new active substances. Of these, seven related to COVID-19 but other indications were also widely represented: other infections (two), cardiovascular (three), metabolic (two), reproduction (three), gastro-intestinal (one), neurological (five), endocrine (four), skin (three), eyes (two), rheumatology (three), haematology (five), cancer (12) and vaccines other than those directed against SARS-CoV2 (two). In previous editions we have not covered vaccines, whether live attenuated organisms or nonliving material derived from pathogenic organisms, opting to concentrate on molecular entities of defined chemical structure. The current wave of vaccines do have defined chemical structures that act as specific targets for the immune cells of the recipient, and we mention these in relevant sections such as that on COVID-19 in the chapter on antiviral drugs, but without

going into detail. Macromolecular drugs (including monoclonal antibody and RNA drugs) that act specifically to cause effects in the host via high affinity binding to targets such as surface membrane receptors represent a new frontier in pharmacology. They contrast in pharmacokinetics, specificity, therapeutic efficacy and range of harmful effects from the small molecule chemical entities that still constitute the main armamentarium of therapeutic drugs. They are covered in greater depth than the novel vaccines in the relevant organ-specific chapters, and the chapter on biopharmaceuticals has been completely revised and updated and now includes a much larger section on RNA drugs. We also, as in previous editions, cover drugs such as anaesthetics and immunosuppressants that enable other therapeutic modalities such as surgery and transplantation. The surprisingly tricky question of 'what is a drug?' raised by such distinctions is addressed in more detail in Chapter 1.

Pharmacology is a lively scientific discipline in its own right, with an importance beyond that of providing a basis for the use of drugs in therapy or for other purposes, and we aim to provide a firm background, not only for future doctors but also for scientists and practitioners of other disciplines such as pharmacy and other professions allied to medicine, especially those who contemplate the possibility of a career in drug discovery and development, which are covered in a separate chapter. We have therefore, where appropriate, described how drugs are used as probes for elucidating cellular and physiological functions, even when they have no clinical use.

Nomenclature. Names of drugs and related chemicals are established through usage and sometimes there is more than one

name in common use. For prescribing purposes, it is important to use standard names, and we follow as far as possible the World Health Organization's list of recommended international non-proprietary names (rINNs). Sometimes these conflict with the familiar names, e.g. amphetamine becomes amfetamine in the rINN list, and the endogenous mediator prostaglandin I_2, the standard name in the scientific literature, becomes 'epoprostenol'– a name unfamiliar to most scientists – in the rINN list. Some trade names have become so familiar as to be widely used outside their original remit. UK consumers once talked of 'hoovering the carpet', and among consumers (patients, doctors and others) 'Heroin', the Bayer trade mark for diamorphine, was similarly colloquialized and extended from the synthetic product to various resins and mixtures obtained by acetylating opium extract; diamorphine (the rINN) is preferred. The same goes for more recent instances (e.g. Herceptin/trastuzumab and Viagra/sildenafil), but with the caveat for prescribers and pharmacists that there are cases where prescribing by trade name is recommended by the British National Formulary because of clinically important pharmacokinetic differences between products. In general, we use rINN names as far as possible in the context of therapeutic use, but often use the common name in describing mediators and familiar drugs. Sometimes English and American usage varies (as with adrenaline/epinephrine and noradrenaline/norepinephrine). Adrenaline and noradrenaline are the official names in EU member states and relate clearly to terms such as 'noradrenergic', 'adrenoceptor' and 'adrenal gland' and we prefer them for these reasons.

Organization. Drug action can be understood only in the context of what else is happening in the body. So, at the beginning of most chapters, we briefly discuss the physiological and biochemical processes relevant to the action of the drugs described in that chapter. As regards the chemical structures of drugs, we have included these only where this helps in understanding how those drugs act or are handled by the body, since chemical structures are readily available for reference online.

The overall organisation of the book has been retained, with sections covering: (1) the general principles of drug action; (2) the chemical mediators and cellular mechanisms with which drugs interact in producing their therapeutic or other effects; (3) the action of drugs on specific organ systems; (4) the action of drugs on the nervous system; (5) the action of drugs used to treat infectious diseases and cancer; (6) a range of special topics comprising harmful effects of drugs, lifestyle drugs and drugs in sport and drug discovery and development. This organization reflects our belief that drug action needs to be understood, not as mere description of the effects of individual drugs and their uses, but as a chemical intervention that perturbs the complex network of chemical and cellular signalling that underlies the function of any living organism. In addition to updating all of the chapters, we have, within this general plan, reorganised the text in various ways, to keep abreast of modern developments:

- A completely revised 'biopharmaceuticals' chapter (**Ch. 5**) updated and now including a much larger section on RNA drugs.

- **Chapter 24** *Haemopoietic system and treatment of anaemia*: updated to incorporate recent advances in oxygen sensing and response to reduced oxygen tension, with a new figure, and safe and effective drugs stemming from this (e.g. daprodustat)
- A new chapter on drugs and the eye (**Ch. 27**) has been included.
- **Chapter 40** *Neurodegenerative diseases,* has been rewritten to broaden its focus on Alzheimer's disease to include other forms of dementia (dementia associated with Lewy bodies and vascular dementia) and their treatment.
- A new chapter (**Ch. 42**) on the pharmacological management of headache (includes the new CGRP antagonists for migraine prophylaxis)
- **Chapter 43** *Analgesic drugs*: a new section on drug treatment of chronic pain.
- A revised chapter (**Ch.51**) on 'Basic principles of antimicrobial therapy' featuring new diagrams illustrating sites of action of antibiotics at ribosomes.
- A completely revised chapter (**Ch. 53**) on antivirals incorporating more information on their mode of replication and a section on COVID-19.
- A significantly updated chapter on Anticancer drugs (**Ch. 57**) which incorporates the great expansion in different types of new anticancer agents that have exploded into the clinic setting in recent years.
- A new section on the background to drug discovery highlighting the current successes and future potential of

small interfering RNA drugs in structure-based drug design which appear set to access many new drug targets and revolutionise medicine.

In selecting new material for inclusion, we have taken into account not only new agents but also recent extensions of basic knowledge that presage further drug development. And where possible, we have given a brief outline of new treatments in the pipeline. We have cut out drugs that have become obsolete, and theories that have had their day.

References and further reading lists are largely restricted to guidance on further reading and review articles that list key original papers.

ACKNOWLEDGEMENTS

We would like to thank the following for their help and advice in writing this edition: Dr Peggy Frith, Professor Eamonn Kelly, Dr Jan Melichar, Dr Katy Sutcliffe, Professor Andrew Owen and Dr William Brown.

We would also like to thank Dr Christine Edmead for her work on the self-assessment questions which are available as additional material in the online edition of this book.

We would like to put on record our appreciation of the team at Elsevier who worked on this edition: Alexandra Mortimer (content strategist), Nicholas Henderson (content development specialist) and Joanna Souch (project manager).

We are also very grateful to readers who have taken the trouble to write to us with constructive comments and suggestions. We have done our best to incorporate these. Comments on the new edition will be welcome.

1: What is pharmacology?

OVERVIEW

In this introductory chapter we explain how pharmacology came into being and evolved as a scientific discipline and describe the present-day structure of the subject, how it continues to develop and its links to other biomedical sciences. The structure that has emerged forms the basis of the organisation of the rest of the book. Readers in a hurry to get to the here-and-now of pharmacology can safely skip this chapter.

What is a Drug?

For the purposes of this book, a drug can be defined as *a chemical substance of known structure, other than a nutrient or an essential dietary ingredient,* [1] *which, when administered to a living organism, produces a biological effect.*

A few points are worth noting. Drugs may be synthetic chemicals, chemicals obtained from plants or animals or products of biotechnology (biopharmaceuticals). A *medicine* is a chemical preparation, which usually, but not necessarily, contains one or more drugs, administered with the intention of producing a therapeutic effect. Medicines usually contain other substances (excipients, stabilisers, solvents, etc.) besides the active drug, to

make them more convenient to use. To count as a drug, the substance must be administered as such, rather than released by physiological mechanisms. Many substances, such as insulin or thyroxine, are endogenous hormones but are also drugs when they are administered intentionally. Many drugs are not used commonly in medicine but are nevertheless useful research tools. The definition of a drug also covers toxins, one or two of which are administered in the clinic whilst many are critical pharmacological tools. In everyday parlance, the word *drug* is often associated with psychoactive substances and addiction – unfortunate negative connotations that tend to bias uninformed opinion against any form of chemical therapy. In this book we focus mainly on drugs used for therapeutic purposes but also describe psychoactive drugs, lifestyle drugs as well as drugs used in sport to enhance performance and provide important examples of drugs used as experimental tools. Poisons fall strictly within the definition of drugs, and indeed 'all drugs are poisons… it is only the dose which makes a thing poison' (an aphorism credited to Paracelsus, a 16th century Swiss physician); conversely, poisons may be effective therapeutic agents when administered in sub-toxic doses. Botulinum toxin ('Botox', see **Ch. 14**) provides a striking example: it is the most potent poison known in terms of its lethal dose but is widely used both medically and cosmetically. General aspects of harmful effects of drugs are considered in **Chapter 58**. Toxicology is the study of toxic effects of chemical substances (including drugs), and toxicological testing is undertaken on new chemical entities during their development as potential medicinal products (see **Ch. 60**), but the subject is not otherwise covered in this book.

Historically the definition of a drug – a chemical substance of known structure – precluded vaccines being included as drugs given that typically they were preparations of antigens made from weakened or killed forms of microbes or viruses, their toxins or their surface proteins. Modern vaccine technology now uses sequences of DNA or RNA of known structure, allowing them to come under our definition of a drug.

Origins and Antecedents

Pharmacology can be defined as the study of the effects of drugs on the function of living systems. As a science, it was born in the mid-19th century, one of a host of new biomedical sciences based on principles of experimentation rather than dogma or intuition that came into being in that remarkable period. Long before that – indeed from the dawn of civilisation – herbal remedies were widely used, pharmacopoeias were written, and the apothecaries' trade flourished. However, nothing resembling scientific principles was applied to therapeutics, which was known at that time as *materia medica*. [2] Even Robert Boyle, who laid the scientific foundations of chemistry in the middle of the 17th century, was content, when dealing with therapeutics (*A Collection of Choice Remedies*, 1692), to recommend concoctions of worms, dung, urine and the moss from a dead man's skull. The impetus for pharmacology came from the need to improve the outcome of therapeutic intervention by doctors, who were at that time skilled at clinical observation and diagnosis but broadly ineffectual when it came to treatment. [3] Until the late 19th century, knowledge of the normal and abnormal functioning of the body was too rudimentary to provide even a

rough basis for understanding drug effects; at the same time, disease and death were regarded as semi-sacred subjects, appropriately dealt with by authoritarian inclinations, rather than scientific doctrines. Clinical practice often displayed an obedience to authority and ignored what appeared to be easily ascertainable facts. For example, cinchona bark was recognised as a specific and effective treatment for malaria, and a sound protocol for its use was laid down by Lind in 1765. In 1804, however, Johnson declared it to be unsafe until the fever had subsided, and he recommended instead the use of large doses of calomel (mercurous chloride) in the early stages – a murderous piece of advice that was slavishly followed for the next 40 years.

The motivation for understanding what drugs can and cannot do came from clinical practice, but the science could be built only on the basis of secure foundations in physiology, pathology and chemistry. It was not until 1858 that Virchow proposed the cell theory. The first use of a structural formula to describe a chemical compound was in 1868. Bacteria as a cause of disease were discovered by Pasteur in 1878. Previously, pharmacology hardly had the legs to stand on, and we may wonder at the bold vision of Rudolf Buchheim, who created the first pharmacology institute (in his own house) in Estonia in 1847.

In its beginnings, before the advent of synthetic organic chemistry, pharmacology concerned itself exclusively with understanding the effects of natural substances, mainly plant extracts – and a few (mainly toxic) chemicals such as mercury and arsenic. An early development in chemistry was the purification of active compounds from plants. Friedrich Sertürner, a young

German apothecary, purified morphine from opium in 1805. Other substances quickly followed, and, even though their structures were unknown, these compounds showed that chemicals, not magic or vital forces, were responsible for the effects that plant extracts produced on living organisms. Early pharmacologists focused most of their attention on such plant-derived drugs as quinine, digitalis, atropine, ephedrine, strychnine and others (many of which are still used today and will have become old friends by the time you have finished reading this book). [4]

Pharmacology in the 20th and 21st Centuries

Beginning in the 20th century, the fresh wind of synthetic chemistry began to revolutionise the pharmaceutical industry, and with it the science of pharmacology. New synthetic drugs, such as barbiturates and local anaesthetics, began to appear, and the era of antimicrobial chemotherapy began with the discovery by Paul Ehrlich in 1909 of arsenical compounds for treating syphilis. Around the same time, William Blair-Bell was world renowned for his pioneering work at Liverpool in the treatment of breast cancers with another relatively poisonous agent, lead colloid mixtures. The thinking was that, yes, drugs were toxic, but they were slightly more toxic to a microbe or cancer cell. This early chemotherapy has laid the foundations for much of the antimicrobial and anticancer therapies still used today. Further breakthroughs came when the sulfonamides, the first antibacterial drugs, were discovered by Gerhard Domagk in 1935 and with the development of penicillin by

Chain and Florey during the Second World War, based on the earlier work of Fleming.

These few well-known examples show how the growth of synthetic chemistry, and the resurgence of natural product chemistry, caused a dramatic revitalisation of therapeutics in the first half of the 20th century. Each new drug class that emerged gave pharmacologists a new challenge, and it was then that pharmacology really established its identity and its status among the biomedical sciences.

In parallel with the exuberant proliferation of therapeutic molecules – driven mainly by chemistry – which gave pharmacologists so much to think about, physiology was also making rapid progress, particularly in relation to chemical mediators, which are discussed in depth throughout this book. Many hormones, neurotransmitters and inflammatory mediators were discovered in this period, and the realisation that chemical communication plays a central role in almost every regulatory mechanism that our bodies possess immediately established a large area of common ground between physiology and pharmacology, for interactions between chemical substances and living systems were exactly what pharmacologists had been preoccupied with from the outset. Indeed, these fields have developed hand-in-hand as wherever there is either a physiological or pathological mechanism, pharmacology could be there to exploit it with a drug. The concept of ‘receptors’ for chemical mediators, first proposed by Langley in 1905, was quickly taken up by pharmacologists such as Clark, Gaddum, Schild and others and is a constant theme in present-day pharmacology (as you will soon discover as you plough through the

next two chapters). The receptor concept, and the technologies developed from it, have had a massive impact on drug discovery and therapeutics. Biochemistry also emerged as a distinct science early in the 20th century, and the discovery of enzymes and the delineation of biochemical pathways provided yet another framework for understanding drug effects. The picture of pharmacology that emerges from this brief glance at history (**Fig. 1.1**) is of a subject evolved from ancient prescientific therapeutics, involved in commerce from the 17th century onwards, and which gained respectability by donning the trappings of science as soon as this became possible in the mid-19th century. Pharmacology grew rapidly in partnership with the evolution of organic chemistry and other biomedical sciences, and was quick to assimilate the dramatic advances in molecular and cell biology in the late 20th century. Now, in the 21st century, we are in the exciting new era of molecular modelling. The elucidation of protein structures at the atomistic level, especially of receptor proteins, allows the use of high-powered in silico modelling and mathematical simulation approaches to reveal how drugs interact with receptors and ion channels. As well as telling us more about how current drugs work, such approaches are revolutionising the design of new drugs.

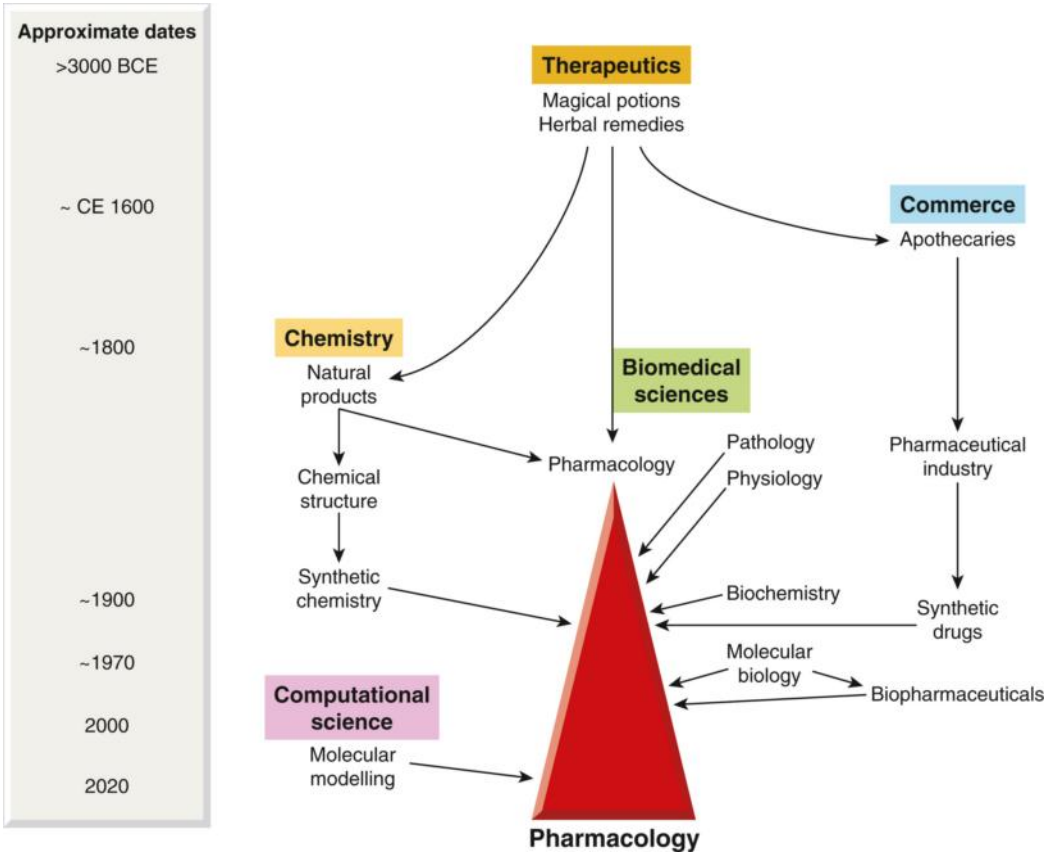

FIG. 1.1 The development of pharmacology.

Alternative Therapeutic Principles

Modern medicine relies heavily on drugs as the main tool of therapeutics. Other therapeutic procedures, such as surgery, vaccination, diet, exercise, psychological treatments, radiotherapy, etc., are also important, of course, as is deliberate non-intervention, but none is so widely applied as drug-based therapeutics.

Before the advent of science-based approaches, repeated attempts were made to construct systems of therapeutics, many of which produced even worse results than pure empiricism. One of these was *allopathy*, espoused by James Gregory (1735–1821). The favoured remedies included bloodletting, emetics and purgatives,

which were used until the dominant symptoms of the disease were suppressed. Many patients died from such treatment, and it was in reaction against it that Hahnemann introduced the practice of *homeopathy* in the early 19th century. The implausible guiding principles of homeopathy are:

- like cures like
- activity can be enhanced by dilution

The system rapidly drifted into absurdity: for example, Hahnemann recommended the use of drugs at dilutions of $1{:}10^{60}$, equivalent to one molecule in a sphere the size of the orbit of Neptune.

Many other systems of therapeutics have come and gone, and the variety of dogmatic principles that they embodied have tended to hinder rather than advance scientific progress. Currently, therapeutic systems that have a basis that lies outside the domain of science remain popular under the general banner of 'alternative' or 'complementary' medicine. Mostly, they reject the 'medical model', which attributes disease to an underlying derangement of normal function that can be defined in physiological or structural terms, scientifically detected by objective means, and influenced beneficially by appropriate chemical or physical interventions. They focus instead mainly on subjective malaise, which may be disease associated or not. Abandoning objectivity in defining and measuring disease goes along with a similar departure from scientific principles in assessing therapeutic efficacy and risk, with the result that principles and practices can gain acceptance without satisfying any of the criteria of validity that would convince a critical scientist,

and that are required by law to be satisfied before a new drug can be introduced into therapy. Demand for 'alternative' therapies by the general public, alas, has little to do with demonstrable efficacy. [6]

THE EMERGENCE OF BIOTECHNOLOGY

Since the 1980s, biotechnology has emerged as a major source of new therapeutic agents in the form of antibodies, enzymes, various regulatory proteins, oligonucleotides and DNA/RNA vaccines (**Clark and Pazderink, 2015**; **Theobold, 2020**). Although such products (known as *biopharmaceuticals*) are generally produced by genetic engineering rather than by synthetic chemistry, the pharmacological principles are essentially the same as for conventional drugs, although the details of absorption, distribution and elimination, specificity, harmful effects and clinical effectiveness all differ markedly between high-molecular-weight biopharmaceuticals and low-molecular-weight drugs – as does their cost! In recent years the development of gene- and cell-based therapies has gathered pace, taking therapeutics into a new domain (see **Ch. 5**). The principles governing gene suppression, gene editing to repair faulty genes (notably through advances in CRISPR-Cas9 gene-editing technologies) and the design, delivery and control of functioning artificial genes introduced into cells, or of engineered cells introduced into the body, are very different from those of drug-based therapeutics and require a different conceptual framework.

Pharmacology Today

As with other biomedical disciplines, the boundaries of pharmacology are not sharply defined, nor are they constant. Its

exponents are, as befits pragmatists, ever ready to poach on the territory and techniques of other disciplines. If it ever had a conceptual and technical core that it could really call its own, this has now dwindled almost to the point of extinction, and the subject is defined by its purpose – to understand what drugs do to living organisms, and more particularly how their effects can be applied to therapeutics – rather than by its scientific coherence.

Fig. 1.2 shows the structure of pharmacology as it appears today. Within the main subject fall a number of compartments (neuropharmacology, immunopharmacology, pharmacokinetics, etc.), which are convenient, if not watertight, subdivisions. These topics form the main subject matter of this book. Around the edges are several interface disciplines, not covered in this book, which form important two-way bridges between pharmacology and other fields of biomedicine. Pharmacology tends to have more of these than other disciplines. Recent arrivals on the fringe are subjects such as pharmacogenomics, pharmacoepidemiology and pharmacoeconomics.

Pharmacogenomics

Pharmacogenetics, the study of genetic influences on responses to drugs, initially focused on familial idiosyncratic drug reactions, where affected individuals show an abnormal – usually adverse – response to a class of drug (see **Nebert and Weber, 1990**). Rebranded as pharmacogenomics, it now covers broader genetically based variations in drug response, where the genetic basis is more complex, the aim being to use genetic information to guide the choice of drug therapy on an individual basis – so-called

personalised medicine (see **Ch. 12**). The underlying principle is that differences between individuals in their response to therapeutic drugs can be predicted from their genetic make-up. Examples that confirm this are steadily accumulating (see **Ch. 12**). So far, they mainly involve genetic polymorphism of drug-metabolising enzymes or receptors. Ultimately, linking specific gene variations with variations in therapeutic or unwanted effects of a particular drug should enable the tailoring of therapeutic choices on the basis of an individual's genotype. Steady improvements in the cost and feasibility of individual genotyping will increase its applicability potentially with far-reaching consequences for therapeutics (see **Ch. 12**). [7]

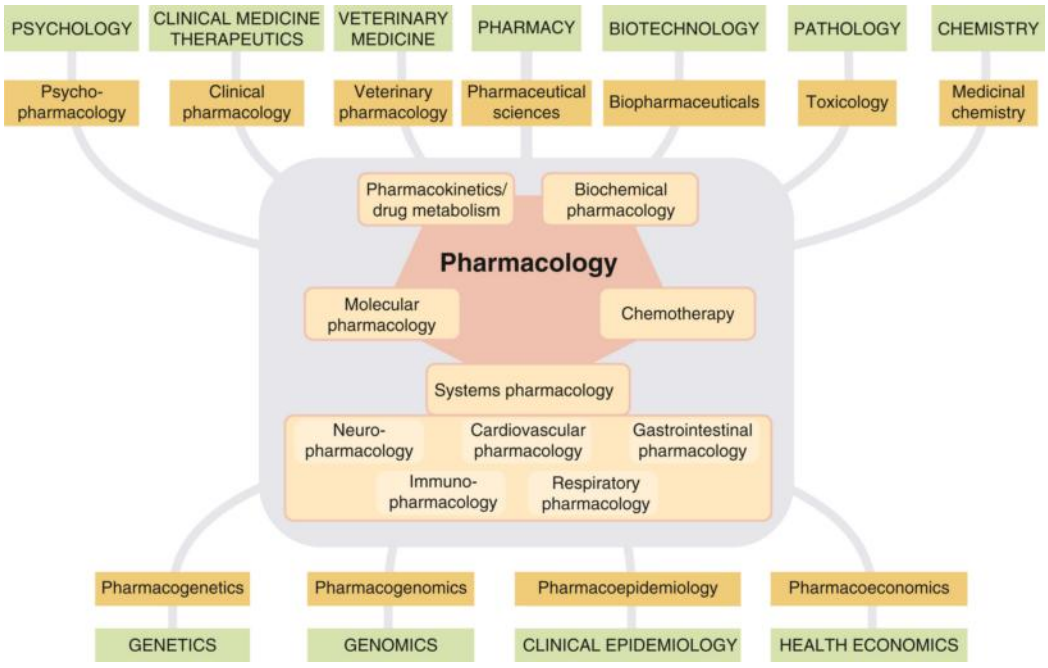

FIG. 1.2 Pharmacology today with its various subdivisions. The *grey box* contains the general areas of pharmacology covered in this book. Interface disciplines *(brown boxes)* link pharmacology to other mainstream biomedical disciplines *(green boxes)*.

Pharmacoepidemiology

This is the study of drug effects at the population level (see **Caparrotta et al., 2019**). It is concerned with the variability of drug effects between individuals in a population, and between populations. It is an increasingly important topic in the eyes of the regulatory authorities who decide whether or not new drugs can be licensed for therapeutic use. Variability between individuals or populations detracts from the utility of a drug, even though its overall effect level may be satisfactory. Pharmacoepidemiological

studies meta-analyse randomised controlled clinical trials, and also take into account patient compliance and other factors that apply when the drug is used under real-world settings.

Pharmacoeconomics

This branch of health economics aims to quantify in economic terms the cost and benefit of drugs used therapeutically. It arose from the concern of many governments to provide for healthcare from tax revenues, raising questions of what therapeutic procedures represent the best value for money. This, of course, raises fierce controversy, because it ultimately comes down to putting monetary value on health and longevity, often using a measure of quality-adjusted life year (QALY) to measure the impact of new therapeutic interventions to judge whether society *should* fund a new drug and for what societal gains. As with pharmacoepidemiology, regulatory authorities are increasingly requiring economic analysis, as well as evidence of individual benefit, when making decisions on licensing. For more information on this complex subject, see **Franklin et al. (2019)**.

---

[1] Like most definitions, this one has its limits. For example, there are a number of essential dietary constituents, such as iron and various vitamins, which are used as medicines. Furthermore, some biological products (e.g. **epoietin**) show batch-to-batch variation in their chemical constitution that significantly affects their properties. There is also the study of pharmaceutical-grade nutrients or ‘nutraceuticals’.

[2] The name persists today in some ancient universities, being attached to chairs of what we would call clinical pharmacology.

[3] Oliver Wendell Holmes, an eminent physician, wrote in 1860: ‘[I] firmly believe that if the whole materia medica, as now used, could

be sunk to the bottom of the sea, it would be all the better for mankind and the worse for the fishes' (see **Porter, 1997**).

4 A handful of synthetic substances achieved pharmacological prominence long before the era of synthetic chemistry began. Diethyl ether, first prepared as 'sweet oil of vitriol' in the 16th century, and nitrous oxide, prepared by Humphrey Davy in 1799, were used to liven up parties before being introduced as anaesthetic agents in the mid-19th century (see Ch. 41). Amyl nitrite (see Ch. 19) was made in 1859 and can claim to be the first 'rational' therapeutic drug; its therapeutic effect in angina was predicted on the basis of its physiological effects – a true 'pharmacologist's drug' and the smelly forerunner of the nitrovasodilators that are widely used today. Aspirin (Ch. 25), the most widely used therapeutic drug in history, was first synthesised in 1853, with no therapeutic application in mind. It was rediscovered in 1897 in the laboratories of the German company Bayer, who were seeking a less toxic derivative of salicylic acid. Bayer commercialised aspirin in 1899 and made a fortune.

6 The UK Medicines and Healthcare Regulatory Agency (MHRA) requires detailed evidence of therapeutic efficacy based on controlled clinical trials before a new drug is registered, but no clinical trials data for homeopathic products or for the many herbal remedies that were on sale before the Medicines Act of 1968.

7 Whole genome sequencing is now offered directly to the public and costs as little as £50.

2: How drugs act

general principles

OVERVIEW

The emergence of pharmacology as a science came when the emphasis shifted from describing what drugs do to explaining how they work. In this chapter we set out some general principles underlying the interaction of drugs with living systems (**Ch. 3** goes into some of the more molecular aspects in detail). The interaction between drugs and cells is described, followed by a more detailed examination of different types of drug–receptor interaction. The receptor concept has been described as the 'big idea' of pharmacology (**Rang, 2006**) and will be a recurring theme throughout this book.

Introduction

To begin with, we should gratefully acknowledge Paul Ehrlich for insisting that drug action must be explicable in terms of conventional chemical interactions between drugs and tissues, and for dispelling the idea that the remarkable potency and specificity of action of some drugs put them somehow out of reach of chemistry and physics and required the intervention of magical 'vital forces'. Although many drugs produce effects in extraordinarily low doses

and concentrations, low concentrations still involve very large numbers of molecules. One drop of a solution of a drug at only 10^{-10} mol/L still contains about 3×10^9 drug molecules, so there is no mystery in the fact that it may produce an obvious pharmacological response. Some bacterial toxins (e.g. diphtheria toxin) act with such precision that a single molecule taken up by a target cell is sufficient to kill it.

One of the basic tenets of pharmacology is that drug molecules must exert some chemical influence on one or more cell constituents in order to produce a pharmacological response. In other words, drug molecules must get so close to these constituent cellular molecules that the two interact chemically in such a way that the function of the latter is altered. Of course, the molecules in the organism vastly outnumber the drug molecules, and if the drug molecules were merely distributed at random, the chance of interaction with any particular class of cellular molecule would be negligible. Therefore pharmacological effects require, in general, the non-uniform distribution of the drug molecule within the body or tissue, which is the same as saying that drug molecules must be 'bound' to particular constituents of cells and tissues in order to produce an effect. Ehrlich summed it up thus: '*Corpora non agunt nisi fixata*' (in this context, 'A drug will not work unless it is bound'). [1]

These critical binding sites are often referred to as 'drug targets' (an obvious allusion to Ehrlich's famous phrase 'magic bullets', describing the potential of antimicrobial drugs). The mechanisms by which the association of a drug molecule with its target leads to a physiological response constitute the major thrust of

pharmacological research. Most drug targets are protein molecules. Even general anaesthetics (see **Ch. 41**), which were long thought to produce their effects by an interaction with membrane lipid only, now appear to interact mainly with membrane proteins (see **Franks, 2008**).

All rules need exceptions, and many antimicrobial and antitumour drugs (see **Chs 51 and 57**), as well as mutagenic and carcinogenic agents (see **Ch. 58**), interact directly with DNA rather than protein; bisphosphonates, used to treat osteoporosis (see **Ch. 36**), bind to calcium salts in the bone matrix, rendering them toxic to osteoclasts. There are also exceptions among the new generation of *biopharmaceutical drugs* that include nucleic acids, proteins and antibodies (see **Ch. 5**), although these do interact with cellular components to produce their effects.

Protein Targets for Drug Binding

Four main kinds of regulatory protein are commonly involved as primary drug targets, namely:

- receptors
- enzymes
- carrier molecules (transporters)
- ion channels

Furthermore, many drugs bind (in addition to their primary targets) to plasma proteins (see **Ch. 9**) and other tissue proteins, without producing any obvious physiological effect. Nevertheless, the generalisation that most drugs act on one or other of the four types of protein listed earlier serves as a good starting point.

Further discussion of the mechanisms by which such binding leads to cellular responses is given in **Chapters 3** and **4**.

Targets for drug action

- A drug is a chemical applied to a physiological system that affects its function in a specific way.
- With some exceptions, drugs act on target proteins, namely:
  - receptors
  - enzymes
  - carriers
  - ion channels.
- The term *receptor* is used in different ways. In pharmacology, it describes protein molecules whose function is to recognise and respond to endogenous chemical signals. Other macromolecules with which drugs interact to produce their effects are known as *drug targets*.
- Specificity is reciprocal: individual classes of drug bind only to certain targets, and individual targets recognise only certain classes of drug.
- No drugs are completely specific in their actions. In many cases, increasing the dose of a drug will cause it to affect targets other than the principal one (so called 'off-target' effects), and this can lead to side effects.

Drug Receptors

What do we Mean by Receptors?

As emphasised in **Chapter 1**, the concept of receptors is central to pharmacology, and the term is most often used to describe the target molecules through which soluble physiological mediators – hormones, neurotransmitters, inflammatory mediators, etc. – produce their effects. Examples such as acetylcholine receptors, cytokine receptors, steroid receptors and growth hormone receptors abound in this book, and generally the term *receptor* indicates a recognition molecule for a chemical mediator through which a response is transduced. Receptor molecules have evolved to allow fine-tuning of the homeostatic control of cells and physiological functions – pharmacology often hijacks these innate control steps.

'Receptor' is sometimes used to denote *any* target molecule with which a drug molecule (i.e. a foreign compound rather than an endogenous mediator) has to combine in order to elicit its specific effect. For example, the voltage-sensitive sodium channel is sometimes referred to as the 'receptor' for **local anaesthetics** (see **Ch. 44**), or the enzyme dihydrofolate reductase as the 'receptor' for **methotrexate** (see **Chs 51 and 57**). The term *drug target*, of which receptors are one type, is preferable in this context.

In the more general context of cell biology, the term receptor is used to describe various cell surface molecules (such as *T-cell receptors, integrins, Toll receptors*, etc.; see **Ch. 7**) involved in the cell-to-cell interactions that are important in immunology, cell growth, migration and differentiation, some of which are also emerging as drug targets. These receptors differ from conventional pharmacological receptors in that they respond to proteins attached to cell surfaces or extracellular structures, rather than to soluble mediators.

Enzymes exist to mediate the biochemical signals within cells or tissues. Some drugs can modulate the activities of these enzymes for our benefit. For example, common anti-inflammatory drugs (NSAIDs; see **Ch. 25**) are used to relieve pain and inflammation – they achieve their effects through inhibiting cyclooxygenase enzymes.

Various carrier proteins are often referred to as receptors, such as the *low-density lipoprotein receptor* that plays a key role in lipid metabolism (see **Ch. 22**) and the *transferrin receptor* involved in iron absorption (see **Ch. 24**). These entities have little in common with pharmacological receptors. Although quite distinct from pharmacological receptors, these proteins play an important role in the action of drugs such as statins (see **Ch. 22**).

Receptors in Physiological Systems

Receptors form a key part of the system of chemical communication that all multicellular organisms use to coordinate the activities of their cells and organs. Without them, we would be unable to function.

Some fundamental properties of receptors are illustrated by the action of **adrenaline** (epinephrine) on the heart. Adrenaline first binds to a receptor protein (the β_1 *adrenoceptor*, see **Ch. 15**) that serves as a recognition site for adrenaline and other catecholamines. When it binds to the receptor, a train of reactions is initiated (see **Ch. 3**), leading to an increase in force and rate of the heartbeat. In the absence of adrenaline, the receptor is normally functionally silent. This is true of most receptors for endogenous mediators (hormones, neurotransmitters, cytokines, etc.), although there are

examples (see **Ch. 3**) of receptors that are 'constitutively active' – that is, they exert a controlling influence even when no chemical mediator is present.

There is an important distinction between *agonists*, which 'activate' the receptors, and *antagonists*, which combine at the same site without causing activation, and block the effect of agonists on that receptor. The distinction between agonists and antagonists exists only for pharmacological receptors; we cannot usefully speak of 'agonists' for the other classes of drug target described earlier.

The characteristics and accepted nomenclature of pharmacological receptors and other drug targets are detailed in the Guide to Pharmacology, an extensive online database as well as in a regularly updated summary (**Alexander et al., 2019**). The origins of the receptor concept and its pharmacological significance are discussed by **Rang (2006)**.

Drug Specificity

For a drug to be useful as either a therapeutic or a scientific tool, it must act selectively on particular cells and tissues. In other words, it must show a high degree of binding site specificity. Conversely, proteins that function as drug targets generally show a high degree of ligand specificity; they bind only molecules of a certain precise type.

These principles of binding site and ligand specificity can be clearly recognised in the actions of a mediator such as **angiotensin** (see **Ch. 21**). This peptide acts strongly on vascular smooth muscle, and on the kidney tubule, but has very little effect on other kinds of smooth muscle or on the intestinal epithelium. Other mediators

affect a quite different spectrum of cells and tissues, the pattern in each case reflecting the specific pattern of expression of the protein receptors for the various mediators. A small chemical change, such as conversion of one of the amino acids in angiotensin from L to D form, or removal of one amino acid from the chain, can inactivate the molecule altogether, because the receptor fails to bind the altered form. The complementary specificity of ligands and binding sites, which gives rise to the very exact molecular recognition properties of proteins, is central to explaining many of the phenomena of pharmacology. It is no exaggeration to say that the ability of proteins to interact in a highly selective way with other molecules – including other proteins – is the basis of living machines. Its relevance to the understanding of drug action will be a recurring theme in this book.

Finally, it must be emphasised that no drug acts with complete specificity. Thus tricyclic antidepressant drugs (see **Ch. 48**) act by blocking monoamine transporters but are notorious for producing side effects (e.g. dry mouth) related to their ability to block various other receptors. In general, the lower the potency of a drug and the higher the dose needed, the more likely it is that sites of action other than the primary one will assume significance. In clinical terms, this is often associated with the appearance of unwanted 'off-target' side effects [2] of which no drug is free.

Since the 1970s, pharmacological research has succeeded in identifying the protein targets of many different types of drug. Drugs such as opioid analgesics (see **Ch. 43**), cannabinoids (see **Ch. 18**) and benzodiazepines (see **Ch. 45**), whose actions have been described in exhaustive detail for many years, are now known

to target well-defined receptors, many of which have been fully characterised by gene-cloning and protein crystallography techniques (see **Ch. 3**).

Receptor Classification

Where the action of a drug can be associated with a particular receptor, this provides a valuable means for classification and refinement in drug design. For example, pharmacological analysis of the actions of histamine (see **Ch. 17**) showed that some of its effects (the H_1 effects, such as smooth muscle contraction) were strongly antagonised by the competitive histamine antagonists then known. Black and his colleagues suggested in 1970 that the remaining actions of histamine, which included its stimulant effect on gastric secretion, might represent a second class of histamine receptor (H_2). Testing a number of histamine analogues, they found that some were selective in producing H_2 effects, with little H_1 activity. By analysing which parts of the histamine molecule conferred this type of specificity, they were able to develop selective H_2 antagonists, which proved to be potent in blocking gastric acid secretion, a development of major therapeutic significance (see **Ch. 30**). [3] Two further types of histamine receptor (H_3 and H_4) were recognised later.

Receptor classification based on pharmacological responses continues to be a valuable and widely used approach. Subsequently, newer experimental approaches produced other criteria on which to base receptor classification. The direct measurement of ligand binding to receptors (see later) allowed many new receptor subtypes to be defined that could not easily be distinguished by studies of

drug effects. Molecular sequencing of the amino acid structure (see **Ch. 3**) provided a completely new basis for classification at a much finer level of detail than can be reached through pharmacological analysis. Finally, analysis of the biochemical pathways that are linked to receptor activation (see **Ch. 3**) provides yet another basis for classification.

The result of this data explosion was that receptor classification suddenly became much more detailed, with a proliferation of receptor subtypes for all the main types of ligand. As alternative molecular and biochemical classifications began to spring up that were incompatible with the accepted pharmacologically defined receptor classes, the International Union of Basic and Clinical Pharmacology (IUPHAR) convened expert working groups to produce agreed receptor classifications for the major types, taking into account the pharmacological, molecular and biochemical information available. These wise people have a hard task; their conclusions will be neither perfect nor final but are essential to ensure a consistent terminology. To the student, this may seem an arcane exercise in taxonomy, generating much detail but little illumination. There is a danger that the tedious lists of drug names, actions and side effects that used to burden the subject will be replaced by exhaustive tables of receptors, ligands and transduction pathways. In this book, we have tried to avoid detail for its own sake and include only such information on receptor classification as seems interesting in its own right or is helpful in explaining the actions of important classes of drugs.

Drug–Receptor Interactions

Occupation of a receptor by a drug molecule may or may not result in *activation* of the receptor. By activation, we mean that the receptor is affected by the bound molecule in such a way as to alter the function of the cell and elicit a tissue response. The molecular mechanisms associated with receptor activation are discussed in **Chapter 3**. Binding and activation represent two distinct steps in the generation of the receptor-mediated response by an agonist (**Fig. 2.1**). If a drug binds to the receptor without causing activation and thereby prevents the agonist from binding, it is termed a *receptor antagonist*. The tendency of a drug to bind to the receptors is governed by its *affinity*, whereas the tendency for it, once bound, to switch the receptor into its active conformation is denoted by its *efficacy*. These terms are defined more precisely later. Drugs of high potency generally have a high affinity for the receptors and thus occupy a significant proportion of the receptors even at low concentrations. Agonists also possess significant *efficacy*, whereas antagonists, in the simplest case, have zero efficacy. Drugs with intermediate levels of efficacy, such that even when 100% of the receptors are occupied the tissue response is submaximal, are known as *partial agonists*, to distinguish them from *full agonists*, the efficacy of which is sufficient that they can elicit a maximal tissue response. These concepts, although clearly an oversimplified description of events at the molecular level (see **Ch. 3**), provide a useful basis for characterising drug effects.

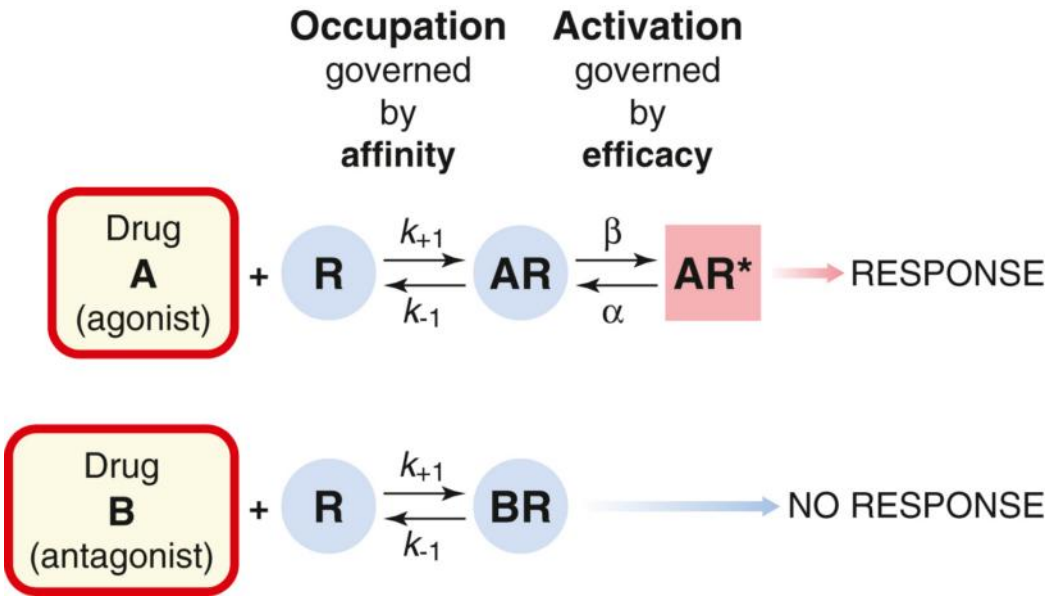

FIG. 2.1 The distinction between drug binding and receptor activation.Ligand *A* is an agonist, because when it is bound, the receptor *(R)* tends to become activated, whereas ligand *B* is an antagonist, because binding does not lead to activation. It is important to realise that for most drugs, binding and activation are reversible, dynamic processes. The rate constants k_{+1}, k_{-1}, α and β for the binding, unbinding and activation steps vary between drugs. For an antagonist, which does not activate the receptor, β = 0.

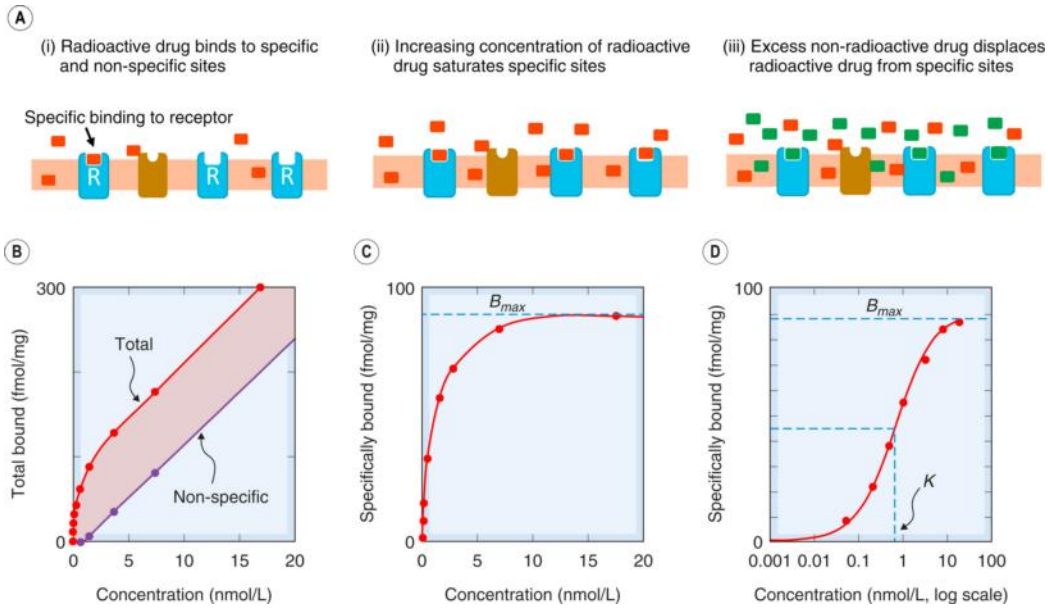

FIG. 2.2 Measurement of receptor binding.(A) (i) Cartoon depicting radioligand (shown in red) binding to its receptor *(R)* in the membrane as well as to non-specific sites on other proteins and lipid. In (ii) when the concentration of radioligand is increased all the specific sites become saturated but non-specific binding continues to increase. In (iii) the addition of a high concentration of a non-radioactive drug *(shown in green)* that also binds to R displaces the radioactive drug from its receptors but not from the non-specific sites. (B–D) Illustrate actual experimental results for radioligand binding to β-adrenoceptors in cardiac cell membranes. The ligand was [^{3}H]-cyanopindolol, a derivative of pindolol (see **Ch. 15**). (B) Measurements of total and non-specific binding at equilibrium. Non-specific binding is measured

in the presence of a saturating concentration of a non-radioactive β-adrenoceptor agonist, which prevents the radioactive ligand from binding to β-adrenoceptors. The difference between the two lines represents specific binding. (C) Specific binding plotted against concentration. The curve is a rectangular hyperbola (**Eq. 2.5**). (D) Specific binding as in (C) plotted against the concentration on a log scale. The sigmoid curve is a *logistic curve* representing the logarithmic scaling of the rectangular hyperbola plotted in panel (C) from which the binding parameters K (the equilibrium dissociation constant) and B_{max} (the binding capacity) can be determined.

We now discuss certain aspects in more detail, namely drug binding, agonist concentration–effect curves, competitive antagonism, partial agonists and the nature of efficacy. Understanding these concepts at a qualitative level is sufficient for many purposes, but for more detailed analysis a quantitative formulation is needed (see later in the chapter).

The Binding of Drugs to Receptors

The binding of drugs to receptors can often be measured directly by the use of drug molecules (agonists or antagonists) labelled with one or more radioactive atoms (usually ^{3}H, ^{14}C or ^{125}I). The usual procedure is to incubate samples of the tissue (or membrane fragments) with various concentrations of radioactive drug until equilibrium conditions are reached (i.e. when the rates of

association [binding] and dissociation [unbinding] of the radioactive drug are equal). The bound radioactivity is measured after removal of the supernatant and any unbound labelled drug.

In such experiments, the radiolabelled drug will exhibit both specific binding (i.e. binding to receptors, which is saturable as there are a finite number of receptors in the tissue) and a certain amount of 'non-specific binding' (i.e. drug taken up by structures other than receptors, which, at the concentrations used in such studies, is normally non-saturable), which obscures the specific component and needs to be kept to a minimum (**Fig. 2.2A,B**). The amount of non-specific binding is estimated by measuring the radioactivity taken up in the presence of a saturating concentration of a (non-radioactive) ligand that inhibits completely the binding of the radioactive drug to the receptors, leaving behind the non-specific component. This is then subtracted from the total binding to give an estimate of specific binding (**Fig. 2.2C**). The *binding curve* (**Fig. 2.2C,D**) defines the relationship between concentration and the amount of drug bound (B), and in most cases it fits well to the relationship predicted theoretically (see **Fig. 2.14**), allowing the affinity of the drug for the receptors to be estimated, as well as the maximal *binding capacity* (B_{max}), representing the density of receptors in the tissue. When combined with functional studies, binding measurements have proved very valuable. It has, for example, been confirmed that the *spare receptor hypothesis* for muscarinic receptors in smooth muscle is correct; agonists are found to bind, in general, with rather low affinity, and a maximal biological effect occurs at low receptor occupancy. It has also been shown, in skeletal muscle and other tissues, that

denervation leads to an increase in the number of receptors in the target cell, a finding that accounts, at least in part, for the phenomenon of *denervation supersensitivity*. More generally, it appears that receptors tend to increase in number, usually over the course of a few days, if the relevant hormone or transmitter is absent or scarce, or to decrease in number if the receptors are activated for a prolonged period, a process of adaptation to continued administration of drugs or hormones.

Non-invasive imaging techniques, such as *positron emission tomography* (PET), using drugs labelled with an isotope of short half-life (such as ^{11}C or ^{18}Fl), can also be used to investigate the distribution of receptors in structures such as the living human brain. This technique has been used, for example, to measure the degree of dopamine-receptor blockade produced by antipsychotic drugs in the brains of patients with schizophrenia (see **Ch. 47**).

Binding curves with agonists often reveal an apparent heterogeneity among receptors. For example, agonist binding to muscarinic receptors (see **Ch. 14**) and also to β-adrenoceptors (see **Ch. 15**) suggests at least two populations of binding sites with different affinities. This may be because the receptors can exist either unattached or coupled within the membrane to another macromolecule, the G protein (see **Ch. 3**), which constitutes part of the transduction system through which the receptor exerts its regulatory effect. Antagonist binding does not show this complexity, probably because antagonists, by their nature, do not lead to the secondary event of G protein coupling. Because agonist binding results in activation, agonist affinity has proved to be a surprisingly elusive concept, about which aficionados love to argue.

The Relation Between Agonist Concentration and Effect

Although binding can be measured directly, it is usually a biological response, such as a rise in blood pressure, contraction or relaxation of a strip of smooth muscle in an organ bath, the activation of an enzyme, or a behavioural response, that we are interested in, and this is often plotted as a *concentration–effect curve* (in vitro) or *dose–response curve* (in vivo), as in **Fig. 2.3**. This allows us to estimate the *maximal response/effect* that the drug can produce (E_{max}) and the concentration or dose needed to produce a 50% maximal response (EC_{50} or ED_{50}). A logarithmic concentration or dose scale is often used. This transforms the curve from a rectangular hyperbola to a sigmoidal curve in which the mid portion is essentially linear (the importance of the slope of the linear portion will become apparent later in this chapter when we consider antagonism and partial agonists). The E_{max}, EC_{50} and slope parameters are useful for comparing different drugs that produce qualitatively similar effects (see **Fig. 2.7** and **Ch. 8**). Although they look similar to the binding curve in **Fig. 2.2D**, concentration–effect curves cannot be used to measure the affinity of agonist drugs for their receptors, because the response produced is not, as a rule, directly proportional to receptor occupancy. This often arises because the maximum response of a tissue may be produced by agonists when they occupy less than 100% of the receptors. Under these circumstances the tissue is said to possess spare receptors (see later).

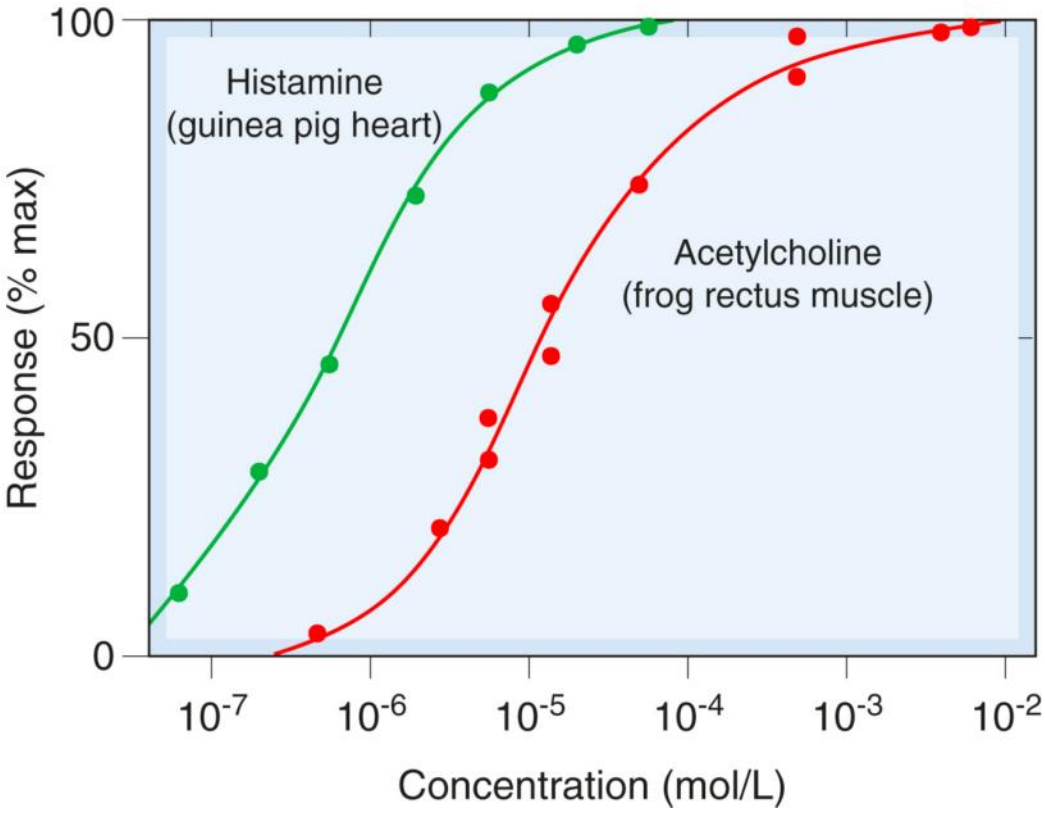

FIG. 2.3 Experimentally observed concentration–effect curves.Although the lines, drawn according to the binding **Eq. 2.5**, fit the points well, such curves do not give correct estimates of the affinity of drugs for receptors. This is because the relationship between receptor occupancy and response is usually non-linear.

In interpreting concentration–effect curves, it must be remembered that the concentration of the drug at the receptors may differ from the known concentration in the bathing solution. Agonists may be subject to rapid enzymic degradation or uptake by cells as they diffuse from the surface towards their site of action, and a steady state can be reached in which the agonist concentration

at the receptors is very much less than the concentration in the bath. In the case of acetylcholine, for example, which is hydrolysed by cholinesterase present in most tissues (see **Ch. 14**), the concentration reaching the receptors can be less than 1% of that in the bath, and an even bigger difference has been found with noradrenaline (norepinephrine), which is avidly taken up by sympathetic nerve terminals in many tissues (see **Ch. 15**). The problem is reduced but not entirely eradicated by the use of recombinant receptors expressed in cells in culture. Thus, even if the concentration–effect curve, as in **Fig. 2.3**, looks just like a facsimile of the binding curve (see **Fig. 2.2D**), it cannot be used directly to determine the affinity of the agonist for the receptors.

Spare Receptors

Stephenson (1956), studying the actions of acetylcholine analogues in isolated tissues, found that many full agonists were capable of eliciting maximal responses at very low occupancies, often less than 1%. This means that the mechanism linking the response to receptor occupancy has a substantial reserve capacity. Such systems may be said to possess *spare receptors*, or a receptor reserve. The existence of spare receptors does not imply any functional subdivision of the receptor pool, but merely that the pool is larger than the number needed to evoke a full response. This surplus of receptors over the number actually needed might seem a wasteful biological arrangement. But in fact it is highly efficient in that a given number of agonist–receptor complexes, corresponding to a given level of biological response, can be reached with a lower concentration of hormone or neurotransmitter than would be the

case if fewer receptors were provided. Economy of hormone or transmitter secretion is thus achieved at the expense of providing more receptors.

Competitive Antagonism

Although one drug can inhibit the response to another in several ways, competition at the receptor level is particularly important, both in the laboratory and in the clinic, because of the high potency and specificity that can be achieved.

In the presence of a competitive antagonist, the agonist occupancy (i.e. proportion of receptors to which the agonist is bound) at a given agonist concentration is reduced, because the receptor can usually accommodate only one molecule at a time. However, because the two are in competition, raising the agonist concentration can restore the agonist occupancy (and hence the tissue response). The antagonism is therefore said to be *surmountable*, in contrast to other types of antagonism (see later) where increasing the agonist concentration fails to overcome the blocking effect. A simple theoretical analysis (see Quantitative Aspects of Drug–Receptor Interactions later) predicts that in the presence of a fixed concentration of the antagonist, the log concentration–effect curve for the agonist will be shifted to the right, without any change in slope or maximum – the hallmark of competitive antagonism (**Fig. 2.4A**). The shift is expressed as a *dose ratio*, *r* (the ratio by which the agonist concentration has to be increased in the presence of the antagonist in order to restore a given level of response). Theory predicts that the dose ratio increases linearly with the concentration of the antagonist. These

predictions are often borne out in practice (**Fig. 2.5A**), providing a relatively simple method for determining the equilibrium dissociation constant of the antagonist (K_B; **Fig. 2.5B**). Examples of competitive antagonism are very common in pharmacology. The surmountability of the block by the antagonist may be important in practice, because it allows the functional effect of the agonist to be restored by an increase in concentration. With other types of antagonism (as detailed later), the block is usually insurmountable.

The salient features of competitive antagonism are:

- a shift of the agonist log concentration–effect curve to the right, without change of slope or maximum (i.e. antagonism can be overcome by increasing the concentration of the agonist)
- linear relationship between agonist dose ratio and antagonist concentration
- evidence of competition from binding studies

Competitive antagonism is the most direct mechanism by which one drug can reduce the effect of another (or of an endogenous mediator).

The characteristics of *reversible competitive antagonism* described previously reflect the fact that agonist and competitive antagonist molecules do not stay bound to the receptor but dissociate and rebind continuously. The rate of dissociation of the antagonist molecules is sufficiently high that a new equilibrium is rapidly established on addition of the agonist. In effect, agonist molecules are able to replace the antagonist molecules on the receptors when the antagonist unbinds, although they cannot, of

course, evict bound antagonist molecules. Displacement occurs because, by occupying a proportion of the vacant receptors, the agonist effectively reduces the rate of association of the antagonist molecules; consequently, the rate of dissociation temporarily exceeds that of association, and the overall antagonist occupancy falls.

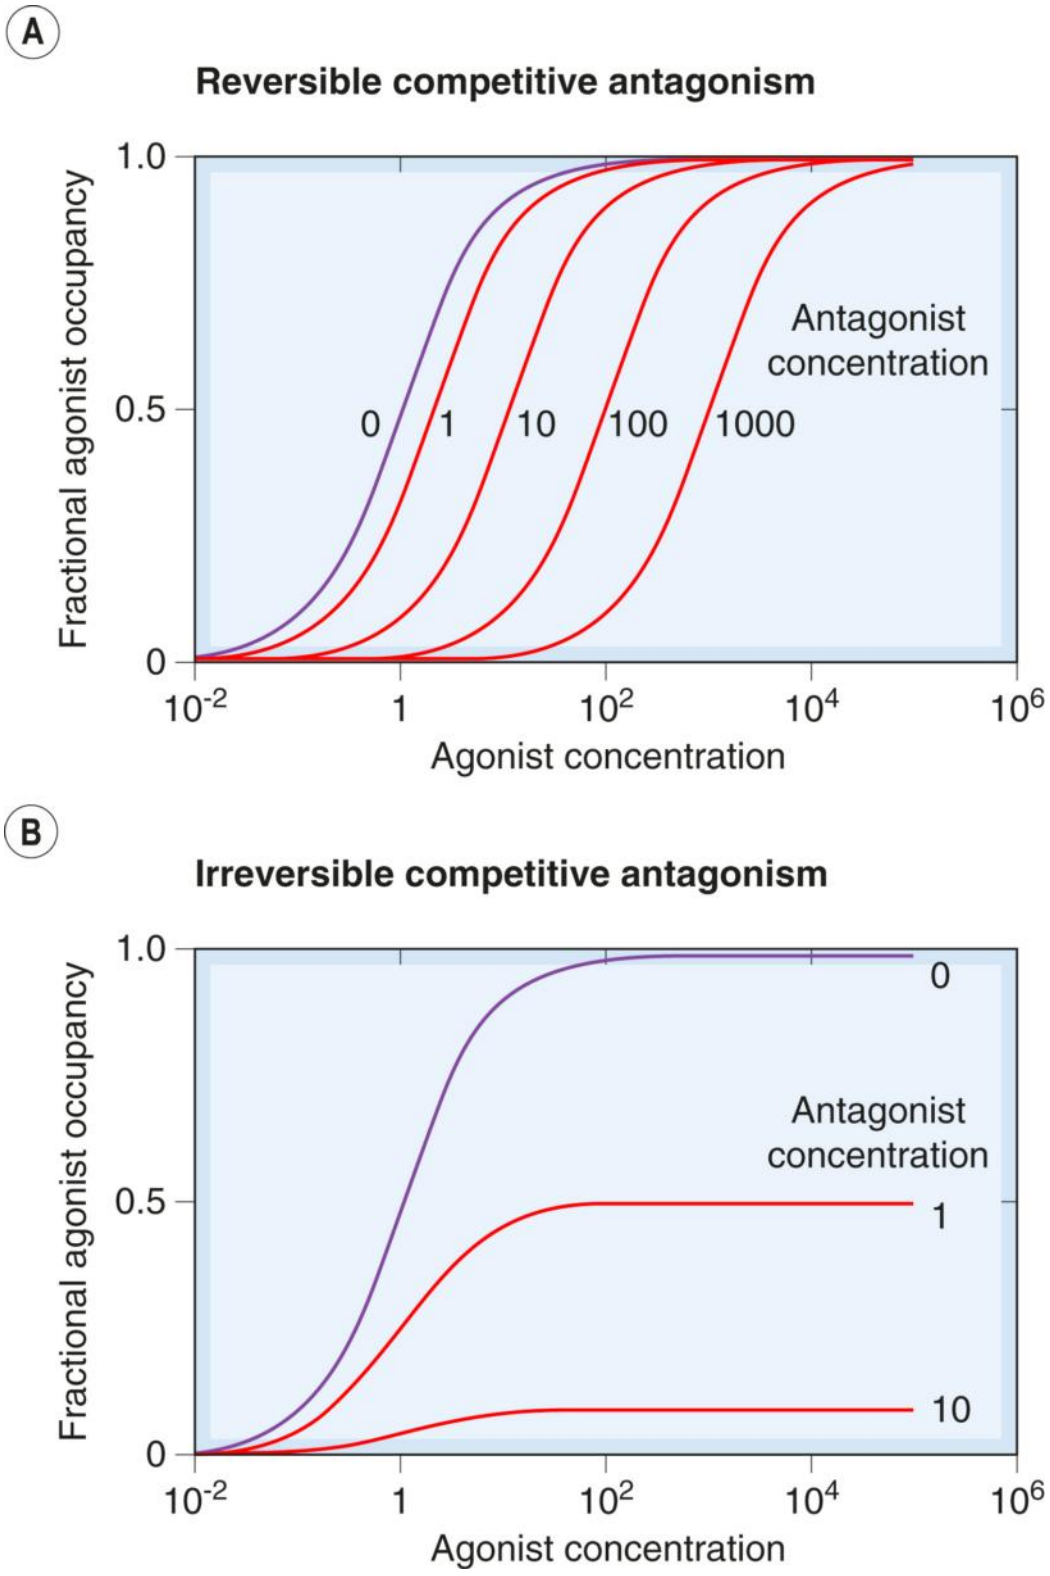

FIG. 2.4 Hypothetical agonist concentration–occupancy curves in the presence of reversible

(A) and irreversible (B) competitive antagonists.The concentrations are normalised with respect to the equilibrium dissociation constants, *K* (i.e. 1.0 corresponds to a concentration equal to *K* and results in 50% occupancy). Note that in (A) increasing the agonist concentration overcomes the effect of a reversible antagonist (i.e. the block is surmountable), so that the maximal response is unchanged, whereas in (B) the effect of an irreversible antagonist is insurmountable and full agonist occupancy cannot be achieved.

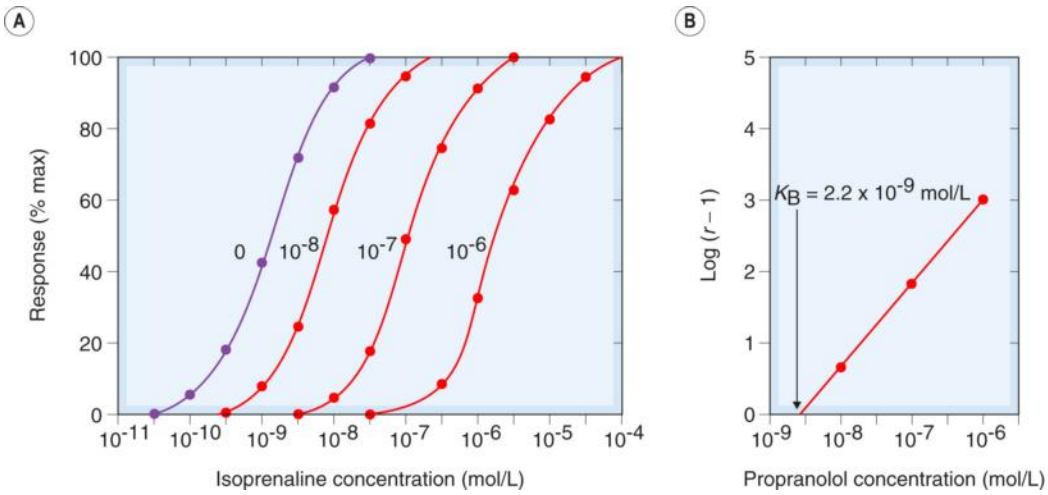

FIG. 2.5 Competitive antagonism of isoprenaline by propranolol measured on isolated guinea pig atria.(A) Concentration–effect curves at various propranolol concentrations (indicated on the curves). Note the progressive shift to the right without a change of slope or maximum. (B) Schild plot (**Eq. 2.10**). *'r'* is the ratio of the concentration of agonist that produces a given level of response in the presence and absence of increasing concentrations of antagonist (discussed later in Quantitative Aspects of Drug Receptor Interactions). The equilibrium dissociation constant (K_B) for propranolol is given by the abscissal intercept, 2.2×10^{-9} mol/L. Note that the subscript 'B' is now used in 'K_B' to indicate that the equilibrium dissociation constant is that of the antagonist (designated drug B) measured in the presence of the agonist (designated drug A). Results from Potter, L.T., 1967. Uptake of

propranolol by isolated guinea pig atria. J. Pharmacol. Exp. Ther. 55, 91–100.

Competitive antagonism

- Reversible competitive antagonism is the commonest and most important type of antagonism; it has two main characteristics.
  - In the presence of the antagonist, the agonist log concentration–effect curve is shifted to the right without change in slope or maximum, the extent of the shift being a measure of the *dose ratio*.
  - The dose ratio increases linearly with antagonist concentration.
- Antagonist affinity, measured in this way, has been widely used as a basis for receptor classification.

Irreversible Competitive Antagonism

Irreversible competitive (or *non-equilibrium*) *antagonism* occurs when the antagonist binds to the same site on the receptor as the agonist but dissociates very slowly, or not at all, from the receptors, with the result that no change in the antagonist occupancy takes place when the agonist is applied. [4]

The predicted effects of reversible and irreversible antagonists are compared in **Fig. 2.4**.

In some cases (**Fig. 2.6A**), the theoretical effect is accurately reproduced with the antagonist reducing the maximum response. However, the distinction between reversible and irreversible competitive antagonism (or even non-competitive antagonism) is not always so clear. This is because of the phenomenon of spare receptors; if the agonist occupancy required to produce a maximal biological response is very small (say 1% of the total receptor pool), then it is possible to block irreversibly nearly 99% of the receptors without reducing the maximal response. The effect of a lesser degree of antagonist occupancy will be to produce a parallel shift of the log concentration–effect curve that is indistinguishable from reversible competitive antagonism (**Fig. 2.6B**). Only when the antagonist occupancy exceeds 99% will the maximum response be reduced.

Irreversible competitive antagonism occurs with drugs that possess reactive groups that form covalent bonds with the receptor. These are mainly used as experimental tools for investigating receptor function, and few are used clinically. Irreversible enzyme inhibitors that act similarly are clinically used, however, and include drugs such as **aspirin** (see **Ch. 25**), **omeprazole** (see **Ch. 30**), monoamine oxidase inhibitors (see **Ch. 48**) and **ibrutinib** (see **Ch. 57**).

Partial Agonists and the Concept of Efficacy

So far, we have considered drugs either as agonists, which in some way activate the receptor when they occupy it, or as antagonists, which cause no activation. However, the ability of a drug molecule to activate the receptor – namely its efficacy – is actually a graded,

rather than an all-or-nothing, property. If a series of chemically related agonist drugs acting on the same receptors is tested on a given biological system, it is often found that the largest response that can be produced differs from one drug to another. Some compounds (known as *full agonists*) can produce a maximal response (the largest response that the tissue is capable of giving), whereas others (*partial agonists*) can produce only a submaximal response. **Fig. 2.7A** shows concentration–effect curves for several α-adrenoceptor agonists (see **Ch. 15**), which cause contraction of isolated strips of rabbit aorta. The full agonist **phenylephrine** produced the maximal response of which the tissue was capable; the other compounds could produce only submaximal responses and are partial agonists. The difference between full and partial agonists lies in the relationship between receptor occupancy and response. In the experiment shown in **Fig. 2.7** it was possible to estimate the affinity of the various drugs for the receptor, and hence (based on the theoretical model described later) to calculate the fraction of receptors occupied (known as *occupancy*) as a function of drug concentration. Plots of response as a function of occupancy for the different compounds are shown in **Fig. 2.7B**, showing that for partial agonists the response at a given level of occupancy is less than for full agonists. The weakest partial agonist, **tolazoline**, produces a barely detectable response even at 100% occupancy, and is usually classified as a *competitive antagonist* (see **Ch. 15**).

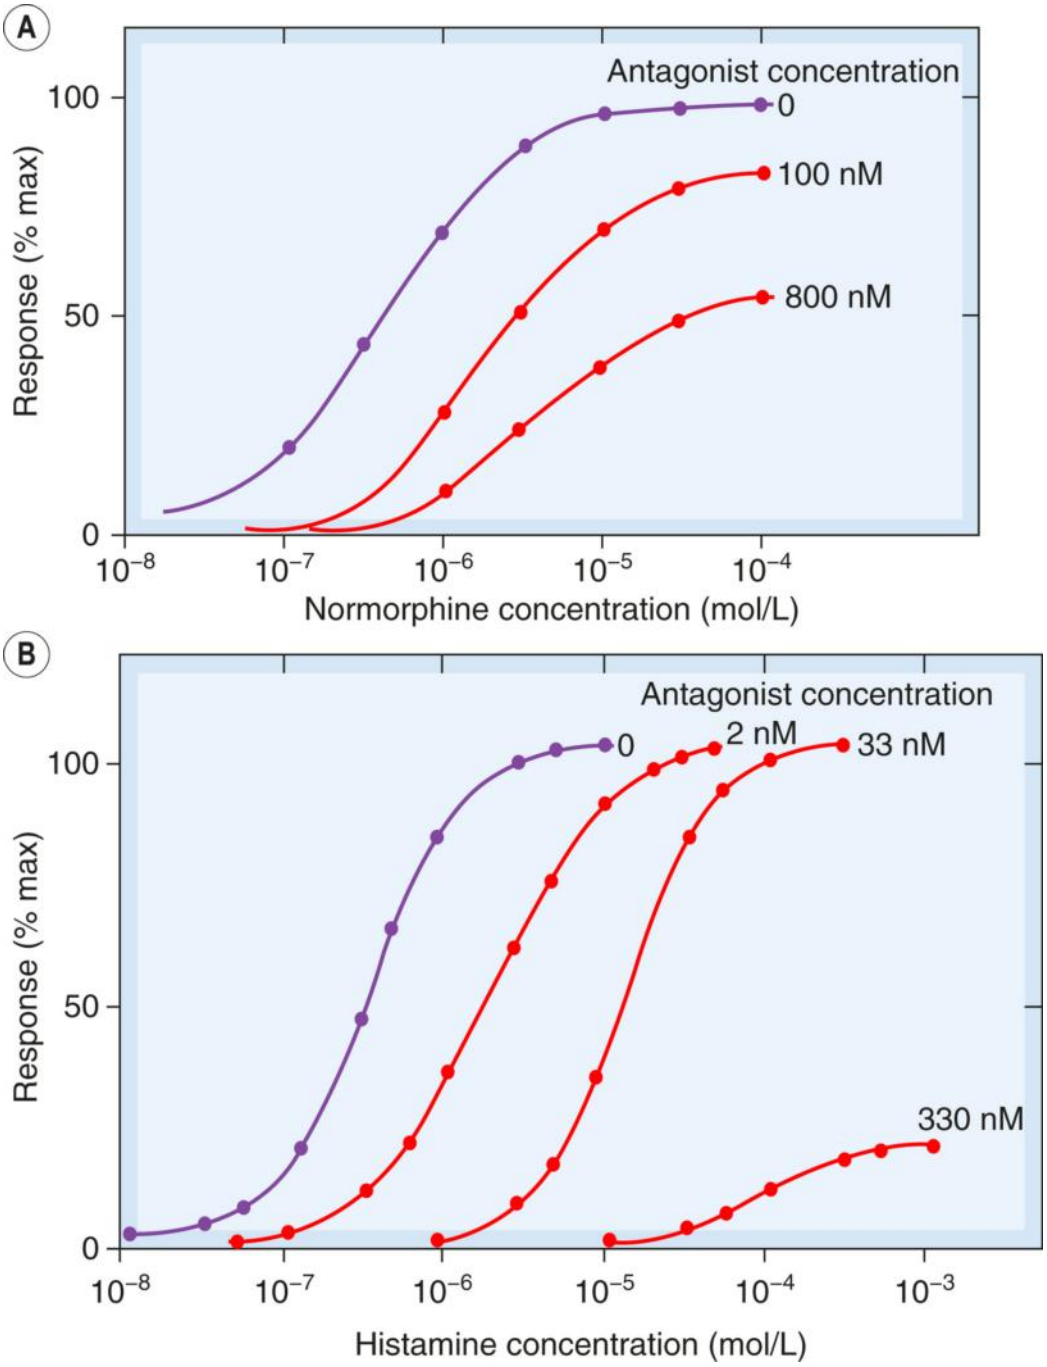

FIG. 2.6 Effects of irreversible competitive antagonists on agonist concentration–effect curves.(A) Rat brain neurons responding to the opioid agonist normorphine before and after being exposed to the irreversible competitive

antagonist β-funaltrexamine for 30 minutes and then washed to remove the antagonist. Note the depression of the maximum response. (B) Responses of the guinea pig ileum to histamine before and after treatment with increasing concentrations of a receptor alkylating agent (GD121) for 5 minutes and then washed to remove the antagonist. Note the concentration–response curve is initially shifted to the right with no depression of the maximum response. Panel [A] after Williams, J.T., North, R.A., 1984. Mol. Pharmacol. 26, 489–497; panel [B] after Nickerson, M., 1955. Nature 178, 696–697.

These differences can be expressed quantitatively in terms of *efficacy* (*e*), a parameter originally defined by **Stephenson (1956)** that describes the 'strength' of the agonist–receptor complex in evoking a response of the tissue. In the simple scheme shown in **Fig. 2.1**, efficacy describes the tendency of the drug–receptor complex to adopt the active (AR∗), rather than the resting (AR), state. A drug with zero efficacy ($e = 0$) has no tendency to cause receptor activation, and causes no tissue response. A full agonist is a drug who efficacy [5] is sufficient that it produces a maximal response when less than 100% of receptors are occupied. A partial agonist has lower efficacy, such that 100% occupancy elicits only a submaximal response.

Subsequently it was appreciated that efficacy is composed of drug-dependent and tissue-dependent components. The drug-

dependent component is referred to as the *intrinsic efficacy*, which is the ability of the agonist drug molecule, once bound, to activate the receptor protein (see **Kelly, 2013**). The tissue-dependent components of efficacy include the number of receptors that it expresses and the efficiency of coupling of receptor activation to the measured tissue response. The number of receptors expressed is especially relevant to the study of receptors in recombinant expression systems when receptors are often very highly expressed and intermediate efficacy agonists then appear as full agonists. Across different cell types expressing the same receptor but at different densities, a given drug of intermediate efficacy may appear as a full agonist in one tissue (high level of receptor expression), a partial agonist in another (lower level of receptor expression) and even as an antagonist in another (very low level of receptor expression). The term 'partial agonist' is therefore only applicable when describing the action of a drug on a specific tissue or cell type.

FIG. 2.7 Partial agonists.(A) Log concentration–effect curves for a series of α-adrenoceptor agonists causing contraction of an isolated strip of rabbit aorta. Phenylephrine is a full agonist. The others are partial agonists with different efficacies. The lower the efficacy of the drug the lower the maximum response and slope of the log concentration–response curve. (B) The relationship between response and receptor occupancy for the series. Note that the full agonist, phenylephrine, produces a near-maximal response when only about half the receptors are occupied, whereas partial agonists produce submaximal responses even when occupying all of the receptors. The efficacy of tolazoline is so low that it is classified as an α-adrenoceptor antagonist (see **Ch. 15**). In these experiments, receptor occupancy was not measured directly, but was calculated from pharmacological estimates of the equilibrium constants of the drugs. Data from Ruffolo, R.R. Jr, et al., 1979. J. Pharmacol. Exp. Ther. 209, 429–436.

For G protein–coupled receptors the elucidation of their X-ray crystal structures (described in **Ch. 3**) and the application of molecular dynamic simulations of drug binding are beginning to tease out the molecular basis of receptor activation and why some

ligands are agonists and some are antagonists. For students starting to study pharmacology the simple theoretical two-state model described later provides a useful starting point.

Partial Agonists as Antagonists

In discussing the efficacy of partial agonists earlier, we considered the situation in which the tissue was exposed to only one drug, the partial agonist. What we should also consider is how the presence of a partial agonist would alter the response of a tissue to a higher efficacy agonist. This is depicted in **Fig. 2.8** where it can be seen that the presence of the partial agonist induces some level of response dependent upon the concentration initially applied, but in addition because the partial agonist is competing with the full agonist for the receptors, it effectively acts as a competitive antagonist, shifting the concentration–response curve of the full agonist to the right. This is not just an obscure theoretical point but something which occurs in clinical practice. In the treatment of heroin users, buprenorphine, a weak partial agonist, not only acts as a weak opioid substitute but also acts as an antagonist and reduces the likelihood of overdose when users relapse and take heroin again (see **Ch. 50**).

Constitutive Receptor Activation and Inverse Agonists

Although we are accustomed to thinking that receptors are activated only when an agonist molecule is bound, there are examples (see **De Ligt et al., 2000**) where an appreciable level of activation (*constitutive activation*) may exist even when no ligand is present. These include receptors for benzodiazepines (see **Ch. 45**),

cannabinoids (see **Ch. 18**), 5-hydroxytryptamine (see **Ch. 16**) and several other mediators. Furthermore, receptor mutations occur – either spontaneously, in some disease states (see **Bond and Ijzerman, 2006**), or experimentally created (see **Ch. 4**) – that result in appreciable constitutive activation. If a ligand reduces activity below the basal level of constitutive activation such drugs are known as *inverse agonists* (**Fig. 2.9**; see **De Ligt et al., 2000**) to distinguish them from *neutral antagonists*, which do not by themselves affect the level of activation. Inverse agonists can be regarded as drugs with negative efficacy, to distinguish them from agonists (positive efficacy) and neutral antagonists (zero efficacy). Neutral antagonists, by binding to the agonist binding site, will antagonise both agonists and inverse agonists. Inverse agonism was first observed at the benzodiazepine receptor (see **Ch. 45**) but such drugs are proconvulsive and thus not therapeutically useful! New examples of constitutively active receptors and inverse agonists are emerging with increasing frequency (mainly among G protein–coupled receptors). **Pimavanserin**, an inverse agonist at the 5-HT_{2A} receptor, has recently been developed for the treatment of psychosis associated with Parkinson's disease (see Chs **40** and **47**). It turns out that most of the receptor antagonists in clinical use are actually inverse agonists when tested in systems showing constitutive receptor activation. However, most receptors – like cats – show a preference for the inactive state, and for these there is no practical difference between a competitive antagonist and an inverse agonist, inverse agonism only being revealed if constitutive activation is observable.

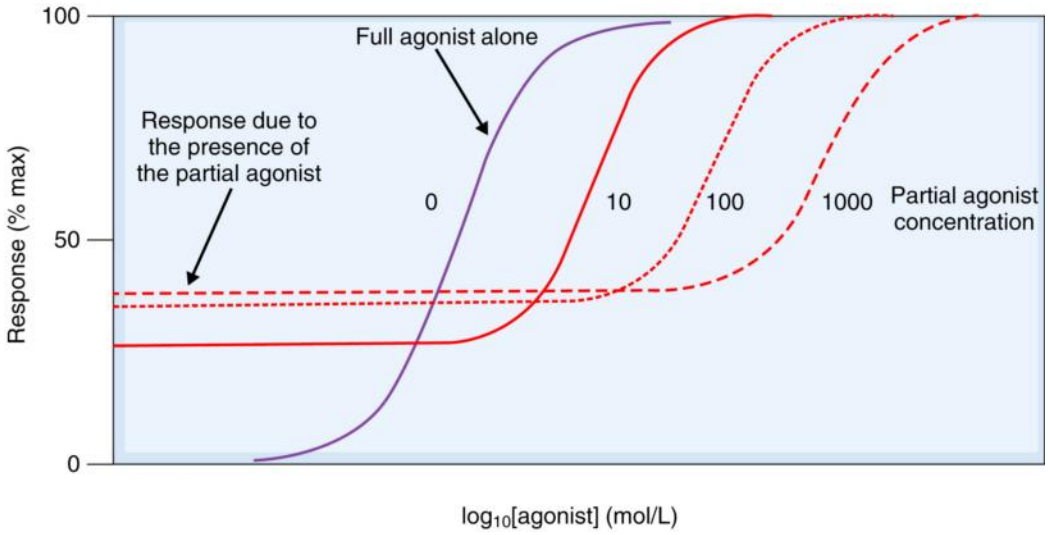

FIG. 2.8 Hypothetical concentration–response curves for a full agonist in the absence and presence of increasing concentrations of a partial agonist.The partial agonist will have agonist action and hence the initial response increases as the partial agonist concentration increases, reaching a maximum equal to the maximum response of the partial agonist. However, when the full agonist is added in the presence of the partial agonist its concentration–response curve is shifted to the right.

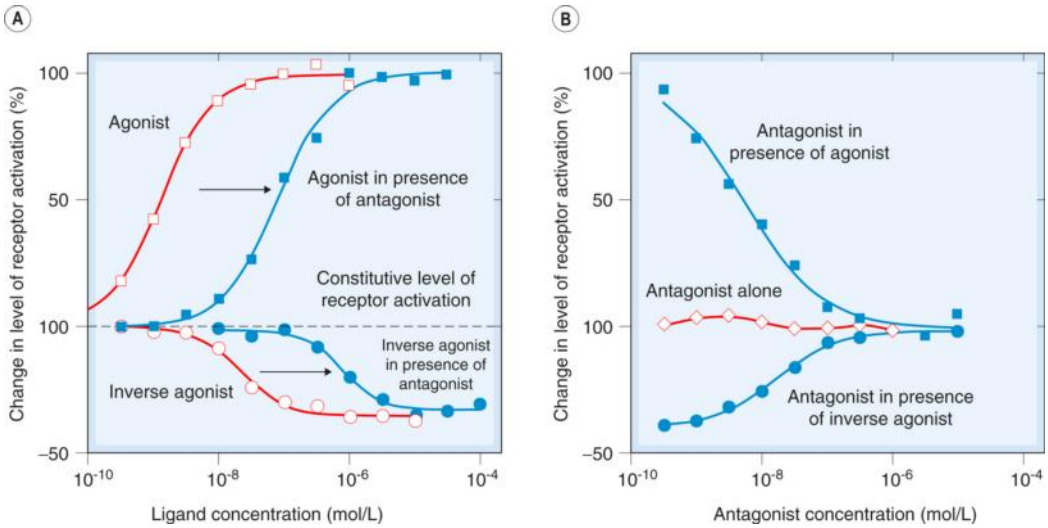

FIG. 2.9 Inverse agonism.The interaction of a competitive antagonist with normal and inverse agonists in a system that shows receptor activation in the absence of any added ligands (constitutive activation). (A) The degree of receptor activation (vertical scale) increases in the presence of an agonist *(open squares)* and decreases in the presence of an inverse agonist *(open circles)*. The addition of a competitive antagonist shifts both curves to the right *(closed symbols)*. (B) The antagonist on its own does not alter the level of constitutive activity *(open symbols)*, because it has equal affinity for the active and inactive states of the receptor. In the presence of an agonist *(closed squares)* or an inverse agonist *(closed circles)*, the antagonist restores the system towards the constitutive level of activity. These data were obtained with cloned human 5-hydroxytryptamine (5-HT)

receptors expressed in a cell line. (Agonist, 5-carboxamidotryptamine; inverse agonist, spiperone; antagonist, WAY 100635; see **Ch. 16** for information on 5-HT receptor pharmacology.) Reproduced with permission from Newman-Tancredi, A., et al., 1997. Br. J. Pharmacol. 120, 737–739.

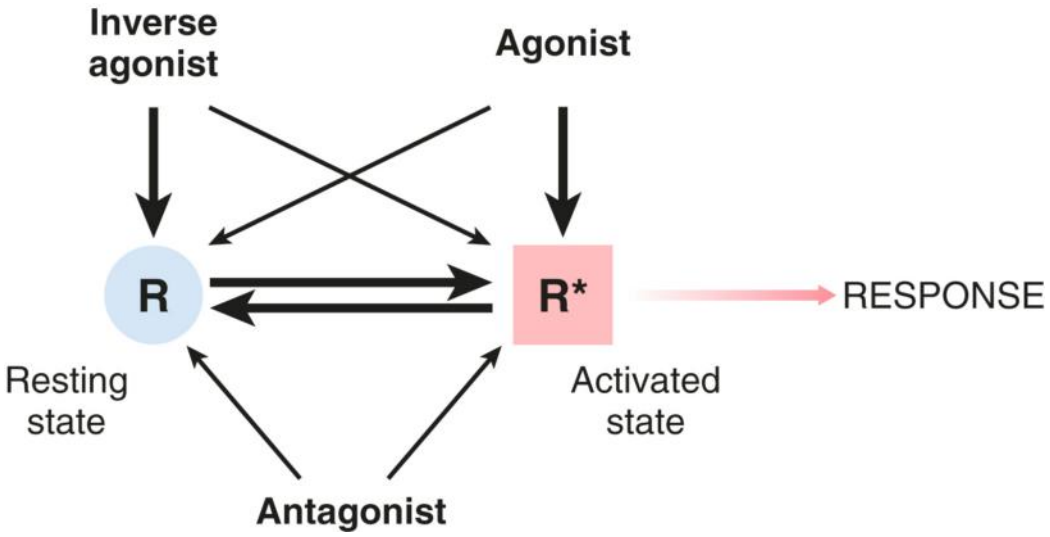

FIG. 2.10 The two-state model.The receptor is shown in two conformational states, *resting (R)* and *activated (R∗)*, which exist in equilibrium. Normally, when no ligand is present, the equilibrium lies far to the left, and few receptors are found in the R∗ state. For constitutively active receptors, an appreciable proportion of receptors adopt the R∗ conformation in the absence of any ligand. Agonists have higher affinity for R∗ than for R, so shift the equilibrium towards R∗. The greater the relative affinity for R∗ with respect to R, the greater the efficacy of the agonist. An inverse agonist has higher affinity for R than for R∗ and so shifts the equilibrium to the left. A *neutral* antagonist has equal affinity for R and R∗ so does not by itself affect the conformational equilibrium but reduces by competition the binding of other ligands.

The following section describes a simple model that explains full, partial and inverse agonism in terms of the relative affinity of different ligands for the resting and activated states of the receptor.

The two-state receptor model

As illustrated in **Fig. 2.1**, agonists and antagonists both bind to receptors, but only agonists activate them. How can we express this difference, and account for constitutive activity, in theoretical terms? The two-state model (**Fig. 2.10**) provides a simple but useful approach.

As shown in **Fig. 2.1**, we envisage that the occupied receptor can switch from its 'resting' (R) state to an activated (R*) state, R* being favoured by binding of an agonist but not an antagonist molecule.

As described earlier, receptors may show constitutive activation (i.e. the R* conformation can exist without any ligand being bound), so the added drug encounters an equilibrium mixture of R and R* (see **Fig. 2.10**). If it has a higher affinity for R* than for R, the drug will cause a shift of the equilibrium towards R* (i.e. it will promote activation and be classed as an agonist). If its preference for R* is very large, nearly all the occupied receptors will adopt the R* conformation and the drug will be a full agonist; if it shows only a modest degree of selectivity for R* (say 5- to 10-fold), a smaller proportion of occupied receptors will adopt the R* conformation and it will be a partial agonist; if it shows no preference, the prevailing R : R* equilibrium will not be disturbed and the drug will be a neutral antagonist (zero efficacy), whereas if it shows selectivity for R it will shift the equilibrium towards R and be an inverse agonist (negative efficacy). We can therefore think of

efficacy as a property determined by the relative affinity of a ligand for R and R$*$, a formulation known as the *two-state model*, which is useful in that it puts a physical interpretation on the otherwise mysterious meaning of efficacy, as well as accounting for the existence of inverse agonists.

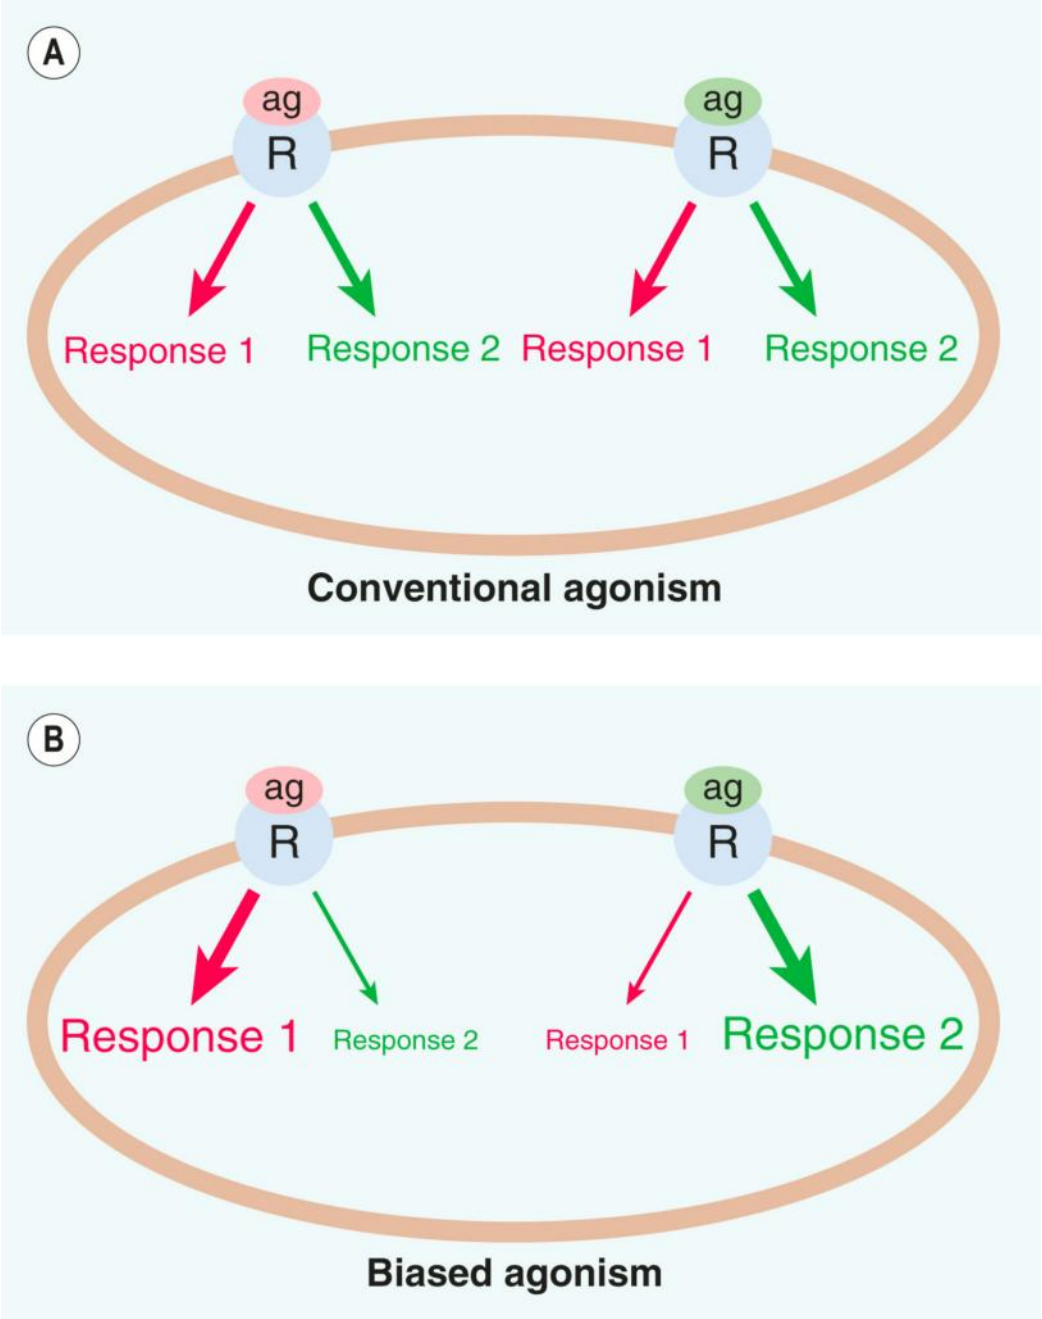

FIG. 2.11 Biased agonism.In (A), the receptor *(R)* is coupled to two intracellular responses – *response 1* and *response 2*. When different agonists indicated in *red* and *green* activate the receptor they evoke both responses in a similar manner. This is what we can consider as being

conventional agonism. In (B), biased agonism is illustrated in which two agonists bind at the same site on the receptor yet the *red* agonist is better at evoking response 1 and the *green* agonist is better at evoking response 2.

Biased Agonism

A major problem with the two-state model is that, as we now know, receptors are not actually restricted to two distinct states but have much greater conformational flexibility, so that there is more than one inactive and active conformation. The different conformations that they can adopt may be preferentially stabilised by different ligands, and may produce different functional effects by activating different signal transduction pathways (see **Ch. 3**).

Receptors that couple to second messenger systems (see **Ch. 3**) can couple to more than one intracellular effector pathway, giving rise to two or more simultaneous responses. One might expect that all agonists that activate the same receptor type would evoke the same array of responses (**Fig. 2.11A**). However, it has become apparent that different agonists can exhibit bias for the generation of one response over another even though they are acting through the same receptor (**Fig. 2.11B**), probably because they stabilise different activated states of the receptor (see **Kelly, 2013**). Agonist bias has become an important concept in pharmacology.

Redefining and attempting to measure agonist efficacy for such a multistate model is problematic, however, and requires a more complicated state transition model than the two-state model

described previously. The errors, pitfalls and a possible way forward have been outlined by **Kenakin and Christopoulos (2013)**.

Allosteric Modulation

In addition to the agonist binding site (now referred to as the *orthosteric* binding site), to which competitive antagonists also bind, receptor proteins possess many other *(allosteric)* binding sites (see **Ch. 3**) through which drugs can influence receptor function in various ways, by increasing or decreasing the affinity of agonists for the agonist binding site, by modifying efficacy or by producing a response themselves (**Fig. 2.12**). Depending on the direction of the effect, the ligands may be allosteric antagonists or allosteric facilitators of the agonist effect, and the effect may be to alter the slope and maximum of the agonist log concentration–effect curve (see **Fig. 2.12**). This type of allosteric modulation of receptor function has attracted much attention recently and occurs at different types of receptors (see review by **Changeux and Christopoulos, 2016**). Well-known examples of allosteric facilitation include glycine at *N*-methyl-D-aspartate (NMDA) receptors (see **Ch. 38**), benzodiazepines at $GABA_A$ receptors (see **Ch. 45**) and **cinacalcet** at the Ca^{2+} receptor (see **Ch. 36**). One reason why allosteric modulation may be important to the pharmacologist and future drug development is that across families of receptors such as the muscarinic receptors (see **Ch. 14**) the orthosteric binding sites are very similar and it has proven difficult to develop selective agonists and antagonists for individual subtypes. The hope is that there will be greater variation in the allosteric sites and that receptor-selective allosteric ligands can be

developed. Furthermore, positive allosteric modulators (PAMs) will exert their effects only on receptors that are being activated by endogenous ligands and have no effect on those that are not activated. This might provide a degree of selectivity (e.g. in potentiating spinal inhibition mediated by endogenous opioids, see **Ch. 43**) and a reduction in side effect profile.

Bitopic Agonists

To further complicate the issue of drug–receptor interactions, some agonists may display a combination of orthosteric and allosteric actions at the same receptor, providing direct agonist and modulatory functions (see **Volpato et al., 2020**). These are termed bitopic agonists and we are likely to hear more about such drugs in the future.

Agonists, antagonists and efficacy

- Drugs acting on receptors may be *agonists* or *antagonists*.
- Agonists initiate changes in cell function, producing effects of various types; antagonists bind to receptors without initiating such changes.
- Agonist potency depends on two parameters: *affinity* (i.e. tendency to bind to receptors) and *efficacy* (i.e. ability, once bound, to initiate changes that lead to effects).
- For antagonists, efficacy is zero.
- *Full agonists* (which can produce maximal effects) have high efficacy; *partial agonists* (which can produce only submaximal effects) have intermediate efficacy.

- According to the two-state model, efficacy reflects the relative affinity of the compound for the resting and activated states of the receptor. Agonists show selectivity for the activated state; antagonists show no selectivity. This model, although helpful, fails to account for the complexity of agonist action.
- *Inverse agonists* show selectivity for the resting state of the receptor, this being of significance only in situations where the receptors show *constitutive activity*.
- *Allosteric modulators* bind to sites on the receptor other than the agonist binding site and can modify agonist activity.

Other Forms of Drug Antagonism

Other mechanisms can also account for inhibitory interactions between drugs.

The most important ones are:

- chemical antagonism
- pharmacokinetic antagonism
- block of receptor–response linkage
- physiological antagonism

Chemical Antagonism

Chemical antagonism refers to the uncommon situation where the two substances combine in solution; as a result, the effect of the active drug is lost. Examples include the use of chelating agents (e.g. **dimercaprol**) that bind to heavy metals and thus reduce their toxicity, and the use of the neutralising antibody **infliximab**, which

has an anti-inflammatory action due to its ability to sequester the inflammatory cytokine tumour necrosis factor (TNF; see **Ch. 17**).

Pharmacokinetic Antagonism

Pharmacokinetic antagonism describes the situation in which the 'antagonist' effectively reduces the concentration of the active drug at its site of action. This can happen in various ways. The rate of metabolic degradation of the active drug may be increased (e.g. the reduction of the anticoagulant effect of **warfarin** when an agent that accelerates its hepatic metabolism, such as **phenytoin**, is given; see Chs **10** and **58**). Alternatively, the rate of absorption of the active drug from the gastrointestinal tract may be reduced, or the rate of renal excretion may be increased. Interactions of this sort, discussed in more detail in **Chapter 58**, are common and can be important in clinical practice.

Block of Receptor–Response Linkage

Non-competitive antagonism describes the situation where the antagonist blocks at some point downstream from the agonist binding site on the receptor, and interrupts the chain of events that leads to the production of a response by the agonist. For example, **ketamine** enters the ion channel pore of the NMDA receptor (see **Ch. 38**) blocking it, thus preventing ion flux through the channels. Drugs such as **verapamil** and **nifedipine** prevent the influx of Ca^{2+} through the cell membrane (see **Ch. 21**) and thus non-selectively block the contraction of smooth muscle produced by drugs acting at any receptor that couples to these calcium channels. As a rule, the effect will be to reduce the slope and maximum of the

agonist log concentration–response curve, although it is quite possible for some degree of rightward shift to occur as well.

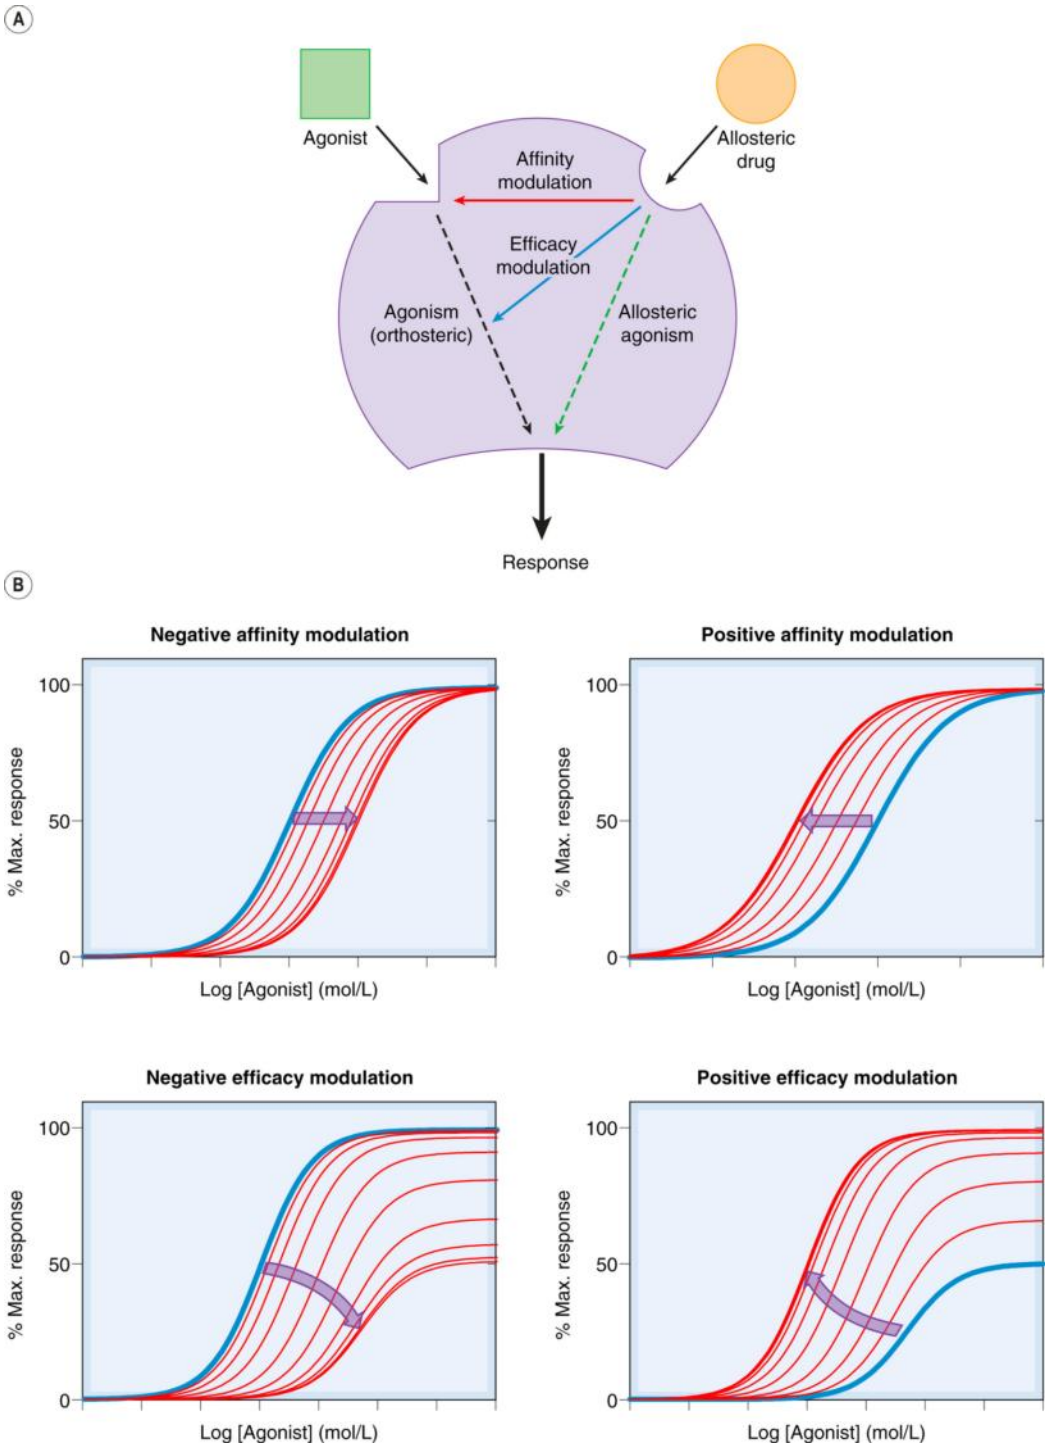

FIG. 2.12 Allosteric modulation.(A) Allosteric drugs bind at a separate site on the receptor to 'traditional' agonists (now often referred to as 'orthosteric' agonists). They can modify the

activity of the receptor by (i) altering agonist affinity, (ii) altering agonist efficacy or (iii) directly evoking a response themselves. (B) Effects of affinity- and efficacy-modifying allosteric modulators on the concentration–effect curve of an agonist *(blue line)*. In the presence of the allosteric modulator the agonist concentration–effect curve *(now illustrated in red)* is shifted in a manner determined by the type of allosteric modulator until a maximum effect of the modulator is reached. Panel [A] adapted with permission from Conn et al., 2009. Nat. Rev. Drug Discov. 8, 41–54; panel [B] courtesy Christopoulos, A.

Physiological Antagonism

Physiological antagonism is a term used loosely to describe the interaction of two drugs whose opposing actions in the body tend to cancel each other. For example, **histamine** acts on receptors of the parietal cells of the gastric mucosa to stimulate acid secretion, while **omeprazole** blocks this effect by inhibiting the proton pump; the two drugs can be said to act as physiological antagonists.

Types of drug antagonism

Drug antagonism occurs by various mechanisms:

- chemical antagonism (interaction in solution)

- pharmacokinetic antagonism (one drug affecting the absorption, metabolism or excretion of the other)
- competitive antagonism (both drugs binding to the same receptors); the antagonism may be reversible or irreversible
- interruption of receptor–response linkage
- physiological antagonism (two agents producing opposing physiological effects)

Desensitisation and Tolerance

Often, the effect of a drug gradually diminishes when it is given continuously or repeatedly. *Desensitisation* and *tachyphylaxis* are synonymous terms used to describe this phenomenon, which often develops in the course of a few minutes. The term *tolerance* is conventionally used to describe a more gradual decrease in responsiveness to a drug, taking hours, days or weeks to develop, but the distinction is not a sharp one. The term *refractoriness* is also sometimes used, mainly in relation to a loss of therapeutic efficacy. *Drug resistance* is a term used to describe the loss of effectiveness of antimicrobial or antitumour drugs (see Chs **51** and **57**). Many different mechanisms can give rise to these phenomena. They include:

- change in receptors
- translocation of receptors
- exhaustion of mediators
- increased metabolic degradation of the drug
- physiological adaptation

- active extrusion of drug from cells (mainly relevant in cancer chemotherapy; see **Ch. 57**)

Change in Receptors

Among receptors directly coupled to ion channels (see **Ch. 3**), desensitisation is often rapid and pronounced. At the neuromuscular junction (**Fig. 2.13A**), the desensitised state is caused by a conformational change in the receptor, resulting in tight binding of the agonist molecule without the opening of the ionic channel. Phosphorylation of intracellular regions of the receptor protein is a second, slower mechanism by which ion channels become desensitised.

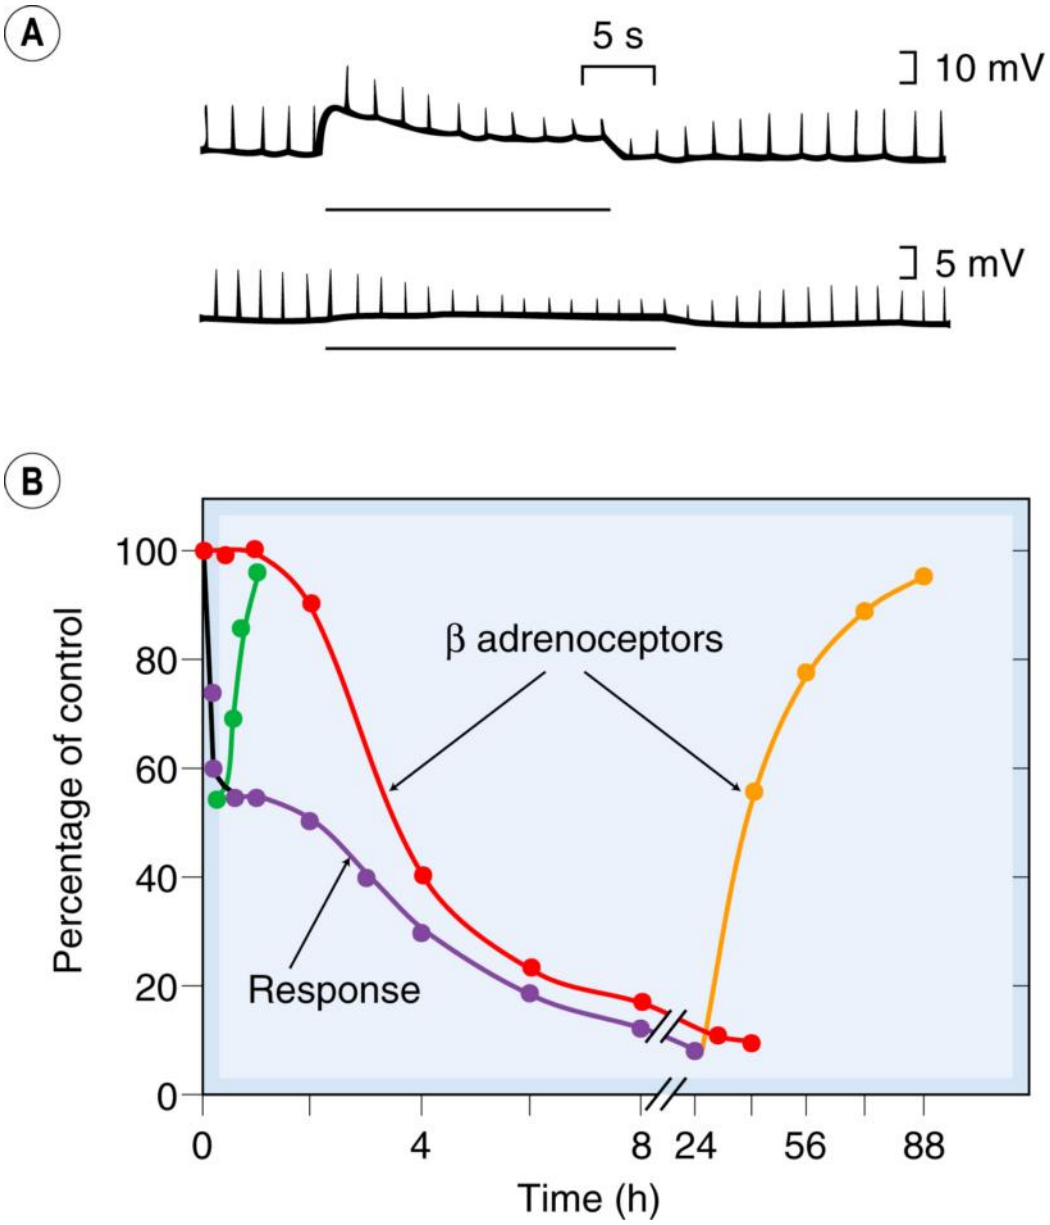

FIG. 2.13 Two kinds of receptor desensitisation.(A) Acetylcholine (ACh) at the frog motor endplate. Brief depolarisations *(upward deflections)* are produced by short pulses of ACh delivered from a micropipette. A long pulse *(horizontal line)* causes the response to decline with a time course of about 20 seconds, owing to desensitisation, and it recovers

with a similar time course. (B) β-Adrenoceptors of rat glioma cells in tissue culture. Isoproterenol (1 μmol/L) was added at time zero, and the adenylyl cyclase response and β-adrenoceptor density measured at intervals. During the early uncoupling phase, the response *(blue line)* declines with no change in receptor density *(red line)*. Later, the response declines further concomitantly with disappearance of receptors from the membrane by internalisation. The *green* and *orange lines* show the recovery of the response and receptor density after the isoproterenol is washed out during the early or late phase. Panel [A] from Katz B., Thesleff S., 1957. J. Physiol. 138, 63; panel [B] from Perkins, J.P., 1981. Trends Pharmacol. Sci. 2, 326.

Most G protein–coupled receptors (see **Ch. 3**) also show desensitisation (**Fig. 2.13B**). Phosphorylation of the receptor interferes with its ability to activate second messenger cascades, although it can still bind the agonist molecule. The molecular mechanisms of this 'uncoupling' are considered further in **Chapter 3**. This type of desensitisation usually takes seconds to minutes to develop, and recovers when the agonist is removed.

It will be realised that the two-state model in its simple form, discussed earlier, needs to be further elaborated to incorporate additional desensitised states of the receptor.

Translocation of Receptors

Prolonged exposure to agonists often results in a gradual decrease in the number of receptors expressed on the cell surface, as a result of *internalisation* of the receptors. This is shown for β adrenoceptors in **Fig. 2.13B** and is a slower process than the uncoupling described earlier. Similar changes have been described for other types of receptor, including those for various peptides. The internalised receptors are taken into the cell by endocytosis of patches of the membrane, a process that normally depends on receptor phosphorylation and the subsequent binding of *arrestin* proteins to the phosphorylated receptor (see **Ch. 3**, **Fig. 3.16)**. This type of adaptation is common for hormone receptors and has obvious relevance to the effects produced when drugs are given for extended periods. It is generally an unwanted complication when agonist drugs are used clinically.

Exhaustion of Mediators

In some cases, desensitisation is associated with depletion of an essential intermediate substance. Drugs such as **amphetamine**, which acts by releasing amines from nerve terminals (see Chs **15** and **49**), show marked tachyphylaxis because the amine stores become depleted.

Altered Drug Metabolism

Tolerance to some drugs, for example **barbiturates** and **ethanol** (see **Ch. 49**), occurs partly because repeated administration of the same dose produces a progressively lower plasma concentration, as a result of increased metabolic degradation. The degree of tolerance that results is generally modest, and in both of these examples other

mechanisms contribute to the substantial tolerance that actually occurs. However, the pronounced tolerance to **nitrovasodilators** (see Chs **19** and **21**) results mainly from decreased metabolism, which reduces the release of the active mediator, nitric oxide.

Physiological Adaptation

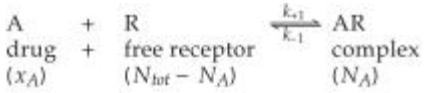
Diminution of a drug's effect may occur because it is nullified by a homeostatic response. For example, the blood pressure-lowering effect of **thiazide diuretics** is limited because of a gradual activation of the renin–angiotensin system (see **Ch. 21**). Such homeostatic mechanisms are very common, and if they occur slowly the result will be a gradually developing tolerance. It is a common experience that many side effects of drugs, such as nausea or sleepiness, tend to subside even though drug administration is continued. We may assume that some kind of physiological adaptation is occurring, presumably associated with altered gene expression resulting in changes in the levels of various regulatory molecules, but little is known about the mechanisms involved.

Quantitative Aspects of Drug–Receptor Interactions

Here we present some aspects of so-called receptor theory, which is based on applying the Law of Mass Action to the drug–receptor interaction and which has served well as a framework for interpreting a large body of quantitative experimental data (see **Colquhoun, 2006**).

The Binding Reaction

The first step in drug action on specific receptors is the formation of a reversible drug–receptor complex, the reactions being governed by the Law of Mass Action. Suppose that a piece of tissue, such as heart muscle or smooth muscle, contains a total number of receptors, N_{tot}, for an agonist such as adrenaline. When the tissue is exposed to adrenaline at concentration x_A and allowed to come to equilibrium, a certain number, N_A, of the receptors will become occupied, and the number of vacant receptors will be reduced to $N_{tot} - N_A$. Normally, the number of adrenaline molecules applied to the tissue in solution greatly exceeds N_{tot}, so that the binding reaction does not appreciably reduce x_A. The magnitude of the response produced by the adrenaline will be related (even if we do not know exactly how) to the number of receptors occupied, so it is useful to consider what quantitative relationship is predicted between N_A and x_A. The reaction can be represented by:



The Law of Mass Action (which states that the rate of a chemical reaction is proportional to the product of the concentrations of reactants) can be applied to this reaction.

$$\text{Rate of forward reaction} = k_{+1} x_A (N_{tot} - N_A) \qquad \textbf{(2.1)}$$

$$\text{Rate of backward reaction} = k_{-1} N_A \tag{2.2}$$

At equilibrium, the two rates are equal:

$$k_{+1} x_A (N_{tot} - N_A) = k_{-1} N_A \tag{2.3}$$

The *affinity constant* of binding is given by k_{+1}/k_{-1} and from **Eq. 2.3** equals $N_A/x_A(N_{tot} - N_A)$. Unfortunately, this has units of reciprocal concentration (L/mol) which for some of us is a little hard to get our heads around. Pharmacologists therefore tend to use the reciprocal of the affinity constant, the equilibrium dissociation constant *(K)*, which has units of concentration (mol/L).

For drug A its equilibrium dissociation constant (K_A) [6] can be represented as

$$K_A = k_{-1}/k_{+1} = x_A (N_{tot} - N_A) / N_A \tag{2.4}$$

The proportion of receptors occupied, or occupancy (P_A), is N_A/N_{tot}. If we manipulate **Eq. 2.4** then

$$P_A = \frac{x_A}{x_A + k_{-1}/k_{+1}} = \frac{x_A}{x_A + K_A} \tag{2.5}$$

Thus if the equilibrium dissociation constant of a drug is known we can calculate the proportion of receptors it will occupy at any concentration as it is independent of N_{tot}.

Eq. 2.5 can be written as:

$$P_A = \frac{x_A / K_A}{x_A / K_A + 1} \qquad \textbf{(2.6)}$$

This important result is known as the Hill-Langmuir equation. [7]

The *equilibrium dissociation constant,* K_A, is a characteristic of the drug and of the receptor; it has the dimensions of concentration and is numerically equal to the concentration of drug required to occupy 50% of the sites at equilibrium. (Verify from **Eq. 2.5** that when $x_A = K_A$ then $P_A = 0.5$.) The higher the affinity of the drug for the receptors, the lower will be the value of K_A. **Eq. 2.6** describes the relationship between occupancy and drug concentration, and it generates a characteristic curve known as a *rectangular hyperbola*, as shown in **Fig. 2.14A**. It is common in pharmacological work to use a logarithmic scale of concentration; this converts the hyperbola to a symmetrical sigmoid curve (**Fig. 2.14B**).

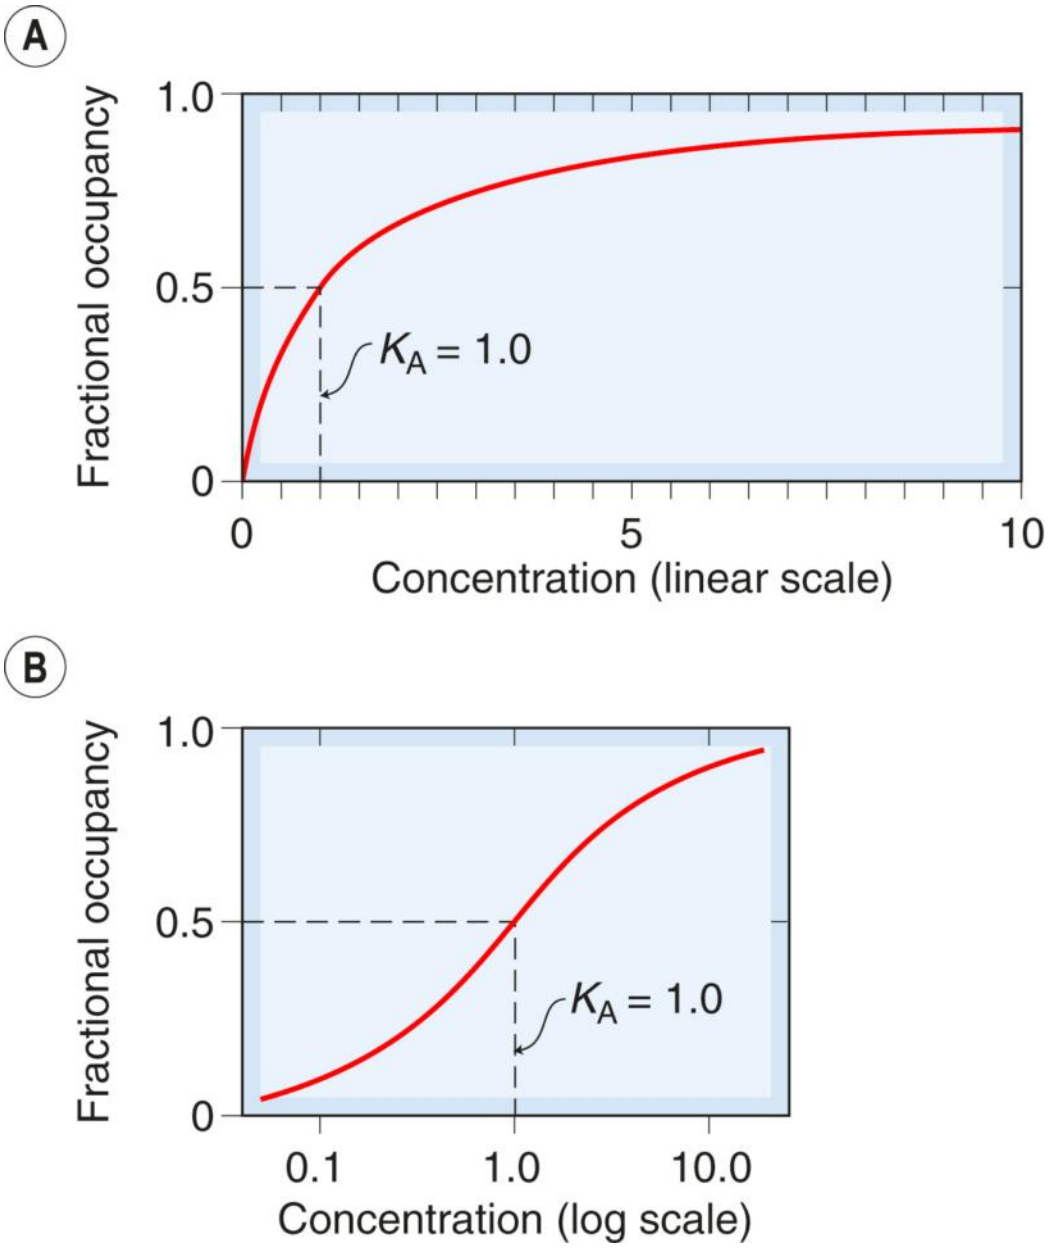


FIG. 2.14 Theoretical relationship between occupancy and ligand concentration.The relationship is plotted according to **Eq. 2.5**. (A) Plotted with a linear concentration scale, this curve is a rectangular hyperbola. (B) Plotted with a log concentration scale, it is a symmetrical

sigmoid curve. K_A is defined in the text and footnote 6.

The same approach is used to analyse data from experiments in which drug binding is measured directly (see **Fig. 2.2**). In this case, the relationship between the amount bound (B) and ligand concentration (x_A) should be:

$$B = B_{max} x_A / (x_A + K_A) \quad \textbf{(2.7)}$$

where B_{max} is the total number of binding sites in the preparation (often expressed as pmol/mg of protein). To display the results in linear form, **Eq. 2.6** may be rearranged to:

$$B / x_A = B_{max} / K_A - B / K_A \quad \textbf{(2.8)}$$

A plot of B/x_A against B (known as a *Scatchard plot*, named after the American physicochemist George Scatchard) gives a straight line from which both B_{max} and K_A can be estimated. Statistically, this procedure is not without problems, and it is now usual to estimate these parameters from the untransformed binding values by an iterative non-linear curve-fitting procedure. [8]

To this point, our analysis has considered the binding of one ligand to a homogeneous population of receptors. To get closer to real-life pharmacology, we must consider (a) what happens when

more than one ligand is present, and (b) how the tissue response is related to receptor occupancy.

Binding when more than one Drug is Present

Suppose that two drugs, A and B, which bind to the same receptor with equilibrium dissociation constants K_A and K_B, respectively, are present at concentrations x_A and x_B. If the two drugs compete (i.e. the receptor can accommodate only one at a time), then, by application of the same reasoning as for the one-drug situation described earlier, the occupancy by drug A is given by:

$$P_A = \frac{x_A / K_A}{x_A / K_A + x_B / K_B + 1} \qquad \textbf{(2.9)}$$

Comparing this result with **Eq. 2.5** shows that adding drug B, as expected, reduces the occupancy by drug A. **Fig. 2.4A** shows the predicted binding curves for A in the presence of increasing concentrations of B, demonstrating the shift without any change of slope or maximum that characterises the pharmacological effect of a competitive antagonist (see **Fig. 2.5**). The extent of the rightward shift, on a logarithmic scale, represents the ratio (r_A, given by x_A'/x_A where x_A' is the increased concentration of A) by which the concentration of A must be increased to overcome the competition by B. Rearranging **Eq. 2.9** shows that

$$r_A = (x_B / K_B) + 1 \qquad \textbf{(2.10)}$$

Thus r_A depends only on the concentration and equilibrium dissociation constant of the competing drug B, not on the concentration or equilibrium dissociation constant of A.

If A is an agonist, and B is a competitive antagonist, and we assume that the response of the tissue will be an unknown function of P_A, then the value of r_A determined from the shift of the agonist concentration–effect curve at different antagonist concentrations can be used to estimate the equilibrium dissociation constant K_B for the antagonist. Such pharmacological estimates of r_A are commonly termed *agonist dose ratios* (more properly concentration ratios, although most pharmacologists use the older term). This simple and very useful **Eq. 2.10** is known as the *Schild equation*, after the pharmacologist who first used it to analyse drug antagonism.

Eq. 2.10 can be expressed logarithmically in the form:

$$\log\ (r_A - 1) = \log x_B - \log K_B \qquad \textbf{(2.11)}$$

Thus a plot of log $(r_A - 1)$ against log x_B, usually called a Schild plot (as in **Fig. 2.5**, earlier), should give a straight line with unit slope (i.e. its gradient is equal to 1) and an abscissal intercept equal to log K_B. Following the pH and pK notation, antagonist potency can be expressed as a pA_2 value; under conditions of competitive antagonism, $pA_2 = -\log K_B$. Numerically, pA_2 is defined as the negative logarithm of the molar concentration of antagonist required to produce an agonist dose ratio equal to 2. As with pH

notation, its principal advantage is that it produces simple numbers, a pA_2 of 6.5 being equivalent to a K_B of 3.2×10^{-7} mol/L.

For competitive antagonism, r shows the following characteristics:

- It depends only on the concentration and equilibrium dissociation constant of the antagonist, and not on the size of response that is chosen as a reference point for the measurements (so long as it is submaximal).
- It does not depend on the equilibrium dissociation constant of the agonist.
- It increases linearly with x_B, and the slope of a plot of $(r_A - 1)$ against x_B is equal to $1/K_B$; this relationship, being independent of the characteristics of the agonist, should be the same for an antagonist against all agonists that act on the same population of receptors.

These predictions have been verified for many examples of competitive antagonism (see **Fig. 2.5**).

In this section, we have avoided going into great detail and have oversimplified the theory considerably. As we learn more about the actual molecular details of how receptors work to produce their biological effects (see **Ch. 3**), the shortcomings of this theoretical treatment will become more obvious. The two-state model can be incorporated without difficulty, but complications arise when we include the involvement of G proteins (see **Ch. 3**) in the reaction scheme (as they shift the equilibrium between R and R∗), and when we allow for the fact that receptor activation is not a simple on–off switch, as the two-state model assumes, but may take different

forms. Despite strenuous efforts by theoreticians to allow for such possibilities, the molecules always seem to remain one step ahead. Nevertheless, this type of basic theory applied to the two-state model remains a useful basis for developing quantitative models of drug action. The book by **Kenakin (1997)** is recommended as an introduction, and the later review (**Kenakin and Christopoulos, 2011**) presents a detailed account of the value of quantification in the study of drug action.

Binding of drugs to receptors

- Binding of drugs to receptors necessarily obeys the *Law of Mass Action*.
- At equilibrium, receptor occupancy is related to drug concentration by the *Hill–Langmuir equation* (**Eq. 2.6**).
- The higher the affinity of the drug for the receptor, the lower the concentration at which it produces a given level of occupancy.
- The same principles apply when two or more drugs compete for the same receptors; each has the effect of reducing the apparent affinity for the other.

The Nature of Drug Effects

In discussing how drugs act in this chapter, we have focused mainly on the rapid consequences of receptor activation. Details of the receptors and their linkage to effects at the cellular level are described in **Chapter 3**. We now have a fairly good understanding

at this level. It is important, however, particularly when considering drugs in a therapeutic context, that their direct effects on cellular function generally lead to secondary, delayed effects, which are often highly relevant in a clinical situation in relation to both therapeutic efficacy and harmful effects (**Fig. 2.15**). For example, activation of cardiac β-adrenoceptors (see Chs **3** and **20**) causes rapid changes in the functioning of the heart muscle, but also slower (minutes to hours) changes in the functional state of the receptors (e.g. desensitisation), and even slower (hours to days) changes in gene expression that produce long-term changes (e.g. hypertrophy) in cardiac structure and function. Opioids (see **Ch. 43**) produce an immediate analgesic effect, but after a time, tolerance and dependence ensue. In these and many other examples, the nature of the intervening mechanism is unclear, although as a general rule any long-term phenotypic change necessarily involves alterations of gene expression. Drugs are often used to treat chronic conditions, and understanding long-term as well as acute drug effects is very important. Pharmacologists have traditionally tended to focus on short-term physiological responses, which are much easier to study, rather than on delayed effects. The focus is now clearly shifting.

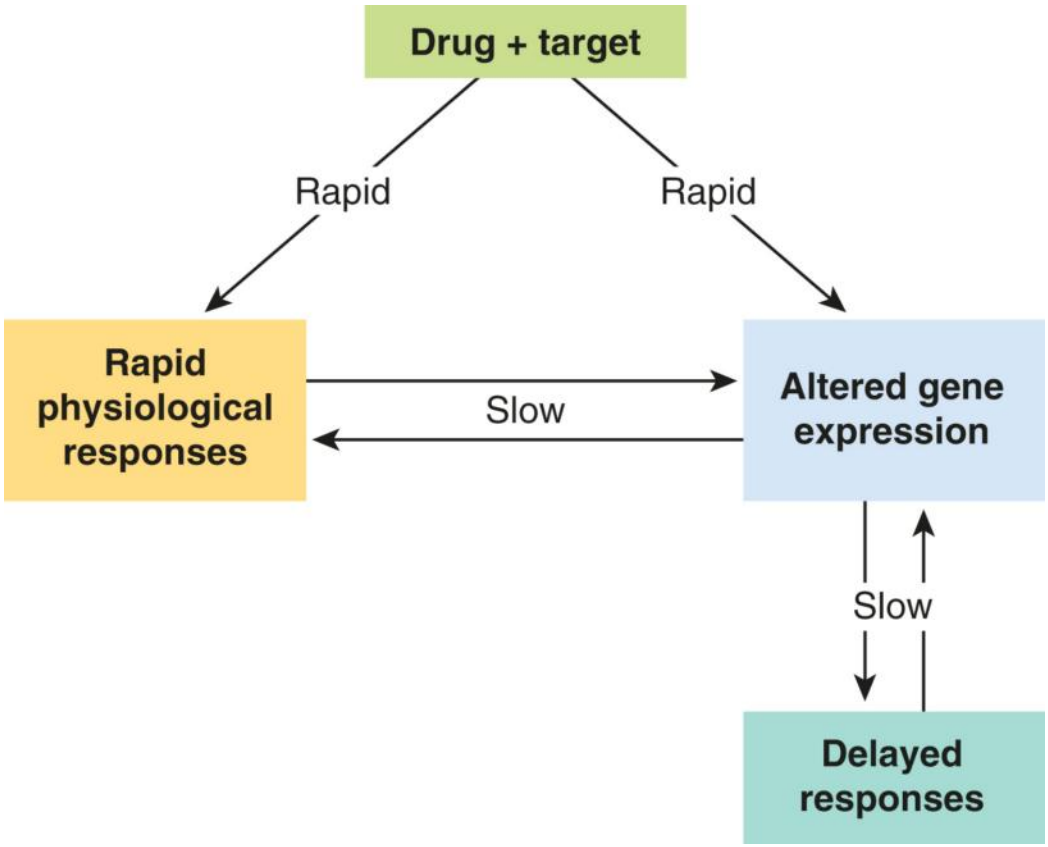

FIG. 2.15 Early and late responses to drugs.Many drugs act directly on their targets *(left-hand arrow)* to produce a rapid physiological response. If this is maintained, it is likely to cause changes in gene expression that give rise to delayed effects. Some drugs *(right-hand arrow)* have their primary action on gene expression, producing delayed physiological responses. Drugs can also work by both pathways. Note the bidirectional interaction between gene expression and response.

Drug effects

- Drugs act mainly on cellular targets, producing effects at different functional levels (e.g. biochemical, cellular, physiological and structural).
- The direct effect of the drug on its target produces acute responses at the biochemical, cellular or physiological levels.
- Prolonged receptor activation generally leads to *delayed long-term effects*, such as desensitisation or down-regulation of receptors, hypertrophy, atrophy or remodelling of tissues, tolerance and dependence.
- Long-term delayed responses result from changes in gene expression, although the mechanisms by which the acute effects bring this about are often uncertain.
- Therapeutic effects may be based on acute responses (e.g. the use of bronchodilator drugs to treat asthma; **Ch. 28**) or delayed responses (e.g. antidepressants; **Ch. 48**).

QUESTIONS

QUESTION 2.1

The concept of receptors is central to pharmacology.

The best pharmacological definition of a receptor is…

OPTIONS:

A. Any target molecule with which a drug molecule interacts.

B. A protein molecule which can be bound by a drug.

C. A protein molecule whose activity is modulated by a drug.

D. A protein molecule whose function is to recognise and respond to endogenous chemical signals.

E. A cell surface molecule involved in the cell-to-cell interactions.

QUESTION 2.2

Knowledge of the mechanisms of drug–receptor interactions is fundamental to pharmacology.

To be an effective drug, a substance must…

OPTIONS:

A. Bind to an intracellular target

B. Bind at the allosteric site on the target molecule

C. Achieve uniform distribution throughout the body

D. Bind to a drug target with high specificity

E. Obey the law of mass action, forming an irreversible drug–receptor complex

QUESTION 2.3

Binding and activation represent two distinct steps in the drug–receptor interaction and drugs are often classified according to their effects on these steps.

Which of the following drug types would show negative efficacy?

OPTIONS:

A. Partial agonists

B. Agonists

C. Antagonists

D. Allosteric modulators

E. Inverse agonists

QUESTION 2.4

Concentration–effect curves allow us to visualise the biological response evoked by a particular concentration of a drug.

Which of the following statements about the interpretation of a concentration–effect curve is INCORRECT?

OPTIONS:

A. It can be used to assess the binding of the drug to spare receptors.

B. It can be used to estimate the enzymatic degradation of the agonist.

C. The concentration needed to evoke 50% of maximal response (EC_{50}) enables the comparison between different drugs.

D. It is used to assess the maximal response in vitro.

E. The response observed is directly proportional to the receptor occupancy.

QUESTION 2.5

In the presence of drug B, the concentration–effect curve of drug A is shifted to the right and the maximal response decreases.

The most likely classification for drug B is that...

OPTIONS:

A. Drug B is a partial agonist.

B. Drug B is an irreversible antagonist.

C. Drug B is an inverse agonist.

D. Drug B is a competitive antagonist.

E. Drug B is a positive affinity allosteric modulator.

ANSWERS

ANSWER 2.1

RATIONALE:

A. Drugs can bind to macromolecular targets such as plasma proteins which do not necessarily elicit a physiological effect.

B. Although many drug targets are proteins, drugs can also bind to lipid and nucleic acids.

C. Many drugs (antagonists) bind to and block access to the endogenous ligand without

modulating the activity of the receptor itself.

D.

E. Although often classified as receptors, these molecules differ from conventional pharmacological receptors in that they respond to other proteins attached to cell surfaces or extracellular structures, rather than to soluble mediators.

CORRECT ANSWER WITH EXPLANATION:

D. A protein molecule whose function is to recognise and respond to endogenous chemical signals.

The pharmacological definition of a receptor is a protein molecule whose function is to recognise and respond to soluble physiological mediators such as hormones, neurotransmitters or inflammatory mediators.

ANSWER 2.2

RATIONALE:

A. Although some drugs penetrate into the cell and exert their effects through binding to intracellular targets many exert their effects by binding to receptors on the plasma membrane.

B. Most drugs interact with the endogenous agonist (orthosteric) site but some drugs can bind at an alternative (allosteric) site on the receptor, which can influence agonist binding.

C. In general, to have a pharmacological effect, drug molecules must be bound to specific constituents of cells and tissues and

therefore show a non-uniform distribution.

D.

E. The law of mass action states that the drug–receptor interaction is reversible such that neither is changed by the interaction.

CORRECT ANSWER WITH EXPLANATION:

D. Bind to a receptor with high specificity

To be effective, the drug must bind to only the target of interest, to minimise unwanted off-target (side) effects.

ANSWER 2.3

RATIONALE:

A. As efficacy is defined by the tendency of a drug to switch the receptor to its active conformation, partial agonists tend to have low but positive efficacy.

B. As efficacy is defined by the tendency of a drug to switch the receptor to its active conformation, agonists tend to have high/ positive efficacy.

C. As efficacy is defined by the tendency of a drug to switch the receptor to its active conformation, antagonists tend to have zero efficacy.

D. As efficacy is defined by the tendency of a drug to switch the receptor to its active conformation, positive allosteric modulators increase the efficacy of an agonist whilst negative allosteric modulators decrease it.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Inverse agonists

Inverse agonists decrease the tendency for a receptor to adopt an active confirmation and are therefore said to have negative efficacy.

ANSWER 2.4

RATIONALE:

A. Spare receptors are those not bound by the drug if full occupancy is not required to reach a maximal effect.

B. This is a possible limitation of the assay and would affect the actual concentration of the drug at the receptor but cannot be estimated from the graph.

C. The EC_{50} can provide a quantitative comparative measure of drug potencies for drugs with qualitatively similar effects.

D. Concentration–effect curves enable the assessment of the maximal effect in vitro and the concentration required to evoke a 50% response (compare with dose–response curves in vivo).

E.

CORRECT ANSWER WITH EXPLANATION:

E. The response observed is directly proportional to the receptor occupancy.

This is incorrect as the maximal response to an agonist can often be achieved at less than 100% receptor occupancy, i.e. there are spare/unbound receptors.

ANSWER 2.5

RATIONALE:

A. Partial agonists often display a change in the slope of the curve and a reduction in the maximal effect.

B.

C. An inverse agonist will result in the opposite response to the agonist, i.e. a reversal in the concentration–effect curve.

D. The concentration–effect curve is shifted to the right without a change in slope or maximum.

E. A positive affinity modulator would enhance the effects of the agonist causing a shift to the left of the concentration–effect curve whilst maintaining the maximal response.

CORRECT ANSWER WITH EXPLANATION:

B. Drug B is an irreversible antagonist.

The antagonist will shift the concentration–effect curve to the right but at high antagonist receptor occupation the maximal response for the agonist will also be decreased.

---

[1] There are, if one looks hard enough, exceptions to Ehrlich's dictum – drugs that act without being bound to any tissue constituent (e.g. osmotic diuretics, osmotic purgatives, antacids and heavy metal chelating agents). Nonetheless, the principle remains true for the great majority.

[2] 'On-target' side effects are unwanted effects mediated through the same receptor as the clinically desired effect, for example constipation and respiratory depression by opioid analgesic drugs (see Ch. 43), whereas 'off-target' side effects are mediated by a different mechanism.

[3] For this work, and the development of ß-adrenoceptor antagonists by a similar experimental approach, Sir James Black was awarded the 1984 Nobel Prize in Physiology or Medicine.

[4] This type of antagonism is sometimes called non-competitive, but that term is ambiguous and best avoided in this context.

[5] In Stephenson's formulation, efficacy is the reciprocal of the occupancy needed to produce a 50% maximal response, thus $e = 25$ implies that a 50% maximal response occurs at 4% occupancy. There is no theoretical upper limit to efficacy; indeed, some agonists are termed *super agonists* because they possess greater efficacy than the receptor's own endogenous agonist (e.g. dexmedetomidine, an a_2 adrenoceptor agonist with greater efficacy than that of either adrenaline or noradrenaline).

[6] Here we now use 'K_A' rather than just 'K' because we will in the next section be going on to consider the situation when two drugs, A and B, are present and there we will use 'K_A' and 'K_B' to denote the equilibrium dissociation constants of the two drugs.

[7] A.V. Hill first published it in 1909, when he was still a medical student. Langmuir, a physical chemist working on gas adsorption, derived it independently in 1916. Both subsequently won Nobel Prizes. Until recently, it was known to pharmacologists as the Langmuir equation, even though Hill deserves the credit.

[8] Such iterative non-linear curve-fitting computer programmes were not available to our pharmacological forebears.

3: How drugs act

molecular aspects

OVERVIEW

In this chapter, we move from the general principles of drug action outlined in **Chapter 2** to the molecules that are involved in recognising chemical signals and translating them into cellular responses. Molecular pharmacology is advancing rapidly, and the new knowledge is changing our understanding of drug action and opening up many new therapeutic possibilities, further discussed in other chapters.

First, we consider the types of target proteins on which drugs act. Next, we describe the main families of receptors and ion channels. Finally, we discuss the various forms of receptor–effector linkage (signal transduction mechanisms) through which receptors are coupled to the regulation of cell function. The relationship between the molecular structure of a receptor and its functional linkage to a particular type of effector system is a principal theme. In the next two chapters, we see how these molecular events alter important aspects of cell function – a useful basis for understanding the effects of drugs on intact living organisms. We are confident that tomorrow's pharmacology will rest solidly on the advances in cellular and molecular biology that are discussed here.

Protein Targets for Drug Action

The protein targets for drug action on mammalian cells (**Fig. 3.1**) that are described in this chapter can be broadly divided into:

- receptors
- ion channels
- enzymes
- transporters (carrier molecules)

The great majority of important drugs act on one or other of these types of protein, but there are exceptions. For example, **colchicine**, used to treat arthritic gout attacks (see **Ch. 25**), interacts with the structural protein tubulin, while several immunosuppressive drugs (e.g. **ciclosporin**; see **Ch. 25**) bind to cytosolic proteins known as immunophilins. Therapeutic antibodies act by sequestering mediators of inflammation (see Chs **5**, **25** and **40**) and oligonucleotide sequences act as antisense or transgenes to alter protein expression (see **Ch. 40**). Targets for chemotherapeutic drugs (see Chs **51**–**57**), where the aim is to suppress invading microorganisms or cancer cells, include DNA and cell wall constituents as well as other proteins.

Receptors

Receptors (see **Fig. 3.1A**) are the sensing elements in the system of chemical communications that coordinate the function and responses of all the different cells in the body, the chemical messengers being the various hormones, transmitters and other mediators discussed in Section 2 of this book. Many therapeutically useful drugs act, either as agonists or antagonists, on receptors for known endogenous mediators. In most cases, the endogenous mediator was discovered before – often many years before – the receptor was characterised pharmacologically and biochemically. In some cases, such as the cannabinoid and opioid receptors (see Chs **18** and **43**), the endogenous mediators were identified later; in others, known as *orphan receptors* (see later) the mediator, if it exists, still remains unknown. The host defence system also utilises a set of receptors (e.g. the 'Toll' receptors) that are adept at recognising fragments of 'foreign'

bacterial and other invading organisms. These are considered separately in **Chapter 7**.

Ion Channels

Ion channels [1] are essentially gateways in cell membranes that selectively allow the passage of particular ions, and that are induced to open or close by a variety of mechanisms. Two important types are *ligand-gated channels* and *voltage-gated channels*. The former open only when one or more agonist molecules are bound, and are properly classified as receptors, since agonist binding is needed to activate them. Voltage-gated channels are gated by changes in the transmembrane potential rather than by agonist binding.

In general, drugs can affect ion channel function in several ways:

1. By binding to the channel protein itself, either to the ligand-binding (*orthosteric*) site of ligand-gated channels or to other (*allosteric*) sites, or, in the simplest case, exemplified by the action of local anaesthetics on the voltage-gated sodium channel (see **Ch. 44**), the drug molecule plugs the channel physically (see **Fig. 3.1B**), blocking ion permeation. Examples of drugs that bind to allosteric sites on the channel protein and thereby affect channel gating include:
    - **benzodiazepines** (see **Ch. 45**). These drugs bind to a region of the $GABA_A$ receptor–chloride channel complex (a ligand-gated channel) that is distinct from the GABA binding site and facilitate the opening of the channel by the inhibitory neurotransmitter GABA (see **Ch. 38**)
    - vasodilator drugs of the **dihydropyridine** type (see **Ch. 21**), which inhibit the opening of L-type calcium channels (see **Ch. 4**).

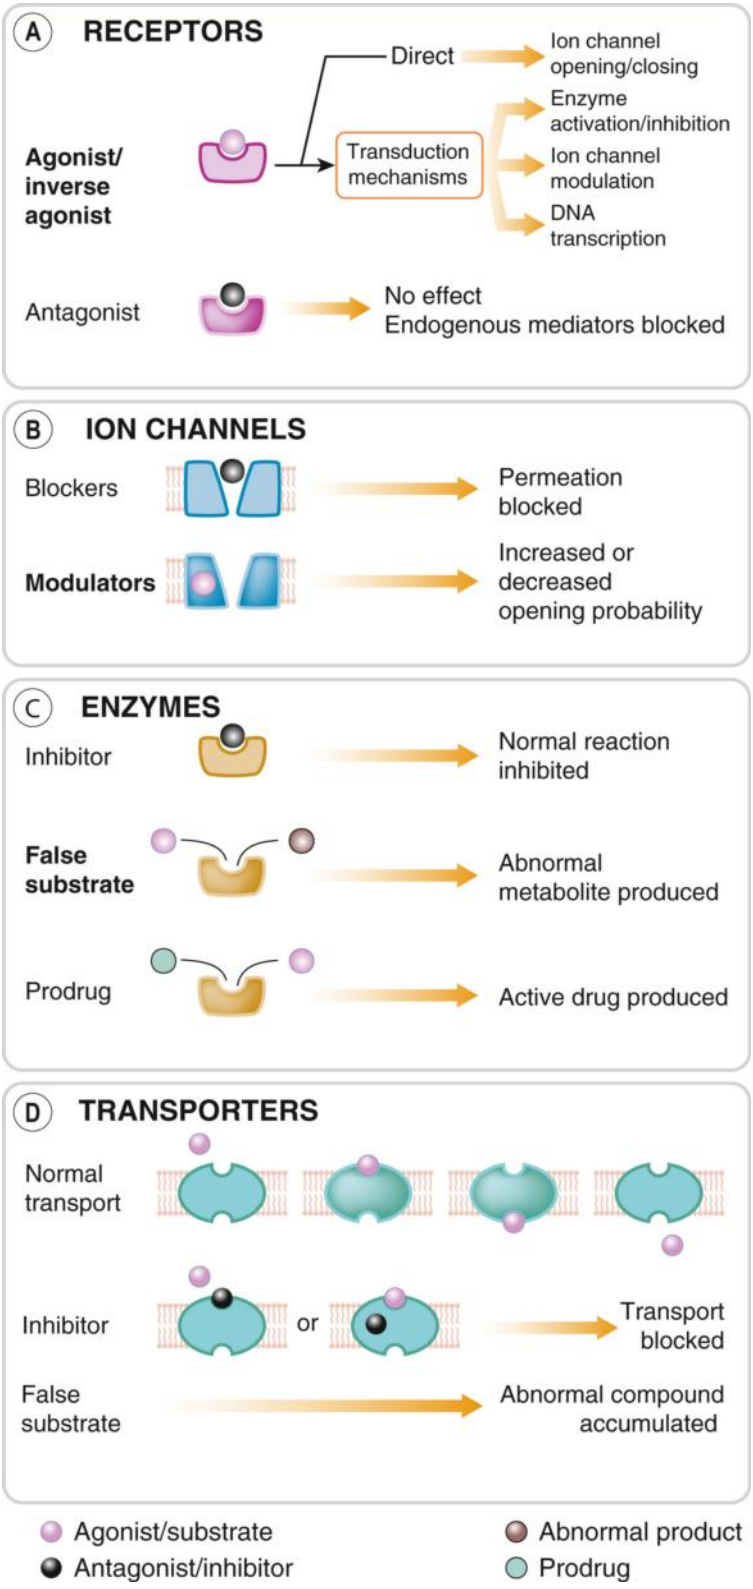

FIG. 3.1 Types of target for drug action.

2. By an indirect interaction, involving an activated G protein subunit or other intermediary.
3. By altering the level of expression of ion channels on the cell surface. For example, **gabapentin** reduces the insertion of neuronal calcium channels into the plasma membrane (see **Ch. 46**).

A summary of the different ion channel families and their functions is given later.

Enzymes

Many drugs target enzymes (see **Fig. 3.1C**). Often, the drug molecule is a substrate analogue that acts as a competitive inhibitor of the enzyme (e.g. **captopril**, acting on angiotensin-converting enzyme; see **Ch. 21**); in other cases, the binding is irreversible and non-competitive (e.g. **aspirin**, acting on cyclo-oxygenase; see **Ch. 25**). Drugs may also act as false substrates, where the drug molecule undergoes chemical transformation to form an abnormal product that subverts the normal metabolic pathway. An example is the anticancer drug **fluorouracil**, which replaces uracil as an intermediate in purine biosynthesis but cannot be converted into thymidylate, thus blocking DNA synthesis and preventing cell division (see **Ch. 57**).

It should also be mentioned that drugs may require enzymic degradation to convert them from an inactive form, the prodrug (see **Ch. 10**), to an active form (e.g. **enalapril** is converted by esterases to enalaprilat, which inhibits angiotensin-converting enzyme). Furthermore, as discussed in **Chapter 58**, drug toxicity often results from the enzymic conversion of the drug molecule to a reactive metabolite. **Paracetamol** (see **Ch. 25**) causes liver damage in this way. As far as the primary action of the drug is concerned, this is an unwanted side reaction, but it is of major practical importance.

Transporters

The movement of ions and small polar organic molecules across cell membranes generally occurs either through channels or through the agency of a transport protein (see **Fig. 3.1D**), because the permeating molecules are often insufficiently lipid-soluble to penetrate lipid membranes on their own. Many such transporters are known; examples of particular pharmacological importance include those responsible for the transport of ions and many organic molecules across the renal tubule, the intestinal epithelium and the blood–brain barrier; the transport of Na^+ and Ca^{2+} out of cells; the uptake of neurotransmitter precursors (such as choline) or of neurotransmitters themselves (such as amines and amino acids) by nerve terminals; and the transport of drug molecules and their metabolites across cell membranes and epithelial barriers. We shall encounter transporters frequently in later chapters.

In many cases, hydrolysis of ATP provides the energy for transport of substances against their electrochemical gradient. Such transport proteins include a distinct ATP-binding site and are termed *ABC* (ATP-Binding Cassette) transporters. Important examples include the sodium pump (Na^+-K^+-ATPase; see **Ch. 4**) and *multidrug resistance* (MDR) transporters that eject cytotoxic drugs from cancer and microbial cells, often conferring resistance to these therapeutic agents (see **Ch. 57**). In other cases, including the neurotransmitter transporters, the transport of organic molecules is coupled to the transport of ions (usually Na^+), either in the same direction (*symport*) or in the opposite direction (*antiport*), and therefore relies on the electrochemical gradient for Na^+ generated by the ATP-driven sodium pump. The carrier proteins embody a recognition site that makes them specific for a particular permeating species, and these recognition sites can also be targets for drugs whose effect is to block the transport system (e.g. cocaine blocks monoamine neurotransmitter uptake into nerve terminals; see **Ch. 49**).

The importance of transporters as a source of individual variation in the pharmacokinetic characteristics of various drugs is increasingly recognised (see **Ch. 11**).

Receptor Proteins

In the 1970s, pharmacology entered a new phase when receptors, which had until then been theoretical entities, began to emerge as biochemical realities. Over the following five decades enormous advances have been made. [2]

A major step forward was in determining the amino acid sequence of receptor proteins first by cloning individual receptors and then thereafter by genome sequencing. Sequence data have revealed many molecular variants (subtypes) of known receptors that had not been evident from pharmacological studies (see IUPHAR/BPS, *Guide to Pharmacology*). Much remains to be discovered about the pharmacological, functional and clinical significance of this abundant molecular polymorphism. It is expected, however, that such variations will account for part of the variability between individuals in response to therapeutic agents (see **Ch. 12**)

Although we already knew many of the endogenous ligands that activated well-characterised receptors it became apparent from the genome sequencing that there were novel receptors for which the endogenous ligands were so far unknown, and they are described as ‘orphan receptors’. [3] Identifying ligands for these presumed receptors was and in some cases still is difficult. Increasingly, there are examples (e.g. free fatty acid receptors) where important endogenous ligands have been linked to hitherto orphan receptors and there is optimism that novel therapeutic agents will emerge by targeting this pool of unclaimed receptors.

Much information has been gained by introducing the cDNA encoding individual receptors into cell lines, producing cells that express the foreign

(recombinant) receptors in a functional form. Such engineered cells allow much more precise control of the expressed receptors than is possible with natural cells or intact tissues (e.g. specific mutations can be introduced in the receptor sequence and the resulting changes in receptor function characterised), and recombinant receptor expression is widely used to study the functional and pharmacological characteristics of receptors. Expressed human receptors, which often differ in their sequence and pharmacological properties from their animal counterparts, can be studied in this way.

Many of the difficulties of obtaining crystals of membrane embedded proteins have been overcome. Obtaining crystals of a receptor protein allows its structure to be analysed at very high resolution by X-ray diffraction techniques. X-ray crystallography and more recently cryo-electron microscopy are being used to elucidate the three-dimensional molecular structure of receptors in detail. This then allows the use of sophisticated computational molecular docking and molecular dynamics simulations to study ligand binding to the receptor and subsequent protein conformational changes associated with activation of the receptor.

Types of Receptor

Receptors elicit many different types of cellular effect. Some of them are very rapid, such as those involved in fast synaptic transmission, operating within milliseconds, whereas other receptor-mediated effects, such as many of those produced by thyroid hormone or various steroid hormones, occur over hours or days. There are many examples of intermediate timescales – catecholamines, for example, usually act in a matter of seconds, whereas many peptides take rather longer to produce their effects. Not surprisingly, very different types of linkage between receptor occupation and the ensuing response are involved. Based on molecular structure and the nature of this linkage (the transduction mechanism), we

can distinguish four receptor types, or superfamilies (Figs **3.2** and **3.3**; **Table 3.1**).

- Type 1: **ligand-gated ion channels** (also known as **ionotropic** receptors [4]). These are the receptors which mediate fast synaptic transmission in the nervous system (see **Table 3.1**).
- Type 2: **G protein–coupled receptors** (GPCRs). These are also known as **metabotropic receptors** or **7-transmembrane** (7-TM, serpentine or heptahelical) **receptors.** They are membrane receptors that are coupled to intracellular effector systems primarily via a G protein. They constitute the largest family [5] and include receptors for many hormones and slow transmitters (**Table 3.1**).
- Type 3: **kinase-linked and related receptors.** This is a large and heterogeneous group of membrane receptors responding mainly to protein mediators. They comprise an extracellular ligand-binding domain linked to an intracellular domain by a single transmembrane helix. In many cases, the intracellular domain is enzymic in nature (with protein kinase or guanylyl cyclase activity). Some lack enzymic activity themselves but link to intracellular effector enzymes through their binding of adaptor proteins.
- Type 4: **nuclear receptors (NRs).** These are receptors that regulate gene transcription. [6] Receptors of this type also recognise many foreign molecules, inducing the expression of enzymes that metabolise them.

Molecular Structure of Receptors

The molecular organisation of typical members of each of these four receptor superfamilies is shown in **Fig. 3.3**. Although individual receptors show considerable sequence variation in particular regions, and the

lengths of the main intracellular and extracellular domains also vary from one to another within the same family, the overall structural patterns and associated signal transduction pathways are very consistent. The realisation that just four main receptor superfamilies provide a solid framework for interpreting the complex welter of information about the effects of a large proportion of the drugs that have been studied has been one of the most refreshing developments in modern pharmacology.

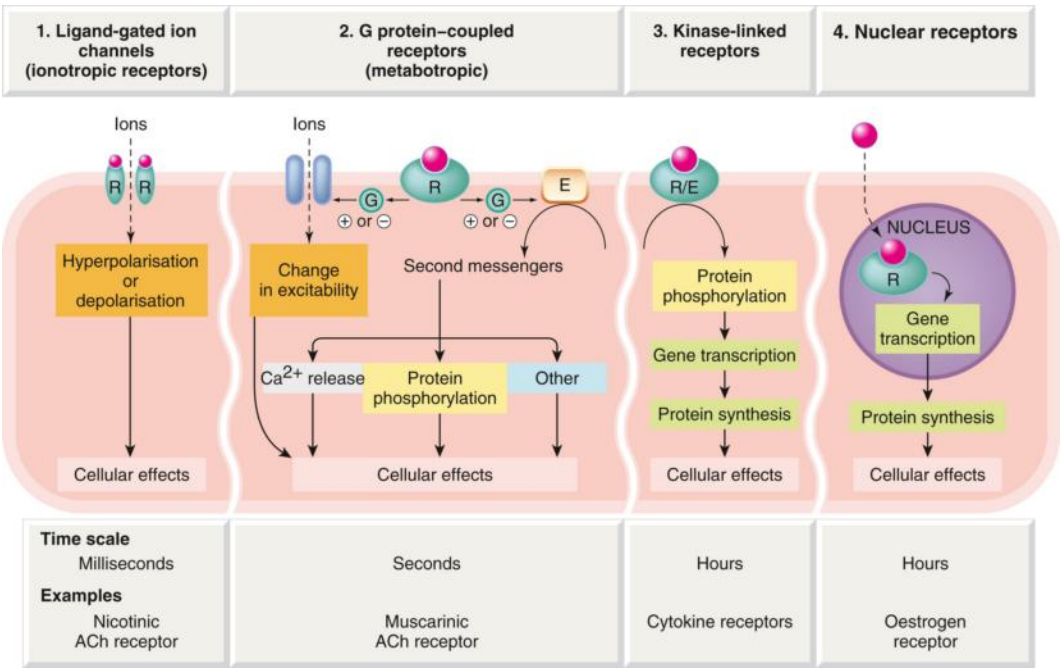

FIG. 3.2 Types of receptor–effector linkage. *ACh,* Acetylcholine; *E,* enzyme; *G,* G protein; *R,* receptor.

Table 3.1

Receptor Heterogeneity and Subtypes

Receptors within a given family generally occur in several molecular varieties, or subtypes, with similar architecture but significant differences in their sequences, and often in their pharmacological properties. [7]

Nicotinic acetylcholine receptors are typical in this respect; distinct subtypes occur in different brain regions (see **Table 39.2**), and these differ from the muscle receptor. Some of the known pharmacological differences (e.g. sensitivity to blocking agents) between muscle and brain acetylcholine receptors correlate with specific sequence differences; however, as far as we know, all nicotinic acetylcholine receptors respond to the same physiological mediator and produce the same kind of synaptic response, so why many variants should have evolved is still a puzzle.

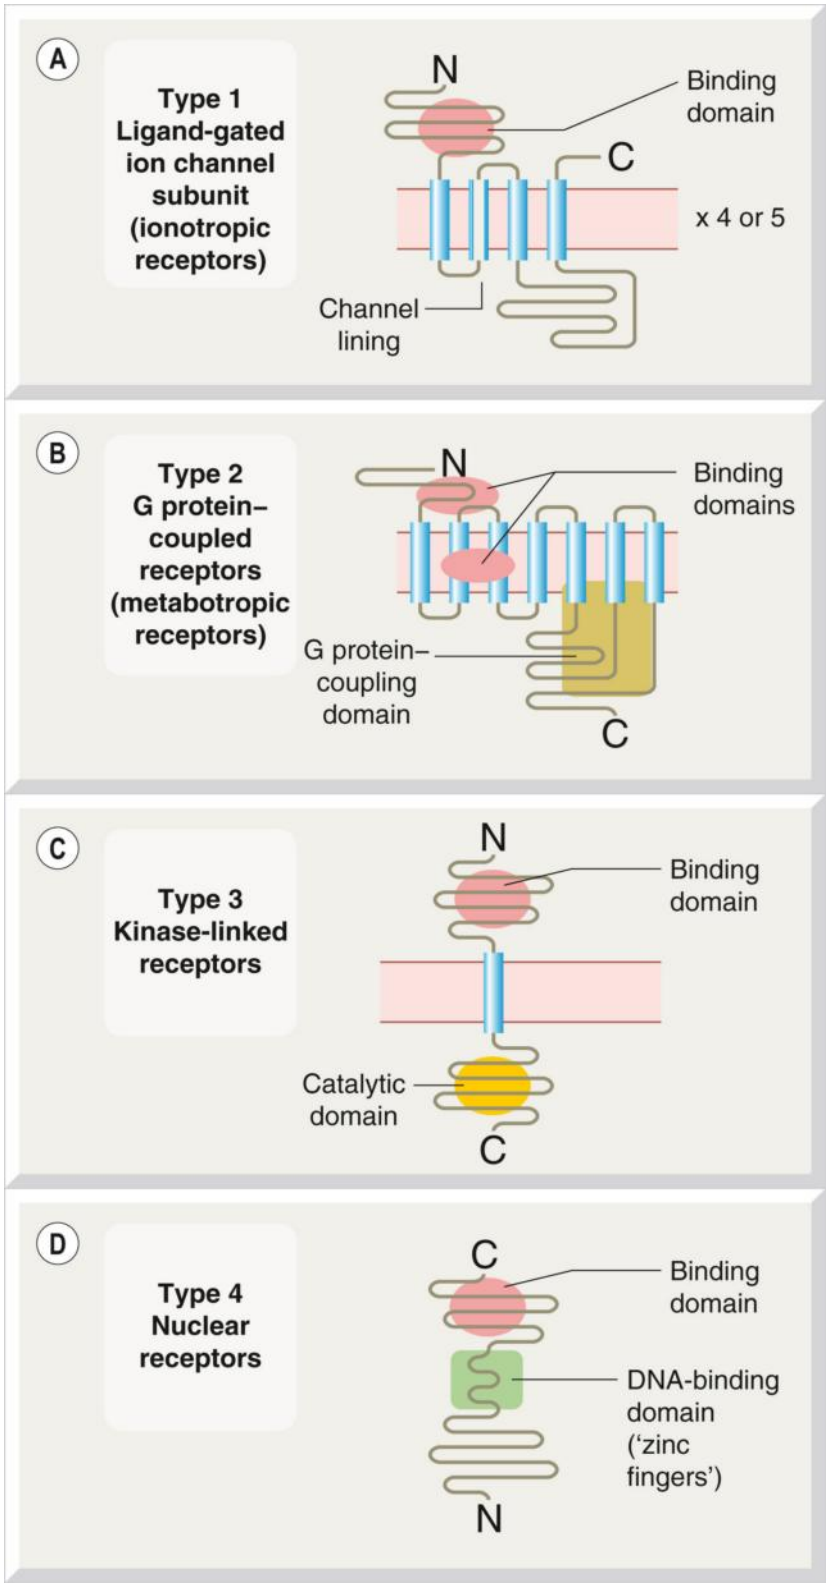

FIG. 3.3 General structure of four receptor families.The rectangular segments represent

hydrophobic α-helical regions of the protein comprising approximately 20 amino acids, which form the membrane-spanning domains of the receptors. The *pink shaded areas* illustrate the region of the orthosteric ligand-binding domains. (A) Type 1: ligand-gated ion channel subunit. The example illustrated here shows the subunit structure of the nicotinic acetylcholine receptor. The subunit structure of other ligand-gated ion channels is shown in **Fig. 3.5**. Many ligand-gated ion channels comprise four or five subunits of the type shown, the whole complex containing 16–20 membrane-spanning segments surrounding a central ion channel. (B) Type 2: G protein–coupled receptors (GPCRs). The two ligand-binding domains shown illustrate the position of the orthosteric ligand-binding domains on different types of GPCRs, there would be only one on each GPCR. (C) Type 3: kinase-linked receptors. Most growth factor receptors incorporate the ligand-binding and enzymatic (kinase) domains in the same molecule, *as shown*, whereas cytokine receptors lack an intracellular kinase domain but link to cytosolic kinase molecules. Other structural variants also exist. (D) Type 4: nuclear receptors that control gene transcription.

Much of the sequence variation that accounts for receptor diversity arises at the genomic level; that is, different genes give rise to distinct receptor subtypes. Additional variation arises from alternative mRNA splicing, which means that a single gene can give rise to more than one receptor isoform. After translation from genomic DNA, the mRNA normally contains non-coding regions (introns) that are excised by mRNA

splicing before the message is translated into protein. Depending on the location of the splice sites, splicing can result in inclusion or deletion of one or more of the mRNA coding regions giving rise to long or short forms of the protein. This is an important source of variation, particularly for GPCRs, producing receptors with different binding characteristics and different signal transduction mechanisms, although its pharmacological relevance remains to be clarified. Another process that can produce different receptors from the same gene is mRNA editing, which involves the mischievous substitution of one base in the mRNA for another, and hence potentially a small variation in the amino acid sequence of the expressed receptor.

Molecular heterogeneity of this kind is a feature of all kinds of receptors – indeed of functional proteins in general. New receptor subtypes and isoforms continue to be discovered, and regular updates of the catalogue are available (**www.guidetopharmacology.org/**). The problems of classification, nomenclature and taxonomy resulting from this flood of data have been mentioned earlier.

We will now describe the characteristics of each of the four receptor superfamilies.

Type 1: Ligand-Gated Ion Channels

The nicotinic acetylcholine receptor, which we find at the skeletal neuromuscular junction (see **Ch. 14**), in autonomic ganglia (see **Ch. 14**) and in the brain (see **Ch. 39**), is a typical example of a ligand-gated ion channel, known as the cys-loop receptors (so called because they have in their structure a large intracellular domain between transmembrane domains 3 and 4 containing multiple cysteine residues [see **Fig. 3.3A**]). Others of this type include the $GABA_A$ and glycine receptors (see **Ch. 38**) as well as the 5-hydroxytryptamine type 3 ($5\text{-}HT_3$; see Chs **16** and **39**) receptor. Other types of ligand-gated ion channel exist – namely ionotropic glutamate receptors (see **Ch. 38**) and purinergic P2X receptors (see Chs

17 and 39) that differ in several respects from the nicotinic acetylcholine receptor (see Fig. 3.5). In addition to the ligand-gated ion channels found on the cell membrane that mediate fast synaptic transmission, there are also intracellular ligand-gated ion channels – namely the inositol trisphosphate (IP_3) and ryanodine receptors (see Ch. 4) that release Ca^{2+} from intracellular stores.

Molecular Structure

Ligand-gated ion channels have structural features in common with other ion channels, described later in this chapter. The nicotinic acetylcholine receptor first cloned from the Torpedo electric ray (Fig. 3.4) [8] consists of a pentameric assembly of different subunits, of which there are four types, termed α, β, γ and δ, each of molecular weight (M_r) 40–58 kDa. The subunits show marked sequence homology, and each contains four membrane-spanning α-helices, inserted into the membrane as shown in Fig. 3.4B. The pentameric structure (α_2, β, γ, δ) possesses two acetylcholine binding sites, each lying at the interface between one of the two α subunits and its neighbour. Both must bind acetylcholine molecules for the receptor to be activated. Fig. 3.4B shows the receptor structure. Each subunit spans the membrane four times, so the channel comprises no fewer than 20 membrane-spanning helices surrounding a central pore.

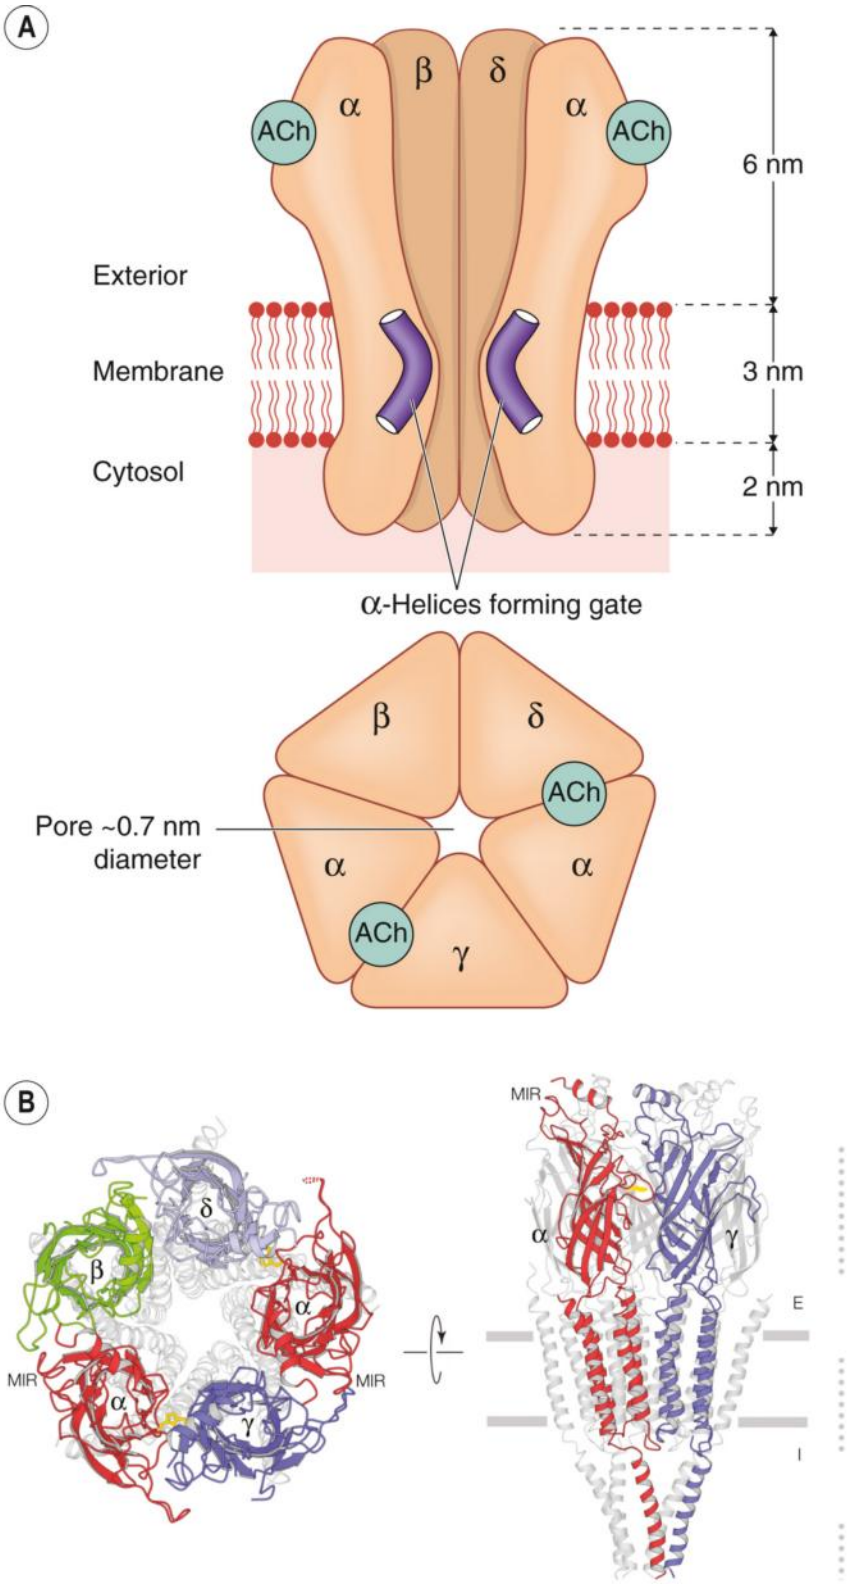

FIG. 3.4 Structure of the nicotinic acetylcholine receptor (a typical ligand-gated ion channel).(A)

Schematic diagram in side view *(upper)* and plan view *(lower)*. The five receptor subunits (α_2, β, γ, δ) form a cluster surrounding a central transmembrane pore, the lining of which is formed by the M_2 helical segments of each subunit. These contain a preponderance of negatively charged amino acids, which makes the pore cation selective. There are two acetylcholine binding sites in the extracellular portion of the receptor, at the interface between the α and the adjoining subunits. When acetylcholine binds, the kinked α-helices either straighten out or swing out of the way, thus opening the channel pore. (B) High-resolution image showing revised arrangement of intracellular domains. Panel [A] based on Unwin, N., 1993. Nicotinic acetylcholine receptor at 9Å resolution. J. Mol. Biol. 229, 1101–1124, and Unwin, N., 1995. Acetylcholine receptor channel imaged in the open state. Nature 373, 37–43; panel [B] reproduced with permission from Unwin, N., 2005. Refined structure of the nicotinic acetylcholine receptor at 4Å resolution. J. Mol. Biol. 346(4), 967–989.

One of the transmembrane helices (M_2) from each of the five subunits forms the lining of the ion channel (see **Fig. 3.4**). The five M_2 helices that form the pore are sharply kinked inwards halfway through the membrane, forming a constriction. When acetylcholine molecules bind, a conformation change occurs in the extracellular part of the receptor, which twists the α subunits, causing the kinked M_2 segments to swivel out of the way, thus opening the channel. The channel lining contains a series of anionic residues, making the channel selectively permeable to cations (primarily Na^+ and K^+, although some types of nicotinic receptor are permeable to Ca^{2+} as well).

The use of site-directed mutagenesis, which enables short regions, or single residues, of the amino acid sequence to be altered, has shown that a mutation of a critical residue in the M_2 helix changes the channel from being cation permeable (hence excitatory in the context of synaptic function) to being anion permeable (typical of receptors for inhibitory transmitters such as GABA and glycine). Other mutations affect properties such as gating and desensitisation of ligand-gated channels.

Other ligand-gated ion channels, such as glutamate receptors (see **Ch. 38**) and P2X receptors (see Chs **16** and **39**), whose subunit structures are shown in **Fig. 3.5**, have a different architecture. Ionotropic glutamate receptors are tetrameric and the pore is built from loops rather than transmembrane helices, in common with many other (non-ligand-gated) ion channels (see **Fig. 3.20**). P2X receptors are trimeric and each subunit has only two transmembrane domains (**North, 2002**). The nicotinic receptor and other cys-loop receptors are pentamers with two agonist binding sites on each receptor. Binding of one agonist molecule to one site increases the affinity of binding at the other site (positive cooperativity) and both sites need to be occupied for the receptor to be activated and the channel to open. Some ionotropic glutamate receptors have as many as four agonist binding sites and P2X receptors have three, but they appear to open when two agonist molecules are bound. Once again we realise that the simple model of receptor activation shown in **Fig. 2.1** is an oversimplification as it only considered one agonist molecule binding to produce a response. For two or more agonist molecules binding, more complex mathematical models are needed (see **Colquhoun, 2006**).

The Gating Mechanism

Receptors of this type control the fastest synaptic events in the nervous system, in which a neurotransmitter acts on the postsynaptic membrane of a nerve or muscle cell and transiently increases its permeability to particular ions. Most excitatory neurotransmitters, such as acetylcholine at

the neuromuscular junction (see **Ch. 14**) or glutamate in the central nervous system (see **Ch. 38**), cause an increase in Na^+ and K^+ permeability and in some instances Ca^{2+} permeability. At negative membrane potentials this results in a net inward current carried mainly by Na^+, which depolarises the cell and increases the probability that it will generate an action potential. The action of the transmitter reaches a peak in a fraction of a millisecond, and usually decays within a few milliseconds. The sheer speed of this response implies that the coupling between the receptor and the ion channel is a direct one, and the molecular structure of the receptor–channel complex (see earlier) agrees with this. In contrast to other receptor families, no intermediate biochemical steps are involved in the transduction process.

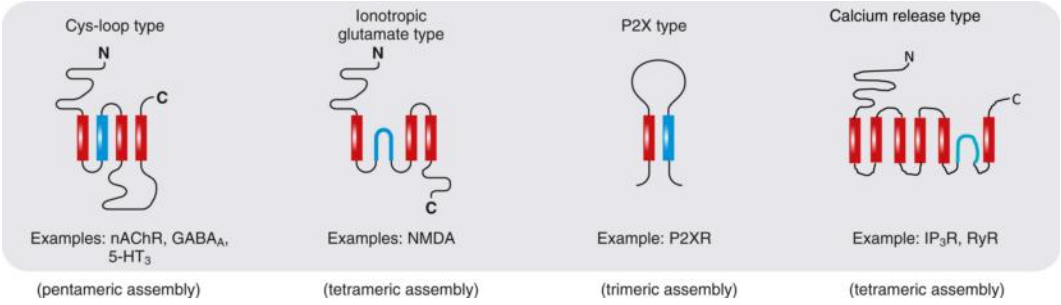

FIG. 3.5 Molecular architecture of ligand-gated ion channels. *Red* and *blue rectangles* represent membrane-spanning α-helices and *blue hairpins* represent the P loop pore-forming regions. *5-HT $_3$*, 5-Hydroxytryptamine type 3 receptor; *GABA $_A$*, GABA type A receptor; *IP $_3$ R,* inositol trisphosphate receptor; *nAChR*, nicotinic acetylcholine receptor; *NMDA, N*-methyl-D-aspartatic acid receptor; *P2XR,* purine P2X receptor; *RyR,* ryanodine receptor.

The *patch clamp recording technique*, devised by Neher and Sakmann, allows the very small current flowing through a single ion channel to be

measured directly (**Fig. 3.6**). The patch clamp technique provides a view, rare in biology, of the physiological behaviour of individual protein molecules in real time, and has given many new insights into the gating reactions and permeability characteristics of both ligand-gated channels and voltage-gated channels. The magnitude of the single channel conductance confirms that permeation occurs through a physical pore through the membrane, because the ion flow is too large (about 10^7 ions per second) to be compatible with a carrier mechanism. The channel conductance produced by different agonists is the same, whereas the mean channel lifetime varies. The ligand–receptor interaction scheme shown in **Chapter 2** is a useful model for ion-channel gating. The conformation R*, representing the open state of the ion channel, is thought to be the same for all agonists, accounting for the finding that the channel conductance does not vary. Kinetically, the mean open time is determined mainly by the closing rate constant, α, and this varies from one drug to another. As explained in **Chapter 2** (see **Fig. 2.1**), an agonist of high efficacy that activates a large proportion of the receptors that it occupies will be characterised by $\beta/\alpha \gg 1$, whereas for a drug of low efficacy β/α has a lower value.

At some ligand-gated ion channels, the situation is more complicated because different agonists may cause individual channels to open to one or more of several distinct conductance levels (see **Fig. 3.6B**). This implies that there is more than one R* conformation. Furthermore, desensitisation of ligand-gated ion channels (see **Ch. 2**) also involves one or more additional agonist-induced conformational states. These findings necessitate some elaboration of the simple scheme in which only a single open state, R*, is represented and are an example of the way in which the actual behaviour of receptors makes our theoretical models look a little threadbare.

Ligand-gated ion channels

- These are sometimes called ionotropic receptors.
- They are involved mainly in fast synaptic transmission.
- There are several structural families, the commonest being heteromeric assemblies of four or five subunits, with transmembrane helices arranged around a central aqueous channel.
- Ligand binding and channel opening occur on a millisecond timescale.
- Examples include the nicotinic acetylcholine, GABA type A ($GABA_A$), glutamate (e.g. *N*-methyl-D-aspartatic acid receptor [NMDA]) and ATP (P2X) receptors.

Type 2: G Protein–Coupled Receptors

GPCRs constitute the commonest single class of targets for therapeutic drugs. The GPCR family comprises many of the receptors that are familiar to pharmacologists, such as muscarinic AChRs, adrenoceptors, dopamine receptors, 5-HT (serotonin) receptors, receptors for many peptides, purine receptors and many others, including the chemoreceptors involved in olfaction and pheromone detection, and also many 'orphans'. For most of these, pharmacological and molecular studies have revealed a variety of subtypes. All have the characteristic heptahelical structure (see **Fig. 3.3B**).

Many neurotransmitters, apart from peptides, can interact with both GPCRs and ligand-gated channels, allowing the same molecule to produce fast (through ligand-gated ion channels) and relatively slow (through GPCRs) effects. Individual peptide hormones, however, generally act either on GPCRs or on kinase-linked receptors (see later), but rarely on both, and a similar choosiness applies to the many ligands that act on NRs.

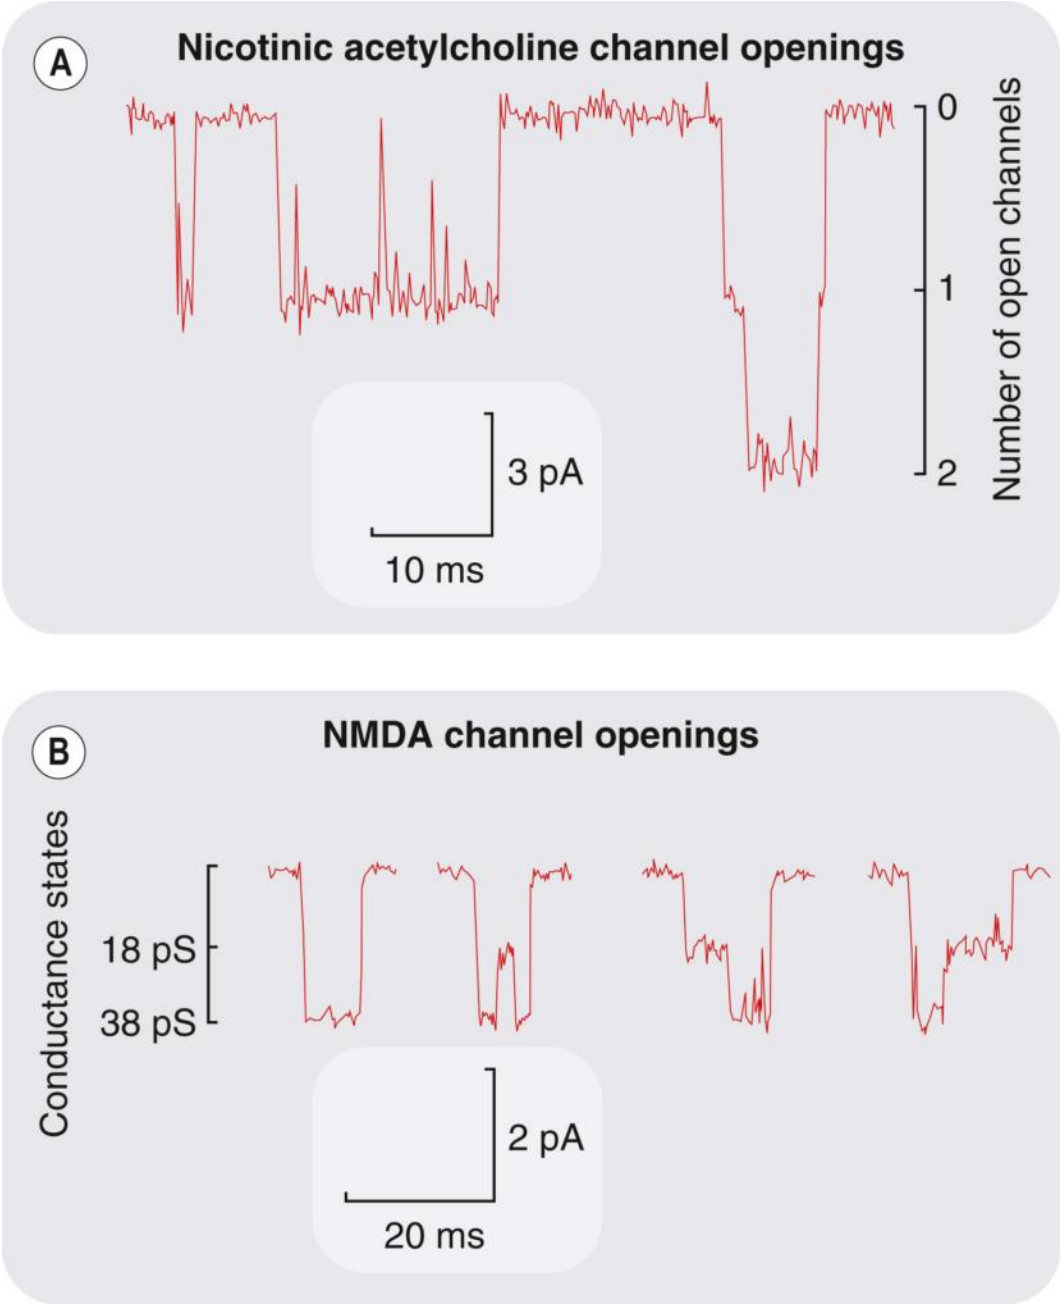

FIG. 3.6 Single channel openings recorded by the patch clamp technique.(A) Acetylcholine-operated ion channels at the frog motor endplate. The pipette, which was applied tightly to the surface of the membrane, contained 10 µmol/L ACh. The downward deflections show the currents flowing through single ion channels in the small patch of membrane under the pipette tip.

Towards the end of the record, two channels can be seen to open with a discrete step from the first to the second. (B) Single-channel *N*-methyl-D-aspartic acid receptor (NMDA) receptor currents recorded from cerebellar neurons in the outside-out patch conformation. NMDA was added to the outside of the patch to activate the channel. The channel opens to multiple conductance levels. In (B) the openings to the higher conductance level and the subsequent closings are smooth, indicating that one channel is opening (two channels would not be expected to open and close simultaneously) whereas in (A) there are discrete steps indicating two channels. Panel [A] courtesy D. Colquhoun and D.C. Ogden; panel [B] reproduced with permission from Cull-Candy, S.G., and Usowicz, M.M., 1987. Multiple-conductance channels activated by excitatory amino acids in cerebellar neurons. Nature 325, 525–528.

Molecular Structure

In 1986 the first pharmacologically relevant GPCR, the β_2 adrenoceptor (see **Ch. 15**), was cloned. Thereafter molecular biology caught up very rapidly with pharmacology, and with the sequencing of the human genome the amino acid sequence of all the GPCRs hitherto identified by their pharmacological properties was revealed, as was the structure of many novel GPCRs. More recently X-ray crystallography and cryo-electron microscopy have been used to study the three-dimensional molecular structure of these receptors in detail (**Fig. 3.7**) (**Garcia-Nafria and Tate, 2019**; **Zhang et al., 2015**). Also, computational molecular docking, molecular dynamics simulation and nuclear magnetic resonance (NMR) methods have been developed to study ligand binding and

subsequent conformational changes associated with activation (see **Sounier et al., 2015**). This has provided important information on agonist- and antagonist-bound receptor conformations as well as receptor–G protein interactions. From such studies we are gaining a clearer picture of the mechanism of activation of GPCRs and the factors determining agonist efficacy, as well as having a better basis for designing new GPCR ligands.

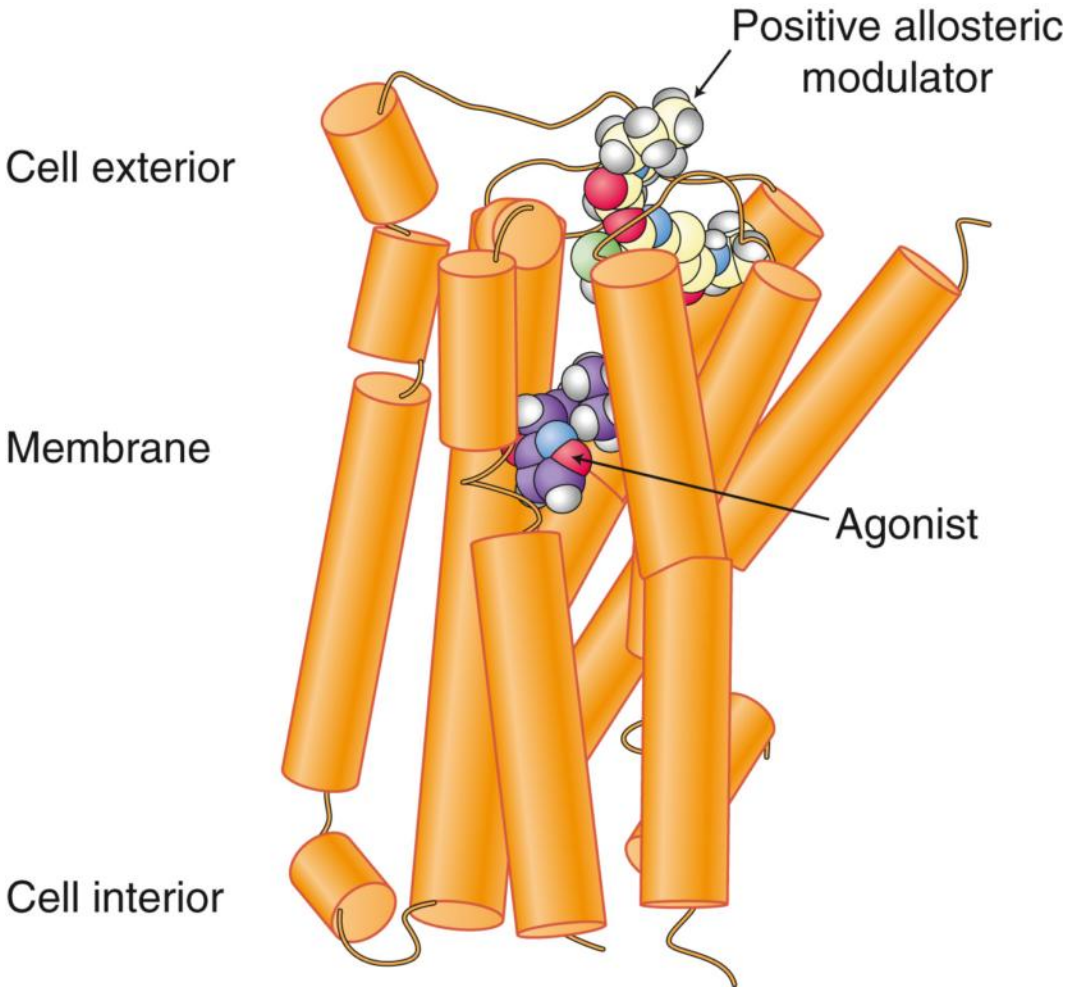

FIG. 3.7 Structure of the M_2 muscarinic receptor.High-resolution image showing the conformation of the M_2 muscarinic receptor bound with both an agonist (orthosteric) and a positive allosteric modulator. The brown cylinders represent the transmembrane domains. The full extent of the N- and C-terminal domains and the third intracellular loop are not shown. Courtesy A. Christopoulos.

GPCRs consist of a single polypeptide chain, usually of 350–400 amino acid residues, but in some cases up to 1100 residues. The general anatomy is shown in **Fig. 3.3B**. Their characteristic structure comprises seven transmembrane α-helices, similar to those of the ion channels discussed

previously, with an extracellular N-terminal domain of varying length, and an intracellular C-terminal domain.

GPCRs are divided into three main classes – A, B and C (**Table 3.2**). There is considerable sequence homology between the members of one class, but little between different classes. They share the same seven transmembrane helix (heptahelical) structures, but differ in other respects, principally in the length of the extracellular N-terminus and the location of the agonist binding domain. Class A is by far the largest, comprising most monoamine, neuropeptide and chemokine receptors. Class B includes receptors for some other peptides, such as calcitonin and glucagon. Class C is the smallest, its main members being the metabotropic glutamate and GABA receptors and the Ca^{2+}-sensing receptors. [10]

Table 3.2

Main G protein–coupled receptor classes [a], [b]

Class	Receptors [b]	Structural features
A: rhodopsin family	The largest group. Receptors for most amine neurotransmitters, many neuropeptides, purines, prostanoids, cannabinoids, etc.	Short extracellular (N-terminal) tail. Ligand binds to transmembrane helices (amines) or to extracellular loops (peptides)
B: secretin/glucagon receptor family	Receptors for peptide hormones, including secretin, glucagon, calcitonin	Intermediate extracellular tail incorporating ligand-binding domain
C: metabotropic glutamate receptor/calcium sensor family	Small group. Metabotropic glutamate receptors, $GABA_B$ receptors, Ca^{2+}-sensing receptors	Long extracellular tail incorporating ligand-binding domain

[a] Other classes include frizzled G protein–coupled receptors (GPCRs), adhesion GPCRs and receptors for pheromones.

[b] For full lists, see **www.guidetopharmacology.org**.

For small molecules, such as noradrenaline (norepinephrine) and acetylcholine, the ligand-binding domain of class A receptors is buried in the cleft between the α-helical segments within the membrane (see Figs **3.3B** and **3.7**), similar to the slot occupied by *retinal* in the *rhodopsin* molecule. [11] Peptide ligands, such as substance P (see **Ch. 17**), bind more superficially to the extracellular loops, as shown in **Fig. 3.3B**. From crystal structures and single-site mutagenesis experiments, it is possible to map the ligand-binding domain of these receptors. Recent advances in computational molecular docking of ligands into the ligand–receptor-binding domain have made it possible to design novel synthetic ligands based primarily on knowledge of the receptor structure (see **Manglik et al., 2016**) – an important milestone in drug development, which has relied up to now mainly on the structure of endogenous mediators (such as histamine) or plant alkaloids (such as morphine) for its chemical inspiration. [12]

Proteinase-Activated Receptors [13]

Although activation of GPCRs is normally the consequence of a diffusible agonist, it can be the result of proteinase activation. Four types of proteinase-activated receptors (PARs) have been identified (see review by **Chandrabalan and Ramachandran, 2021**). Many proteinases, such as thrombin (a proteinase involved in the blood-clotting cascade; see **Ch. 24**), activate PARs by snipping off the end of the extracellular N-terminal tail of the receptor (**Fig. 3.8**) to expose five or six N-terminal residues that bind to receptor domains in the extracellular loops, functioning as a 'tethered agonist'. Receptors of this type occur in many tissues and they appear to play a role in inflammation and other responses to tissue damage where tissue proteinases are released. A PAR can be activated only once, because the cleavage cannot be reversed, and thus continuous resynthesis of the receptor protein is necessary. Inactivation occurs by a further proteolytic cleavage that frees the tethered ligand, or by

desensitisation, involving phosphorylation (see **Fig. 3.8**), after which the receptor is internalised and degraded, to be replaced by newly synthesised protein.

G protein–coupled receptors

- These are sometimes called metabotropic or seven-transmembrane-domain (7-TDM) receptors.
- Structures comprise seven membrane-spanning α-helices.
- The G protein is a membrane protein comprising three subunits (α, β, γ), the α subunit possessing GTPase activity.
- The G protein interacts with a binding pocket on the intracellular surface of the receptor.
- When the G protein binds to an agonist-occupied receptor, the α subunit binds GTP, dissociates and is then free to activate an effector (e.g. a membrane enzyme). In some cases, the βγ subunit is the activator species.
- Activation of the effector is terminated when the bound GTP molecule is hydrolysed, which allows the α subunit to recombine with βγ.
- There are several types of G protein, which interact with different receptors and control different effectors.
- Examples include muscarinic acetylcholine receptors, adrenoceptors, neuropeptide and chemokine receptors, and proteinase-activated receptors.

G Proteins and Their Role

G proteins comprise a family of membrane-resident proteins whose function is to respond to GPCR activation and pass on the message inside

the cell to the effector systems that generate a cellular response. They represent the level of middle management in the organisational hierarchy, intervening between the receptors – choosy mandarins, alert to the faintest whiff of their preferred chemical – and the effector enzymes or ion channels – the blue-collar brigade that gets the job done without needing to know which hormone authorised the process. They are the go-between proteins but were actually called G proteins because of their interaction with the guanine nucleotides, GTP and GDP. For more detailed information on the structure and functions of G proteins, see the review by **Li et al. (2020)**. G proteins consist of three subunits: α, β and γ (**Fig. 3.9**). Guanine nucleotides bind to the α subunit, which has enzymic (GTPase) activity, catalysing the conversion of GTP to GDP. The β and γ subunits remain together as a βγ complex. The 'γ' subunit is anchored to the membrane through a fatty acid chain, coupled to the G protein through a reaction known as *prenylation*. In the 'resting' state (see **Fig. 3.9**), the G protein exists as an αβγ trimer, which may or may not be precoupled to the receptor, with GDP occupying the site on the α subunit. When a GPCR is activated by an agonist this induces small changes in residues around the ligand-binding pocket that translate to larger rearrangements of the intracellular regions of the receptor that open a cavity on the intracellular side of the receptor into which the G protein can bind, resulting in a high-affinity interaction of αβγ and the receptor. This agonist-induced interaction of αβγ with the receptor occurs within about 50 ms, causing the bound GDP to dissociate and to be replaced with GTP (GDP–GTP exchange), which in turn causes dissociation of the G protein trimer, releasing α–GTP from the βγ subunits; these are the 'active' forms of the G protein, which diffuse in the membrane and can associate with various enzymes and ion channels, causing activation of the target (see **Fig. 3.9**). It was originally thought that only the α subunit had a signalling function, the βγ complex serving merely as a chaperone to keep the flighty α subunits out of range of the various effector proteins that they might

otherwise excite. However, the βγ complexes actually make assignations of their own, and control effectors in much the same way as the α subunits. The association of α or βγ subunits with target enzymes or channels can cause either activation or inhibition, depending on which G protein is involved (see **Table 3.3**). G protein activation results in amplification, because a single agonist–receptor complex can activate several G protein molecules in turn, and each of these can remain associated with their effector enzyme for long enough to produce many molecules of product. The product (see later) is often a 'second messenger', and further amplification occurs before the final cellular response is produced. Signalling is terminated when the hydrolysis of GTP to GDP occurs through the inherent GTPase activity of the α subunit. The resulting α–GDP then dissociates from the effector, and reunites with βγ, completing the cycle.

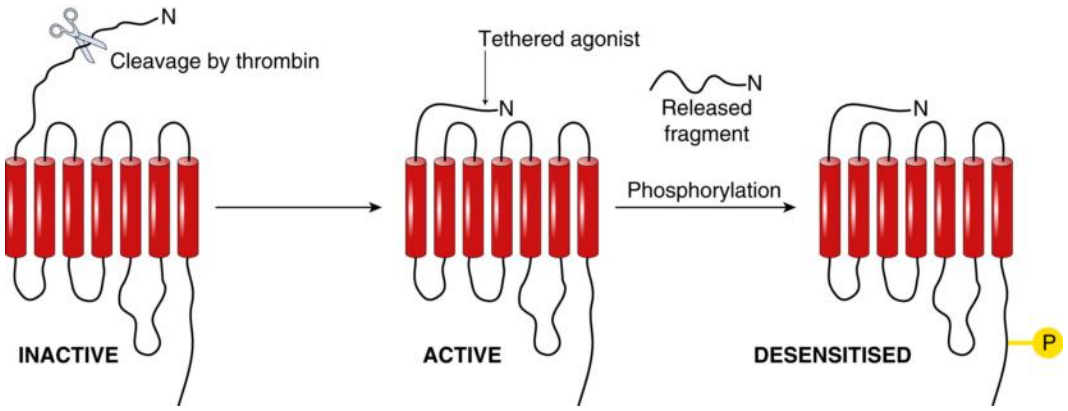

FIG. 3.8 Activation of a proteinase-activated receptor by cleavage of the N-terminal extracellular domain.Inactivation occurs by phosphorylation. Recovery requires resynthesis of the receptor.

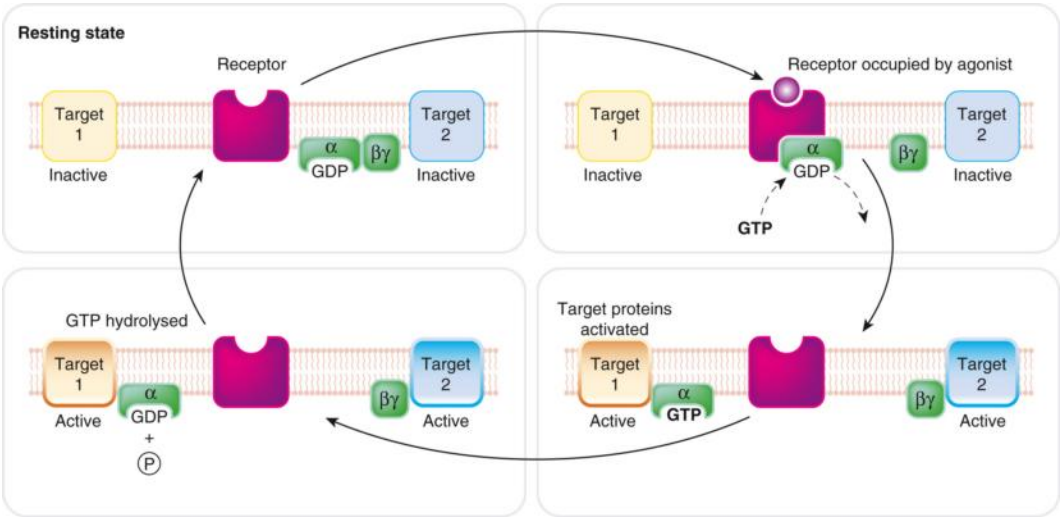

FIG. 3.9 Function of the G protein.The G protein consists of three subunits (α, β, γ), which are anchored to the membrane through attached lipid residues. Coupling of the α subunit to an agonist-occupied receptor causes the bound GDP to exchange with intracellular GTP; the α–GTP complex then dissociates from the receptor and from the βγ complex, and interacts with a target protein (target 1, which may be an enzyme, such as adenylyl cyclase or phospholipase C). The βγ complex also activates a target protein (target 2, which may be an ion channel or a kinase). The GTPase activity of the α subunit is increased when the target protein is bound, leading to hydrolysis of the bound GTP to GDP, whereupon the α subunit reunites with βγ.

Attachment of the α subunit to an effector molecule actually increases its GTPase activity, the magnitude of this increase being different for different types of effector. Because GTP hydrolysis is the step that terminates the ability of the α subunit to produce its effect, regulation of its GTPase activity by the effector protein means that the activation of the effector tends to be self-limiting. In addition, there is a family of about 20

cellular proteins, regulators of G protein signalling (RGS) proteins (see review by **Sjögren, 2017**), that possess a conserved sequence that binds specifically to α subunits to increase greatly their GTPase activity, so hastening the hydrolysis of GTP and inactivating the complex. RGS proteins thus exert an inhibitory effect on G protein signalling, a mechanism that is thought to have a regulatory function in many situations.

Different GPCRs couple to different G proteins and thus produce distinct cellular responses. For example, M_2 muscarinic acetylcholine receptors (mAChRs) and β_1 adrenoceptors, both of which occur in cardiac muscle cells, produce opposite functional effects (see Chs **14** and **15**). Four main classes of G protein (G_s, G_i, G_o and G_q) are of pharmacological importance (**Table 3.3**). These differ primarily in the α subunit they contain. [14] G proteins show selectivity with respect to both the receptors and the effectors with which they couple, having specific recognition domains in their structure complementary to specific G protein-binding domains in the receptor and effector molecules. For example, G_s and G_i produce, respectively, stimulation and inhibition of the enzyme *adenylyl cyclase* (**Fig. 3.10**).

One functional difference that has been useful as an experimental tool to distinguish which type of G protein is involved in different situations concerns the action of two bacterial toxins, *cholera toxin* and *pertussis toxin* (see **Table 3.3**). These toxins, which are enzymes, catalyse a conjugation reaction (ADP ribosylation) on the α subunit of G proteins. Cholera toxin acts only on G_s, and it causes persistent activation. Many of the symptoms of cholera, such as the excessive secretion of fluid from the gastrointestinal epithelium (leading to 'rice-water stools'), are due to the uncontrolled activation of adenylyl cyclase that occurs. Pertussis toxin specifically blocks G_i and G_o by preventing dissociation of the G protein trimer. Pertussis toxin is released from *Bordetella pertussis* bacteria, which cause whooping cough. As with cholera toxin, the symptoms caused

by pertussis toxin are related to its effects on G proteins, but in this case by inhibiting G_i and G_o rather than activating G_s and leading to changes in respiratory tract secretion and a distinctive cough rather than the copious diarrhoea of cholera.

Table 3.3

GPCR, G protein–coupled receptor.

[a] This table lists only those isoforms of major pharmacological significance. Many more have been identified, some of which play roles in olfaction, taste, visual transduction and other physiological functions.

[b] Initially the subscripts 's' and 'i' were used to denote stimulatory and inhibitory actions on adenylyl cyclase but, subsequently, the terms used, 'q' and '12/13', have little logic behind their use.

Targets for G Proteins

The main targets for G proteins, through which GPCRs control different aspects of cell function (see **Table 3.3**), are:

- *adenylyl cyclase*, the enzyme responsible for cAMP formation;
- *phospholipase C*, the enzyme responsible for inositol phosphate and diacylglycerol (DAG) formation;
- *ion channels*, particularly calcium and potassium channels;
- *Rho A/Rho kinase*, a system that regulates the activity of many signalling pathways controlling cell growth, proliferation and motility, smooth muscle contraction, etc.;
- *mitogen-activated protein (MAP) kinase*, a system that controls many cell functions, including cell division and is also a target of several kinase-linked receptors.

The adenylyl cyclase/cAMP system

The discovery by Sutherland and his colleagues of the role of cAMP (cyclic 3′,5′-adenosine monophosphate) as an intracellular mediator demolished at a stroke the barriers that existed between biochemistry and pharmacology, and introduced the concept of second messengers in signal transduction. cAMP is a nucleotide synthesised within the cell from ATP by the action of a membrane-bound enzyme, adenylyl cyclase. It is produced continuously and inactivated by hydrolysis to 5′-adenosine monophosphate (AMP) by the action of a family of enzymes known as phosphodiesterases (PDEs). Many different drugs, hormones and neurotransmitters act on GPCRs and increase or decrease the catalytic activity of adenylyl cyclase (see **Fig. 3.10**), thus raising or lowering the concentration of cAMP within the cell. In mammalian cells there are 10 different molecular isoforms of the enzyme, some of which respond selectively to $G\alpha_s$ or $G\alpha_i$.

cAMP regulates many aspects of cellular function including, for example, enzymes involved in energy metabolism, cell division and cell differentiation, ion transport, ion channels and the contractile proteins in smooth muscle. These varied effects are, however, all brought about by a common mechanism, namely the activation of protein kinases by cAMP (known as cAMP-dependent protein kinases) in eukaryotic cells. One important cAMP-dependent protein kinase is *protein kinase A* (PKA). Protein kinases regulate the function of many different cellular proteins by controlling protein phosphorylation. **Fig. 3.11** shows how increased cAMP production in response to β-adrenoceptor activation affects enzymes involved in glycogen and fat metabolism in liver, fat and muscle cells. The result is a coordinated response in which stored energy in the form of glycogen and fat is made available as glucose to fuel muscle contraction.

Other examples of regulation by PKA include the increased activity of voltage-gated calcium channels in heart muscle cells (see **Ch. 20**). Phosphorylation of these channels increases the amount of Ca^{2+} entering

the cell during the action potential, and thus increases the force of contraction of the heart.

In smooth muscle, PKA phosphorylates (thereby inactivating) another enzyme, *myosin light-chain kinase*, which is required for contraction. This accounts for the smooth muscle relaxation produced by many drugs that increase cAMP production in smooth muscle (see **Ch. 4**).

As mentioned earlier, receptors linked to G_i rather than G_s inhibit adenylyl cyclase, and thus reduce cAMP formation to elicit opposing responses to those receptors which activate G_s. Examples include certain types of mAChR (e.g. the M_2 receptor of cardiac muscle; see **Ch. 14**), α_2 adrenoceptors in smooth muscle (see **Ch. 15**) and opioid receptors (see **Ch. 43**). Adenylyl cyclase can be activated directly by drugs such as **forskolin**, which is used experimentally to study the role of the cAMP system.

cAMP is hydrolysed within cells by *PDEs*, an important and ubiquitous family of enzymes. Twenty-four PDE subtypes exist, of which some are more selective for cAMP, while others are more selective for cGMP. Most are weakly inhibited by drugs such as methylxanthines (e.g. **theophylline** and **caffeine**; see Chs **28** and **49**). **Roflumilast** (used to treat chronic obstructive pulmonary disease [COPD]; see **Ch. 28**) is selective for PDE_{4B}, expressed in inflammatory cells; **milrinone** (a positive inotrope that makes the heart beat harder and is sometimes used for symptoms in patients awaiting heart transplantation; see **Ch. 20**) is selective for PDE_{2A}, which is expressed in heart muscle; **sildenafil** (better known as Viagra; see **Ch. 35**) is selective for PDE_{5A}, and consequently enhances the vasodilator effects of nitric oxide (NO) and drugs that release NO, whose effects are mediated by cGMP (see **Ch. 19**). The similarity of some of the actions of these drugs to those of sympathomimetic amines (see **Ch. 15**) probably reflects their common property of increasing the intracellular concentration of cAMP.

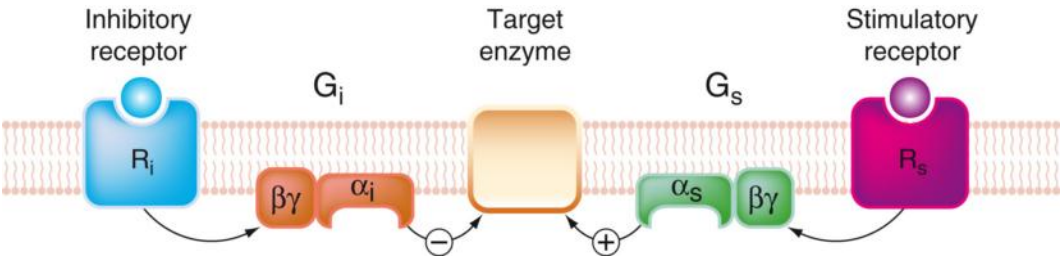

FIG. 3.10 Bidirectional control of a target enzyme, such as adenylyl cyclase by G_s and G_i.Heterogeneity of G proteins allows different receptors to exert opposite effects on a target enzyme.

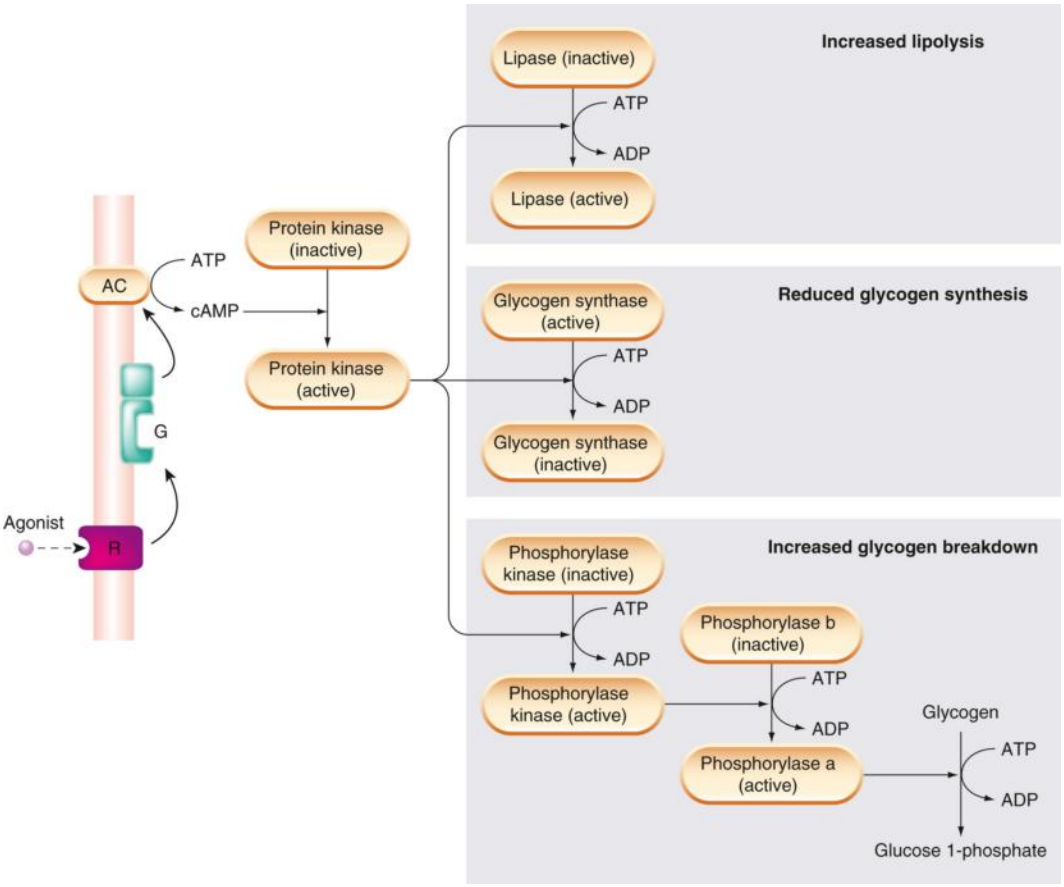

FIG. 3.11 Regulation of energy metabolism by cAMP. *AC,* Adenylyl cyclase.

The phospholipase C/inositol phosphate system

The *phosphoinositide* system, an important intracellular second messenger system, was first discovered in the 1950s by Hokin and Hokin, whose recondite interests centred on the mechanism of salt secretion by the nasal glands of seabirds. They found that secretion was accompanied by increased turnover of a minor class of membrane phospholipids known as phosphoinositides (collectively known as PIs; **Fig. 3.12**). Subsequently, Michell and Berridge found that many hormones that produce an increase in free intracellular Ca^{2+} concentration (which include, for example, muscarinic agonists and α-adrenoceptor agonists acting on smooth muscle and salivary glands) also increase PI turnover. It was later found that one particular member of the PI family, namely phosphatidylinositol (4,5) bisphosphate (PIP_2), which has additional phosphate groups attached to the inositol ring, plays a key role. PIP_2 is the substrate for a membrane-bound enzyme, phospholipase Cβ (PLCβ), which splits it into *DAG* and *inositol (1,4,5) trisphosphate* (IP_3; **Fig. 3.13**), both of which function as second messengers. The activation of PLCβ by various agonists is mediated through a G protein (G_q, see **Table 3.3**). After cleavage of PIP_2, the status quo is restored, as shown in **Fig. 3.13**, DAG being phosphorylated to form phosphatidic acid (PA), while the IP_3 is dephosphorylated and then recoupled with PA to form PIP_2 once again. [15] Lithium, an agent used in psychiatry (see **Ch. 48**), blocks this recycling pathway (see **Fig. 3.13**).

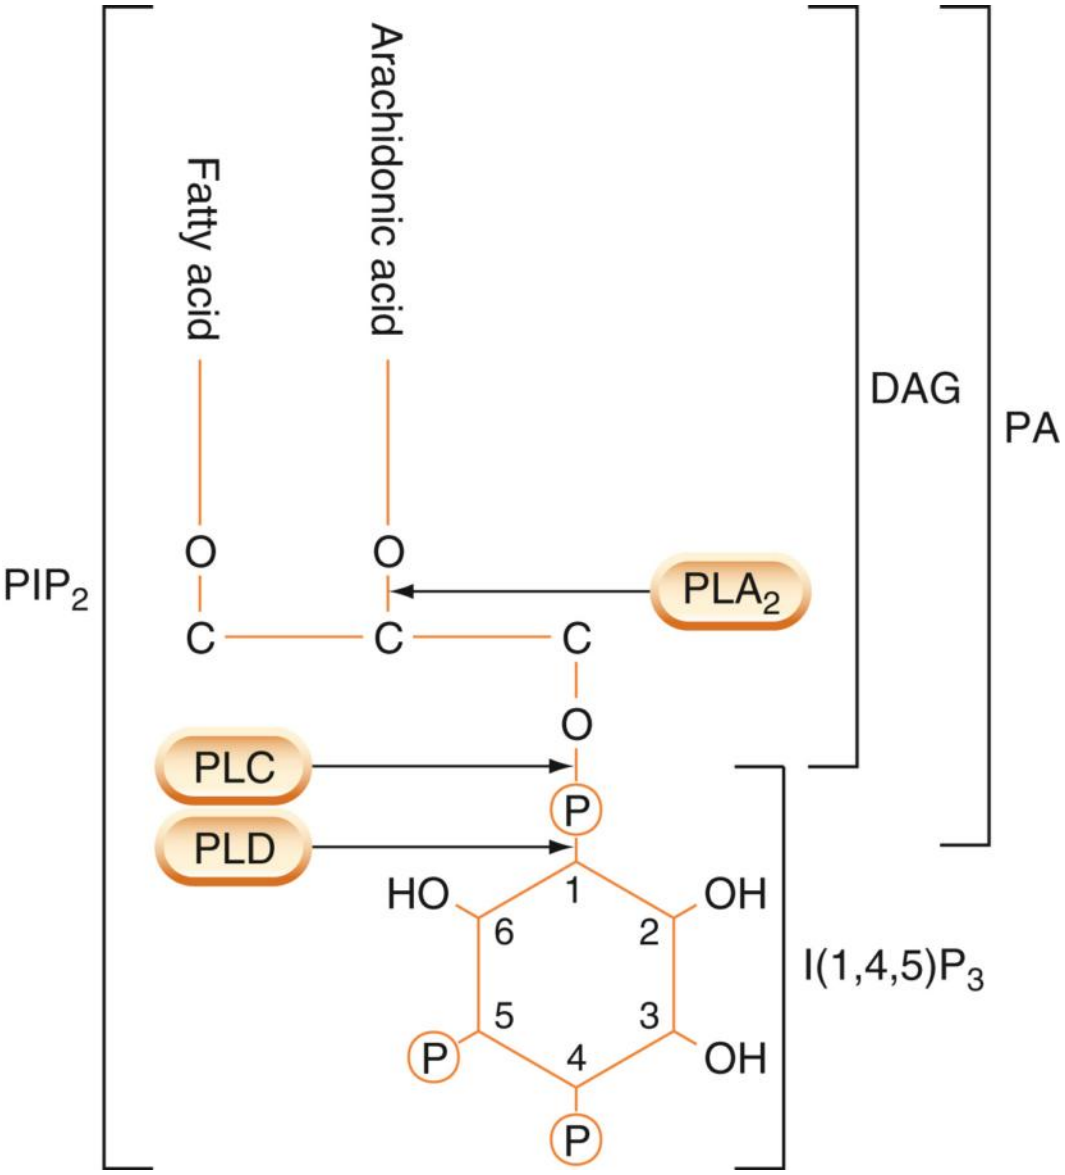

FIG. 3.12 Structure of phosphatidylinositol bisphosphate (PIP_2), showing sites of cleavage by different phospholipases to produce active mediators.Cleavage by phospholipase A2 (PLA_2) yields arachidonic acid. Cleavage by phospholipase C (PLC) yields inositol trisphosphate ($I(1,4,5)P_3$) and diacylglycerol (DAG). *PA,* Phosphatidic acid; *PLD,* phospholipase D.

Inositol phosphates and intracellular calcium

Inositol (1,4,5) trisphosphate (IP_3) is a water-soluble mediator that is released into the cytosol and acts on a specific receptor – the IP_3 receptor – which is a ligand-gated calcium channel present on the membrane of the endoplasmic reticulum (see **Figs 3.5** and **4.1**). The main role of IP_3, described in more detail in **Chapter 4**, is to control the release of Ca^{2+} from intracellular stores. Because many drug and hormone effects involve intracellular Ca^{2+}, this pathway is particularly important.

DAG and protein kinase C

DAG is produced, as well as IP_3, whenever receptor-induced PI hydrolysis occurs. The main effect of DAG is to activate a protein kinase, *protein kinase C* (PKC), which catalyses the phosphorylation of several intracellular proteins. DAG, unlike the inositol phosphates, is highly lipophilic and remains within the membrane. It binds to a specific site on the PKC molecule, causing the enzyme to migrate from the cytosol to the cell membrane, thereby becoming activated. There are at least 10 different mammalian PKC subtypes, which have distinct cellular distributions and phosphorylate different proteins. Several are activated by DAG and raised intracellular Ca^{2+}, both of which are produced by activation of GPCRs. [16] PKCs are also activated by *phorbol esters* (highly irritant, tumour-promoting compounds produced by certain plants), which have been extremely useful in studying the functions of PKC. One of the subtypes is activated by the lipid mediator *arachidonic acid* (see **Ch. 17**) generated by the action of phospholipase A_2 on membrane phospholipids, so PKC activation can also occur with agonists that activate this enzyme. The various PKC isoforms, like the tyrosine kinases discussed later, act on many different functional proteins, such as ion channels, receptors, enzymes (including other kinases), transcription factors and cytoskeletal proteins. Protein phosphorylation by kinases plays a central role in signal transduction and controls many different aspects of cell function. The

DAG–PKC link provides a mechanism whereby GPCRs can mobilise this army of control freaks.

Ion channels as targets for G proteins

Another major function of GPCRs is to control ion channel function directly by mechanisms that do not involve second messengers such as cAMP or inositol phosphates. Direct G protein–channel interaction, through the βγ subunits of G_i and G_o proteins, appears to be a general mechanism for controlling K^+ and Ca^{2+} channels. In cardiac muscle, for example, mAChRs enhance K^+ permeability in this way (thus hyperpolarising the cells and inhibiting electrical activity; see **Ch. 20**). Similar mechanisms operate in neurons, where many inhibitory drugs, such as opioid analgesics, reduce excitability by opening certain K^+ channels – known as G protein-activated inwardly rectifying K^+ channels (GIRK) – or by inhibiting voltage-activated N and P/Q type Ca^{2+} channels, thus reducing neurotransmitter release (see Chs **4** and **43**).

The Rho/Rho kinase system

The Rho/Rho kinase signalling pathway consists of three small GTPases – Rho A, B and C – that can activate downstream kinases, Rho kinase 1 and 2 (sometimes referred to as ROCK 1 and ROCK 2 – ROCK being an acronym for *Rho-associated coiled-coil containing protein kinase*) (see **Porazinski et al., 2020**). Rho A can be activated by certain GPCRs (and also by non-GPCR mechanisms), which couple to G proteins of the $G_{12/13}$ type. The free G protein α subunit interacts with a *guanosine nucleotide exchange factor*, which facilitates GDP–GTP exchange at another GTPase, Rho. Rho–GDP, the resting form, is inactive, but when GDP–GTP exchange occurs, Rho are activated, and in turn activate Rho kinases. Rho kinases phosphorylate many substrate proteins and control a wide variety of cellular functions, including smooth muscle contraction and proliferation, cell movement and migration, angiogenesis and synaptic remodelling.

They have been implicated in numerous disease states including glaucoma (see **Ch. 27**), cardiovascular disease (see Chs **20** and **21**), neurodegenerative disorders (see **Ch. 40**) and cancer (see **Ch. 57**). Rho kinase inhibitors (e.g. **fasudil**, **netarsudil**) have been developed and are used clinically in some countries for the treatment of glaucoma and cognitive decline following stroke. Their progress in clinical trials to determine their efficacy in the treatment of pulmonary hypertension seems to have stalled.

The MAP kinase system

The MAP kinase system involves several signal transduction pathways (**Fig. 3.15**) that are activated not only by various cytokines and growth factors acting on kinase-linked receptors (**Fig. 3.17**), but also by ligands activating GPCRs. The coupling of GPCRs to different families of MAP kinases can involve G protein α and βγ subunits as well as *Src* and *arrestins* – proteins also involved in GPCR desensitisation. The MAP kinase system controls many processes involved in gene expression, cell division, apoptosis and tissue regeneration.

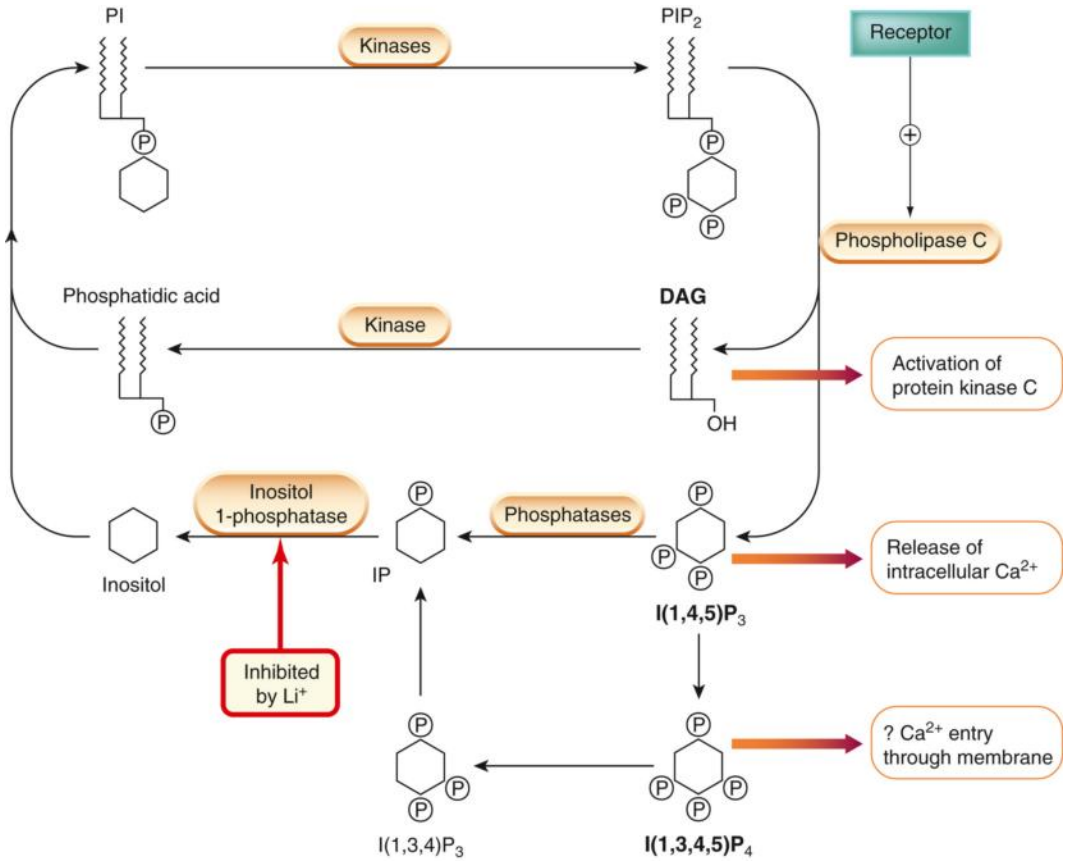

FIG. 3.13 The phosphatidylinositol (PI) cycle.Receptor-mediated activation of phospholipase C results in the cleavage of phosphatidylinositol bisphosphate (PIP_2), forming diacylglycerol (DAG) (which activates protein kinase C) and inositol trisphosphate (IP_3) (which releases intracellular Ca^{2+}). The role of inositol tetraphosphate (IP_4), which is formed from IP_3 and other inositol phosphates, is unclear, but it may facilitate Ca^{2+} entry through the plasma membrane. IP_3 is inactivated by dephosphorylation to inositol. DAG is converted to phosphatidic acid, and these two products are used to regenerate PI and PIP_2.

Effectors controlled by G proteins

GPCRs couple through G proteins to second messenger pathways and ion channels:

- Adenylyl cyclase/cAMP:
  - can be activated or inhibited by pharmacological ligands, depending on the nature of the receptor and G protein;
  - adenylyl cyclase catalyses formation of the intracellular messenger cAMP;
  - cAMP activates protein kinases such as PKA that control cell function in many different ways by causing phosphorylation of various enzymes, carriers and other proteins.
- Phospholipase C/inositol trisphosphate (IP_3)/DAG:
  - catalyses the formation of two intracellular messengers, IP_3 and DAG, from membrane phospholipid;
  - IP_3 acts to increase free cytosolic Ca^{2+} by releasing Ca^{2+} from intracellular compartments
  - increased free Ca^{2+} initiates many events, including contraction, secretion, enzyme activation and membrane hyperpolarisation;
  - DAG activates various PKC isoforms, which control many cellular functions by phosphorylating a variety of proteins.
- Ion channels:
  - opening potassium channels (GIRKs), resulting in membrane hyperpolarisation;
  - inhibiting voltage-activated calcium channels, thus reducing neurotransmitter release.
- Phospholipase A_2 (and thus the formation of arachidonic acid and eicosanoids).

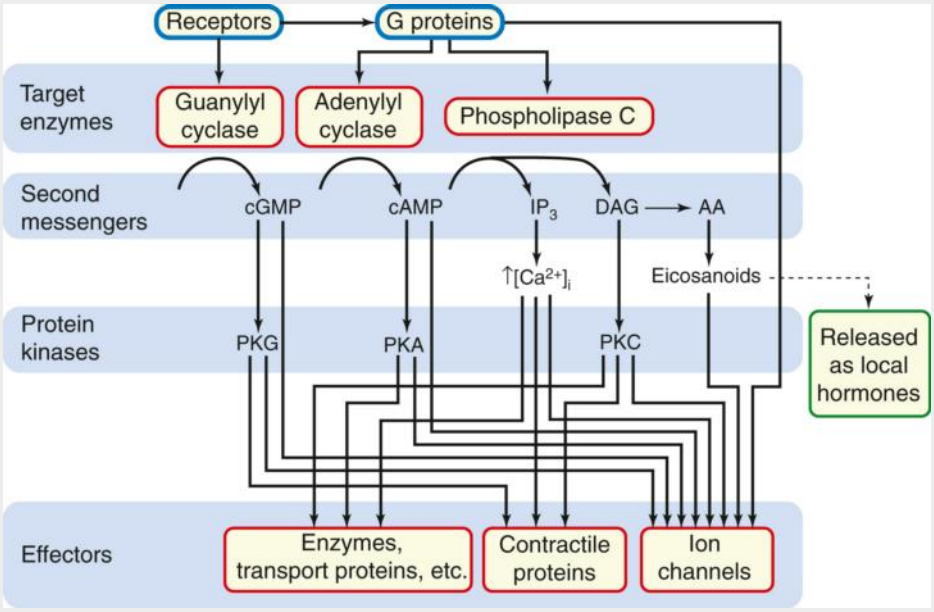

FIG. 3.14 G protein and second messenger control of cellular effector systems.Not shown in this diagram are signalling pathways where arrestins, rather than G proteins, link G protein–coupled receptors to downstream events (see text and **Fig. 3.15**). *AA,* Arachidonic acid; *DAG,* diacylglycerol; *IP* $_3$, inositol trisphosphate; *PKA,* protein kinase A; *PKC,* protein kinase C; *PKG,* cGMP-dependent protein kinase.

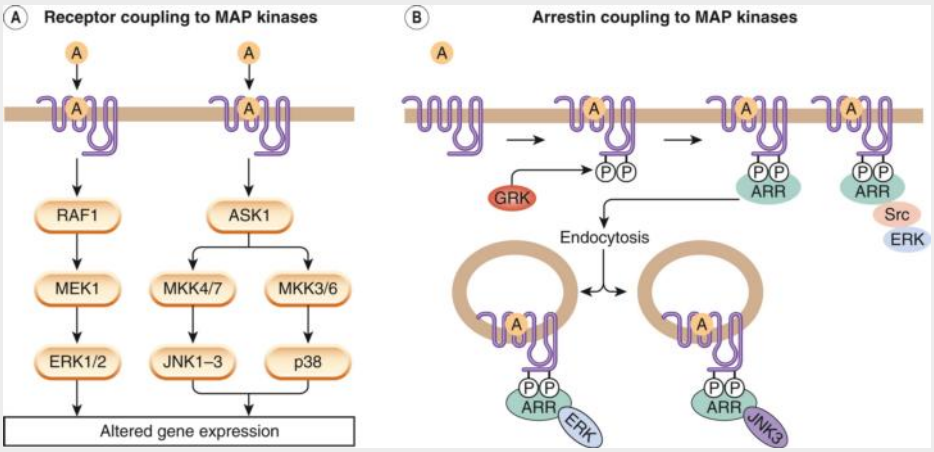

FIG. 3.15 G protein–coupled receptor (GPCR) activation of mitogen-activated protein (MAP) kinase cascade.(A) Sequential activation of the multiple components of the MAP kinase cascade. GPCR activation of MAP kinases can involve Gα and βγ subunits (not shown). (B) Activation of ERK and JNK3 through interaction with arrestins (βARR). Activation of ERK can occur either at the plasma membrane involving Src or by direct activation after internalisation of the receptor/arrestin complex. *ARR,* Arrestin; *GRK,* G protein–coupled receptor kinase.

The main postulated roles of GPCRs in controlling enzymes and ion channels are summarised in **Fig. 3.14**.

Further Developments in GPCR Biology

By the early 1990s, we thought we had more or less got the measure of GPCR function, as described previously. Since then, the plot has thickened, and further developments have necessitated a substantial overhaul of the basic model.

GPCR desensitisation

As described in **Chapter 2**, desensitisation is a feature of most GPCRs, and the mechanisms underlying it have been extensively studied. *Homologous desensitisation* is restricted to the receptors activated by the desensitising agonist, while *heterologous desensitisation* affects other GPCRs in addition. Two main processes are involved (see **Kelly et al., 2008**):

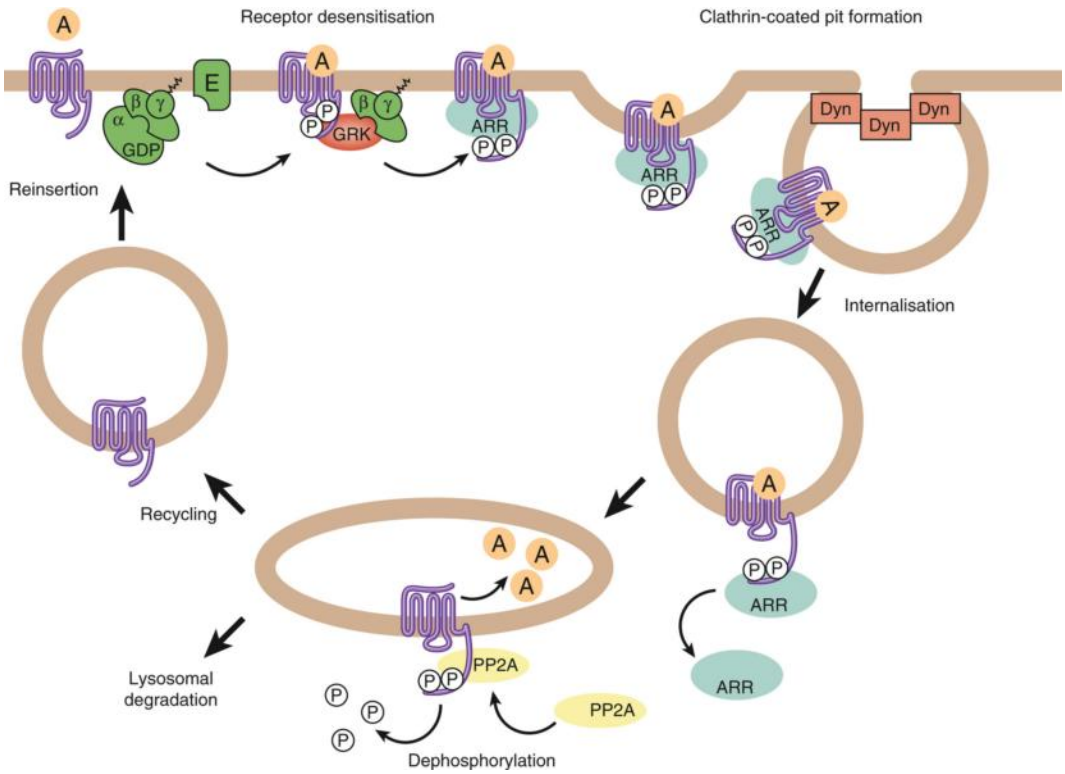

FIG. 3.16 Desensitisation and trafficking of G protein–coupled receptors (GPCRs).On prolonged agonist activation of the GPCR, selective GPCR kinases (GRKs) are recruited to the plasma membrane and phosphorylate the receptor. Arrestin (ARR) then binds and traffics the GPCR to clathrin-coated pits for subsequent internalisation into endosomes in a dynamin-dependent process. The GPCR is then dephosphorylated by a phosphatase (PP2A) and either recycled back to the plasma membrane or trafficked to lysosomes for degradation. *Dyn,* Dynamin; *GRK,* G protein–coupled receptor kinase; *PP2A,* phosphatase 2A.

- receptor phosphorylation
- receptor internalisation (endocytosis)

The sequence of GPCRs includes certain residues (serine and threonine), mainly in the C-terminal cytoplasmic tail, which can be phosphorylated by specific GPCR kinases (GRKs) and by kinases such as PKA and PKC.

On receptor activation GRK2 and GRK3 are recruited to the plasma membrane by binding to free G protein βγ subunits. GRKs then phosphorylate the receptors in their activated (i.e. agonist-bound) state. The phosphorylated receptor serves as a binding site for arrestins, intracellular proteins that block the interaction between the receptor and the G proteins producing a selective *homologous desensitisation*. Arrestin binding also targets the receptor for endocytosis in clathrin-coated pits (**Fig. 3.16**). The internalised receptor can then either be dephosphorylated and reinserted into the plasma membrane (*resensitisation*) or trafficked to lysosomes for degradation (*inactivation*). This type of desensitisation seems to occur with most GPCRs but with subtle differences that fascinate the aficionados.

Phosphorylation by PKA and PKC at residues different from those targeted by GRKs generally leads to impaired coupling between the activated receptor and the G protein, so the agonist effect is reduced. This can give rise to either homologous or heterologous desensitisation, depending on whether or not receptors other than that for the desensitising agonist are simultaneously phosphorylated by the kinases, some of which are not very selective. Receptors phosphorylated by second messenger kinases are probably not internalised and are reactivated by dephosphorylation by phosphatases when the agonist is removed.

GPCR oligomerisation

The earlier view that GPCRs exist and function as monomeric proteins (in contrast to ion channels, which generally comprise multimeric complexes) was first overturned by work on the $GABA_B$ receptor. Two subtypes of this GPCR exist, encoded by different genes, and the functional receptor

consists of a heterodimer of the two (see **Ch. 38**). A similar situation arises with G protein–coupled glutamate receptors. Oddly, although the $GABA_B$ dimer has two potential agonist binding sites, one on each subunit, only one is functional and signalling is transmitted through the dimer to the other receptor in the dimer which couples to the G protein (see **Fig. 39.9**).

Other GPCRs are functional as monomers but it now seems likely that most, if not all, GPCRs can exist as either homomeric or heteromeric oligomers (i.e. dimers or larger oligomers) (**Ferré et al., 2015**). Within the opioid receptor family (see **Ch. 43**), the μ receptor was crystallised as a dimer, and stable and functional heterodimers of κ and δ receptors, whose pharmacological properties differ from those of either parent, have been created in cell lines. More diverse GPCR combinations have also been found, such as that between dopamine (D_2) and somatostatin receptors, on which both ligands act with increased potency. Roaming even further afield in search of functional assignations, the dopamine receptor D_5 can couple directly with a ligand-gated ion channel, the $GABA_A$ receptor, inhibiting the function of the latter without the intervention of any G protein (**Liu et al., 2000**). These interactions have so far been studied mainly in engineered cell lines, but they also occur in native cells. Functional dimeric complexes between angiotensin (AT_1) and bradykinin (B_2) receptors occur in human platelets and show greater sensitivity to angiotensin than 'pure' AT_1 receptors (**AbdAlla et al., 2001**). In women suffering from pregnancy-related hypertension (pre-eclamptic toxaemia), the number of these dimers increases due to increased expression of B_2 receptors, resulting – paradoxically – in increased sensitivity to the vasoconstrictor action of angiotensin.

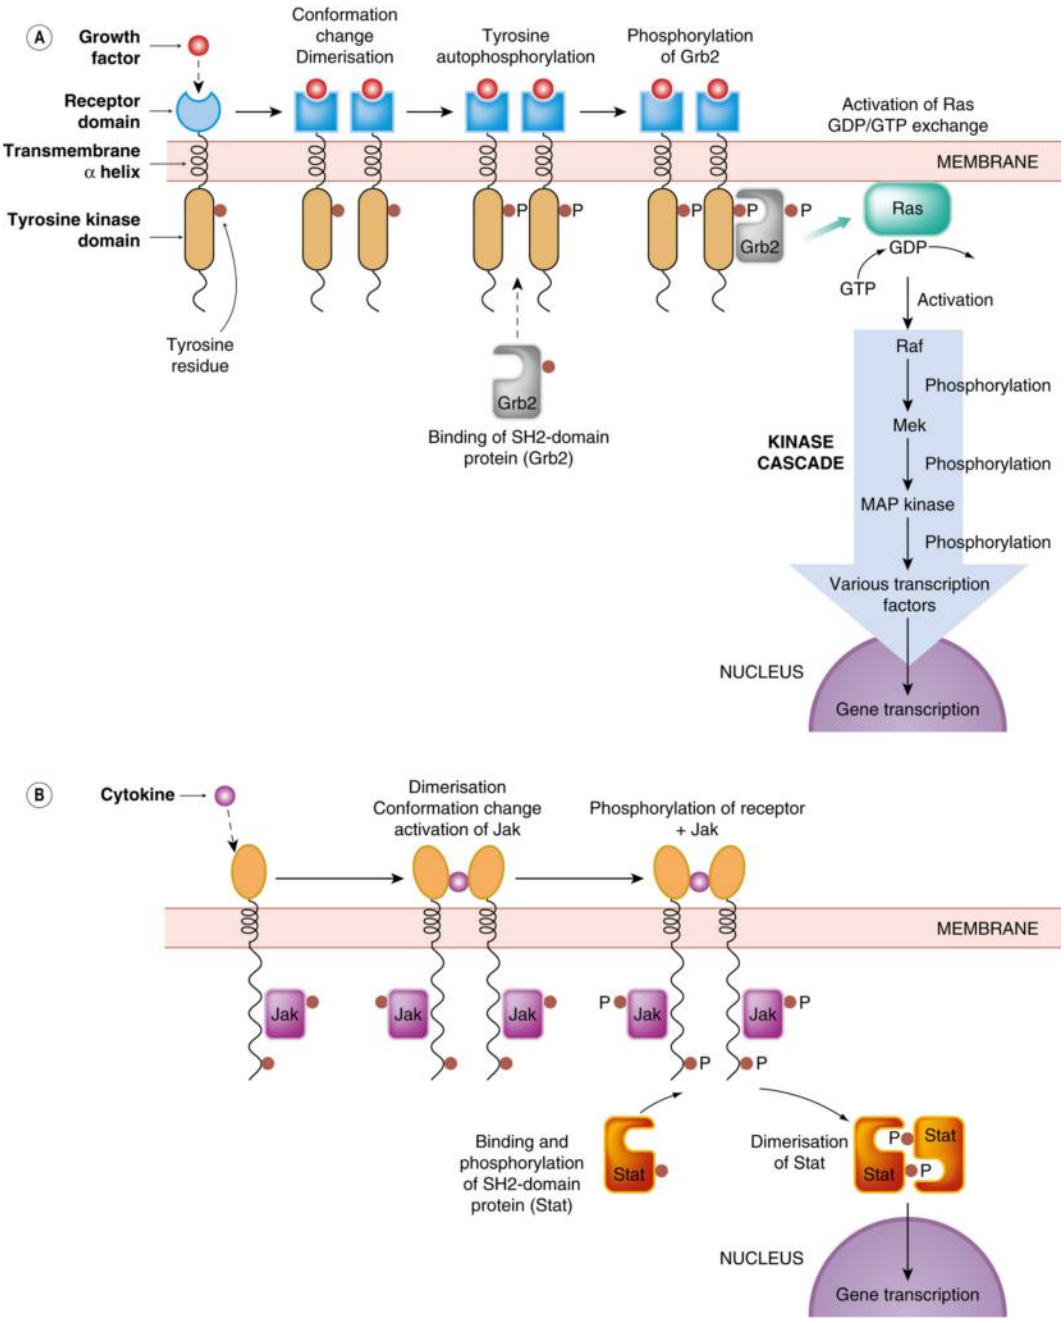

FIG. 3.17 Transduction mechanisms of kinase-linked receptors.The first step following agonist binding is dimerisation, which leads to autophosphorylation of the intracellular domain of each receptor. SH2-domain proteins then bind to the phosphorylated receptor and are themselves phosphorylated. Two well-characterised pathways are shown: (A) the growth factor

(Ras/Raf/mitogen-activated protein [MAP] kinase) pathway (see also **Ch. 6**). Grb2 can also be phosphorylated but this negatively regulates its signalling. (B) Simplified scheme of the cytokine (Jak/Stat) pathway (see also **Ch. 57**). Some cytokine receptors may pre-exist as dimers rather than dimerise on cytokine binding. Several other pathways exist, and these phosphorylation cascades interact with components of G protein systems.

Constitutively active receptors

GPCRs may be constitutively (i.e. spontaneously) active in the absence of any agonist (see **Ch. 2** and review by **Costa and Cotecchia, 2005**). This was first shown for δ opioid receptors (see **Ch. 43**). There are now many other examples of native GPCRs that show constitutive activity when studied in vitro. The histamine H_3 receptor also shows constitutive activity in vivo, and this may prove to be a quite general phenomenon. It means that inverse agonists (see **Ch. 2**), which suppress this basal activity, may exert effects distinct from those of neutral antagonists, which block agonist effects without affecting basal activity.

Agonist specificity

It was thought that the linkage of a particular GPCR to a particular signal transduction pathway depends mainly on the structure of the receptor, which confers specificity for a particular G protein, from which the rest of the signal transduction pathway follows. This would imply, in line with the two-state model discussed in **Chapter 2**, that all agonists acting on a particular receptor stabilise the same activated (R*) state and should activate the same signal transduction pathway, and produce the same type of cellular response. It is now clear that this is an oversimplification. In many cases, for example, with agonists acting on angiotensin receptors, or

with inverse agonists on β adrenoceptors, the cellular effects are qualitatively different with different ligands, implying the existence of more than one – probably many – R* states (sometimes referred to as *biased agonism*; see **Ch. 2**). Binding of arrestins to GPCRs initiates MAP kinase signalling, such that agonists that induce GRK/arrestin 'desensitisation' will terminate some GPCR signalling but may also activate signalling through arrestins that may continue even after the receptor/arrestin complex has been internalised (see **Fig. 3.15**).

Biased agonism has profound implications – indeed heretical to many pharmacologists, who are accustomed to thinking of agonists in terms of their affinity and efficacy, and nothing else; it has added a new dimension to the way in which we think about drug efficacy and specificity (see **Kenakin and Christopoulos, 2013**).

Receptor activity-modifying proteins

Receptor activity-modifying proteins (RAMPs) are a family of membrane proteins that associate with some GPCRs and alter their functional characteristics. They were discovered in 1998 when it was found that the functionally active receptor for the neuropeptide *calcitonin gene-related peptide* (CGRP) (see Chs **16** and **19**) consisted of a complex of a GPCR – called calcitonin receptor-like receptor (CRLR) – that by itself lacked activity, with another membrane protein (RAMP1). More surprisingly, CRLR when coupled with another RAMP (RAMP2) showed a quite different pharmacology, being activated by an unrelated peptide, *adrenomedulin*. In other words, the agonist specificity is conferred by the associated RAMP as well as by the GPCR itself. More RAMPs have emerged, and so far nearly all the examples involve Class B peptide receptors (see **Table 3.2**), the calcium-sensing receptor being an exception. RAMPs are an example of how protein–protein interactions influence the pharmacological behaviour of the receptors in a highly

selective way and may be novel targets for drug development (**Hay and Pioszak, 2015**).

G protein–independent signalling

In using the term *G protein–coupled receptor* to describe the class of receptors characterised by their heptahelical structure, we are following conventional textbook dogma but neglecting the fact that G proteins are not the only link between GPCRs and the various effector systems that they regulate. In this context, signalling mediated through arrestins bound to the receptor, rather than through G proteins, is important (see review by **Lefkowitz, 2013**). Arrestins can act as an intermediary for GPCR activation of the MAP kinase cascade (see **Fig. 3.15B**).

There are many examples where the various 'adapter proteins' that link receptors of the tyrosine kinase type to their effectors can also interact with GPCRs (see **Brzostowski and Kimmel, 2001**), allowing the same effector systems to be regulated by receptors of either type.

In summary, the simple dogma that has underpinned much of our understanding of GPCRs, namely, one GPCR gene – one GPCR protein – one functional GPCR – one G protein – one response, is showing distinct signs of wear. In particular:

- one gene, through alternative splicing, RNA editing, etc., can give rise to more than one receptor protein;
- one GPCR protein can associate with others, or with other proteins such as RAMPs, to produce more than one type of functional receptor;
- different agonists may affect a receptor in different ways and elicit qualitatively different responses;
- the signal transduction pathway from 'GPCR' does not invariably require G proteins, and there can be cross-talk with tyrosine kinase-linked receptors.

GPCRs are evidently versatile and adventurous molecules around which much modern pharmacology revolves, and nobody imagines that we have reached the end of the story.

Type 3: Kinase-Linked and Related Receptors

These membrane receptors are quite different in structure and function from ligand-gated channels and GPCRs. They are activated by a wide variety of protein mediators, including growth factors and cytokines (see **Ch. 19**), and hormones such as insulin (see **Ch. 31**) and leptin (see **Ch. 32**), whose effects are exerted mainly at the level of gene transcription. Most of these receptors are large proteins consisting of a single chain of up to 1000 residues, with a single membrane-spanning helical region, linking a large extracellular ligand-binding domain to an intracellular domain of variable size and function. The basic structure is shown in **Fig. 3.3C**, but many variants exist (see later). Over 100 such receptors have been cloned, and many structural variations exist. For more detail, see the review by **Hubbard and Miller (2007)**. Examples of the related (indirect) kinase-linked receptor types include cytokine receptors (e.g. tumour necrosis factor [TNF] receptors) and pattern recognition receptors (PRRs) that recognise pathogen-associated molecular patterns (PAMPs) or danger-associated molecular patterns (DAMPs) found in pathogens, which stimulate the innate immune system host defence network (see **Ch. 7**). PRR receptors include the cell surface Toll-like receptors (TLRs), and the cytoplasmic receptors such as RIG-I-like receptors (RLRs) and NOD-like receptors (NLRs). All these immune receptors signal their intracellular effects through adaptor proteins and kinases to alter the cell's transcription to elicit the correct immune response needed to fight against any pathogenic invaders. All these receptors play a major role in controlling cell division, intermediary metabolism, growth, differentiation, inflammation, tissue repair, apoptosis and immune responses, discussed further in **Chapters 6** and 19.

The main types are as follows:

Receptor tyrosine kinases (RTKs)

These receptors have the basic structure shown in **Fig. 3.17A**, incorporating a tyrosine kinase moiety in the intracellular region. They include receptors for many growth factors, such as **epidermal growth factor** and **nerve growth factor**, and also the group of *TLRs* that recognise bacterial lipopolysaccharides and play an important role in the body's reaction to infection (see **Ch. 7**). The insulin receptor (see **Ch. 31**) also belongs to the RTK class, although it has a more complex dimeric structure, and links indirectly to intracellular tyrosine kinases.

Receptor serine/threonine kinases

This smaller class is similar in structure to RTKs but they phosphorylate serine and/or threonine residues rather than tyrosine. The main example is the receptor for **transforming growth factor** (TGF).

Cytokine receptors

These receptors (**Fig. 3.17B**) lack intrinsic enzyme activity. When occupied, they activate various tyrosine kinases, such as Jak (the Janus kinase). Ligands for these receptors include cytokines such as **interferons** and **colony-stimulating factors** involved in immunological responses as well as cell growth and differentiation.

Kinase-linked receptors

- Receptors for various growth factors incorporate tyrosine kinase in their intracellular domain.
- Cytokine receptors have an intracellular domain that binds and activates cytosolic kinases when the receptor is occupied.

- The receptors all share a common architecture, with a large extracellular ligand-binding domain connected via a single membrane-spanning helix to the intracellular domain.
- Signal transduction generally involves dimerisation of receptors, followed by autophosphorylation of tyrosine residues. The phosphotyrosine residues act as acceptors for the SH2 domains of a variety of intracellular proteins, thereby allowing control of many cell functions.
- They are involved mainly in events controlling cell growth and differentiation, and act indirectly by regulating gene transcription.
- Two important pathways are:
  - the Ras/Raf/MAP kinase pathway, which is important in cell division, growth and differentiation;
  - the Jak/Stat pathway activated by many cytokines, which controls the synthesis and release of many inflammatory mediators.

Protein Phosphorylation and Kinase Cascade Mechanisms

Protein phosphorylation (see **Cohen, 2002**) is a key mechanism for controlling the function of proteins (e.g. enzymes, ion channels, receptors, transport proteins) involved in regulating cellular processes. Phosphorylation and dephosphorylation are accomplished by *kinases* and *phosphatases*, respectively – enzymes, of which several hundred subtypes are represented in the human genome – which are themselves subject to regulation dependent on their phosphorylation status. Much effort is currently being invested in mapping the complex interactions between signalling molecules that are involved in drug effects and pathophysiological processes such as oncogenesis, neurodegeneration, inflammation and much else. Here we can present only a few

pharmacologically relevant aspects of what has become an enormous subject.

In many cases, ligand binding to the receptor leads to dimerisation. The association of the two intracellular kinase domains allows a mutual autophosphorylation of intracellular tyrosine residues to occur. The phosphorylated tyrosine residues then serve as high-affinity docking sites for other intracellular proteins that form the next stage in the signal transduction cascade. One important group of such proteins is known as the *SH2 domain proteins* (standing for *Src* homology, because they were first identified in the *Src* oncogene product). [17] These possess a highly conserved sequence of about 100 amino acids, forming a recognition site for the phosphotyrosine residues of the receptor. Individual SH2 domain proteins, of which many are now known, bind selectively to particular receptors, so the pattern of events triggered by particular growth factors is highly specific. The mechanism is summarised in **Fig. 3.17**.

What happens when the SH2 domain protein binds to the phosphorylated receptor varies greatly according to the receptor that is involved; many SH2 domain proteins are enzymes, such as protein kinases or phospholipases. Some growth factors activate a specific subtype of phospholipase C (PLCγ), thereby causing phospholipid breakdown, IP_3 formation and Ca^{2+} release. Other SH2-containing proteins couple phosphotyrosine-containing proteins with a variety of other functional proteins, including many that are involved in the control of cell division and differentiation. The end result is to activate or inhibit, by phosphorylation, a variety of transcription factors that migrate to the nucleus and suppress or induce the expression of particular genes. For more detail, see **Jin and Pawson (2012)**. *Nuclear factor kappa B* (NF-κB) is a transcription factor that plays a key role in multiple disorders including inflammation and cancer (see Chs **18** and **57**; **Karin et al., 2004**). It is normally present in the cytosol, complexed with an inhibitor (I-κB). Phosphorylation of I-κB occurs when a specific kinase (IKK) is

activated in response to various inflammatory cytokines and GPCR agonists. This results in dissociation of I-κB from NF-κB and migration of NF-κB to the nucleus, where it switches on various proinflammatory and anti-apoptotic genes.

Two well-defined signal transduction pathways are summarised in **Fig. 3.17**. The Ras/Raf pathway mediates the effect of many growth factors and mitogens. Ras, which is a proto-oncogene product, functions like a G protein, and conveys the signal (by GDP/GTP exchange) from the SH2-domain protein, Grb. Activation of Ras in turn activates Raf, which is the first of a sequence of three serine/threonine kinases, each of which phosphorylates, and activates, the next in line. The last of these, MAP kinase (which is also activated by GPCRs, see earlier), phosphorylates one or more transcription factors that initiate gene expression, resulting in a variety of cellular responses, including cell division. This three-tiered MAP kinase cascade forms part of many intracellular signalling pathways involved in a wide variety of disease processes, including malignancy, inflammation, neurodegeneration, atherosclerosis and much else. The kinases form a large family, with different subtypes serving specific roles. They are thought to represent an important target for future therapeutic drugs. Many cancers are associated with mutations in the genes coding for proteins involved in this cascade, leading to activation of the cascade in the absence of the growth factor signal (see Chs **6** and **57**). For more details, see the review by **Avruch (2007)**.

A second pathway, the Jak/Stat pathway (see **Fig. 3.17B**), is involved in responses to many cytokines. Dimerisation of these receptors occurs when the cytokine binds, and this attracts a cytosolic tyrosine kinase unit (Jak) to associate with, and phosphorylate, the receptor dimer. Jaks belong to a family of proteins, different members having specificity for different cytokine receptors. Among the targets for phosphorylation by Jak are a family of transcription factors (Stats). These are SH2-domain proteins that bind to the phosphotyrosine groups on the receptor–Jak complex, and are

themselves phosphorylated. Thus activated, Stat migrates to the nucleus and activates gene expression.

Other important mechanisms centre on *phosphatidylinositol-3 kinase* (PI_3 kinases; see **Vanhaesebroeck et al., 1997**), a ubiquitous enzyme family that is activated both by GPCRs and RTKs and attaches a phosphate group to position 3 of PIP_2 to form PIP_3. Other protein kinases, particularly protein kinase B (PKB, [18] also known as Akt), have recognition sites for PIP_3 and are thus activated, controlling a wide variety of cellular functions, including apoptosis, differentiation, proliferation and trafficking. Akt also causes NO synthase activation in the vascular endothelium (see **Ch. 21**).

Recent work on signal transduction pathways has produced a bewildering profusion of molecular detail, often couched in a jargon that is apt to deter the faint-hearted. Perseverance will be rewarded, however, for there is no doubt that important new drugs, particularly in the areas of inflammation, immunology and cancer, will come from the targeting of these proteins (**Wilson et al., 2018**). A breakthrough in the treatment of chronic myeloid leukaemia was achieved with the introduction of the first explicitly designed kinase inhibitor, **imatinib**, a drug that inhibits a specific tyrosine kinase involved in the pathogenesis of the disease (see **Ch. 57**).

Fig. 3.18 illustrates the central role of protein kinases in signal transduction pathways in a highly simplified and schematic way. Many, if not all, of the proteins involved, including the receptors and the kinases themselves, are substrates for kinases, so there are many mechanisms for feedback and cross-talk between the various signalling pathways. Given that there are over 500 protein kinases, and similarly large numbers of receptors and other signalling molecules, the network of interactions can look bewilderingly complex. Dissecting out the details has become a major theme in cell biology. For pharmacologists, the idea of a simple connection between receptor and response, which guided thinking throughout the

20th century, is undoubtedly crumbling, although it will take some time before the complexities of signalling pathways are assimilated into a new way of thinking about drug action.

Protein phosphorylation in signal transduction

- Many receptor-mediated events involve protein phosphorylation, which controls the functional and binding properties of intracellular proteins.
- Receptor-linked tyrosine kinases, cyclic nucleotide-activated tyrosine kinases and intracellular serine/threonine kinases comprise a 'kinase cascade' mechanism that leads to amplification of receptor-mediated events.
- There are many kinases, with differing substrate specificities, allowing specificity in the pathways activated by different hormones.
- Desensitisation of GPCRs occurs as a result of phosphorylation by specific receptor kinases, causing the receptor to become non-functional and to be internalised.
- There is a large family of phosphatases that act to dephosphorylate proteins and thus reverse the effects of kinases.

Type 4: Nuclear Receptors

By the 1970s, it was clear from experiments with radiolabelled tracers that receptors for steroid hormones such as oestrogen and the glucocorticoids (Chs **33** and **35**) were present in the cytoplasm of cells and translocated into the nucleus after binding with their steroid partner. Other hormones, such as the thyroid hormone T_3 (see **Ch. 34**) and the fat-soluble vitamins D and A (retinoic acid), were found to act in a similar fashion. In the mid-

1980s, the genes for oestrogen and glucocorticoid receptors were identified using the (then) relatively new molecular cloning techniques. Comparisons of gene and protein sequence data led to the recognition that these receptors were similar and in fact were members of a much larger family of some 50 related proteins. We now know these as the *nuclear receptor (NR) family*.

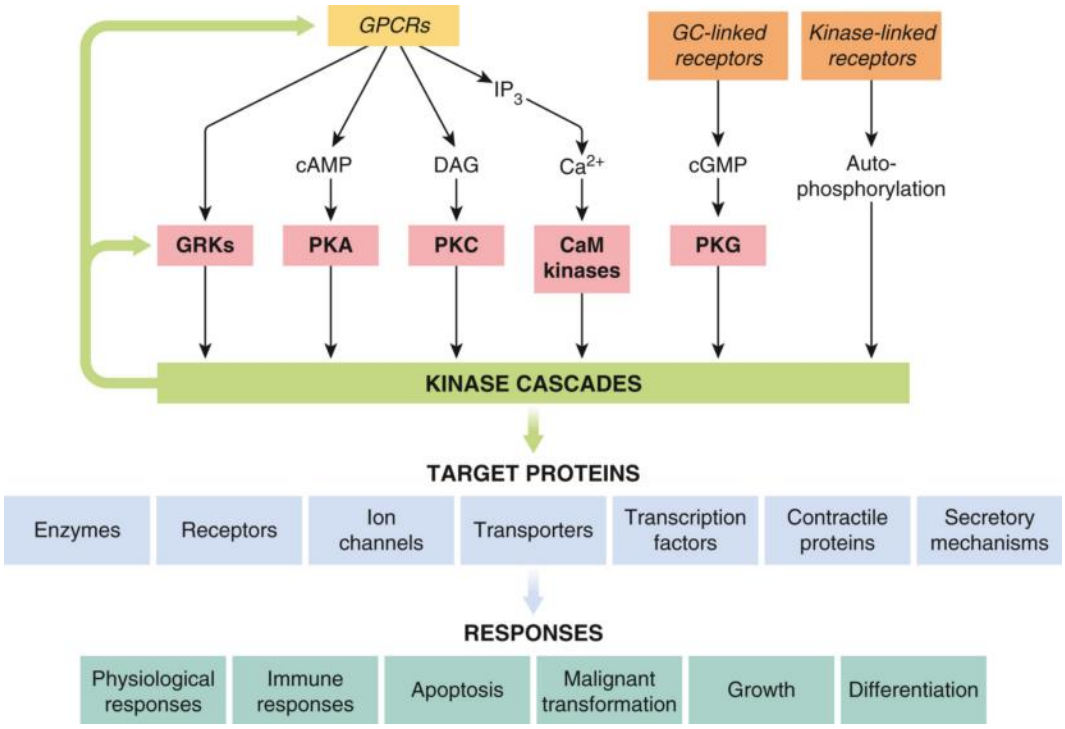

FIG. 3.18 Central role of kinase cascades in signal transduction.Kinase cascades (e.g. those shown in **Fig. 3.15**) are activated by G protein–coupled receptors (GPCRs), either directly or via different second messengers, by receptors that generate cGMP, or by kinase-linked receptors. The kinase cascades regulate various target proteins, which in turn produce a wide variety of short- and long-term effects. *CaM kinase,* Ca^{2+}/calmodulin-dependent kinase; *DAG,* diacylglycerol; *GC,* guanylyl cyclase; *GRK,* GPCR kinase; *IP* $_3$, inositol trisphosphate; *PKA,* cAMP-dependent protein kinase; *PKC,* protein kinase C; *PKG,* cGMP-dependent protein kinase.

The ligands for most endocrine receptors were, of course, already known but the NR family also comprised many (some 36) other *orphan receptors* – receptors with no known well-defined endogenous ligands. The first of these to be described, in the 1990s, was the *retinoid X receptor* (RXR),

which was cloned on the basis of its similarity with the vitamin A receptor and which was subsequently found to bind the vitamin A derivative 9-*cis*-retinoic acid (**Evans et al., 2014**). This event triggered intense interest in the NR field and, during the intervening years, specific binding partners have been characterised for at least 11 further NRs ('adopted orphans', e.g. RXR) were discovered, but the ligands for the remaining 25 'true orphans' have yet to be identified – or perhaps do not exist as such, as one possible function of these receptors is their 'promiscuous' ability to bind to many related compounds (such as dietary factors) with low affinity.

Whilst there are 48 known NRs in man, more proteins may arise through alternative splicing events. While this represents a rather small proportion of all receptors (less than 10% of the total number of GPCRs for example), the NRs are very important drug targets (**Burris et al., 2013**), being responsible for the biological effects of approximately 10%–15% of all prescription drugs. They can recognise an extraordinarily diverse group of substances (mostly small hydrophobic molecules), which may exhibit full or partial agonist, antagonist or inverse agonist activity. Many NRs which bind their ligands with high affinity (e.g. oestrogen receptor [ER] and glucocorticoid receptor [GR]) are involved predominantly in endocrine signalling, but many bind their ligands with low affinity and probably act as metabolic (e.g. lipid) sensors. They are thus crucial links between our dietary and metabolic status and the expression of genes that regulate the metabolism and disposition of lipids (**Goto, 2019**). NRs also regulate the expression of many drug-metabolising enzymes and transporters. Pregnane X (PXR) and *constitutive androstane receptor (CAR),* for example, are akin to airport security guards who alert the bomb disposal squad when suspicious luggage is found. When they sense foreign molecules (xenobiotics), they induce drug-metabolising enzymes such as CYP3A (which is responsible for metabolising about 60% of all prescription drugs; see **Ch. 10** and **di Masi et al., 2009**). They also bind

some prostaglandins and non-steroidal drugs, as well as the antidiabetic thiazolidinediones (see **Ch. 31**) and fibrates (see **Ch. 22**).

Classification of NRs

NRs are usually classified into subfamilies according to their phylogeny (see **Germain et al., 2006**). For our purposes, however, it is more useful to classify them on the basis of their molecular mechanism into two main classes (I and II) and two other minor groups of receptors (III, IV).

Class I consists largely of endocrine steroid receptors which normally act as homodimers. These include the GR (2 subtypes) and mineralocorticoid receptors (MRs), as well as the ERs (two subtypes), progesterone and androgen receptors (PR and AR, respectively). The hormones recognised by these receptors generally act in a negative feedback fashion to control biological events (see **Ch. 33** for more details). In the absence of their ligand, these NRs are predominantly located in the cytoplasm (although possibly reversibly attached to the cytoskeleton or other intracellular structures) complexed with 'chaperone' heat shock proteins (HSPs) and other 'co-chaperone' factors.

Unlike the receptors in class I, NRs in Class II almost always operate as heterodimers together with RXR, the retinoid X receptor. Two types of heterodimer may then be formed: a *non-permissive heterodimer*, which can be activated only by the RXR ligand itself, and the *permissive heterodimer*, which can be activated either by retinoic acid itself or by its partner's ligand. Class II NRs are generally bound to co-repressor proteins. These dissociate when the ligand binds and allows recruitment of co-activator proteins and hence changes in gene transcription. They tend to mediate positive feedback effects (e.g. occupation of the receptor amplifies rather than inhibits a particular biological event).

Class III NRs are very similar to Class I in the sense that they form homodimers, whereas Class IV NRs may function as monomers or dimers. Many of the remaining orphan receptors belong to these latter classes.

Structure of NRs

The NR superfamily probably evolved from a single distant evolutionary ancestral gene by duplication and other events. All NRs are monomeric proteins of 50–100 kDa, which share a broadly similar structural configuration as revealed by X-ray crystallography (see **Fig. 3.19** and **Bourguet et al., 2000**, for further details). Alternative splicing of genes may yield several receptor isoforms, each with slightly different N-terminal regions although in the case of the ER, each of the two subtypes is encoded by a different gene.

The *N-terminal domain* of the receptor family displays the most heterogeneity. It harbours a crucial *activation function 1 (AF1)* site which binds to other cell-specific transcription factors in a ligand-independent way and modifies the binding or regulatory capacity of the receptor itself. In the presence of the ligand, it synergises with a further activation sequence, *AF2,* to produce a fully active complex. The AF2 region is important in ligand-dependent activation and is generally highly conserved, although it is absent in *Rev-erbA*α and *Rev-erbA*β, NRs that regulate metabolism (and also function as part of a circadian molecular clock mechanism).

The *core domain* of the receptor is highly conserved and consists of the structure responsible for DNA recognition and binding. At the molecular level, this comprises two *zinc fingers* – cysteine- (or cystine-/histidine-) rich loops in the amino acid chain that are held in a particular conformation by zinc ions. The main function of this portion of the molecule is to bind to recognition elements located in the genes that are regulated by this family of receptors, but it also regulates NR receptor dimerisation. The highly flexible *hinge region* is crucial to this latter function of NRs but also regulates the intracellular trafficking of the receptor.

Finally, the *C-terminal domain* contains the *ligand-binding module.* This region is not well conserved amongst NRs (although it is structurally

similar) and is specific to each class of receptor, thereby enabling it to recognise its cognate ligands. It is also important in dimerisation and binding co-activator and co-repressor proteins. Also located near the C-terminal are motifs that contain *nuclear localisation signals* and others that may, in the case of some receptors, bind *accessory heat shock* and other proteins.

Control of Gene Transcription by NRs

Unlike the other receptors described in this chapter, NRs can interact with DNA directly, and may thus be regarded as *ligand-activated transcription factors* that produce their effects by modifying gene transcription. Through this mechanism they can control the transcription and expression of many genes and proteins so, as might be imagined, they are key players in regulating metabolic, developmental and other critical physiological processes.

Another characteristic property is that NRs are not generally embedded in membranes like GPCRs or ion channels (although there are important exceptions) but are present in other compartments of the cell. Some, such as the endocrine receptors, which are predominately located in the cytoplasm, are activated by their ligand and translocate from the cytoplasm to the nucleus, while others, such as the RXR, probably dwell mainly within the nuclear compartment. Having said this, there is increasing evidence for the existence of small pools of some NRs, such as ERs and GRs associated with the plasma membrane, in organelles such as the mitochondria (**Levin and Hammes, 2016**) and even in cells without nuclei such as platelets, where they can apparently regulate other targets such as protein kinases to bring about immediate biological actions (**Shaqura et al., 2016**).

To bring about changes in gene transcription, activated NRs bind to *hormone response elements* (HREs) in the genome. HREs are short (usually 4–6 base pairs) sequences of DNA which are generally present

symmetrically in pairs or *half-sites* with one half on each DNA strand. These typically comprise *inverted repeats* separated by three nucleotide bases, although there may different arrangements (e.g. *simple,* rather than inverted repeats). Each NR exhibits a preference for a particular *consensus sequence* and the nucleotide spacing between them, but because of the family homology, they all share a close similarity. Some NRs, particularly those in Class III, function as homodimers but they can bind to HREs, which do not have an inverted repeat sequence, whereas Class IV NRs may function as monomers or dimers but only bind to one HRE half site.

In the nucleus, the AF1 and AF2 domains of the ligand-bound receptor recruit large complexes of other proteins including *co-activators* or *co-repressors* to modify gene expression. Some of these co-activators are enzymes involved in chromatin remodelling, such as histone acetylase/deacetylase which, together with other enzymes, regulate the unravelling of the DNA to facilitate access by polymerase enzymes and hence gene transcription. Co-repressor complexes are recruited by some receptors and comprise histone deacetylase and other factors that cause the chromatin to become tightly packed, preventing further transcriptional activation. The case of the *CAR* (see later) is particularly interesting: like some G proteins described earlier in this chapter, CAR can adopt a constitutively active complex that is terminated when it binds its ligand. The mechanisms of negative gene regulation by NRs are particularly complex (see **Santos et al., 2011**, for a good account).

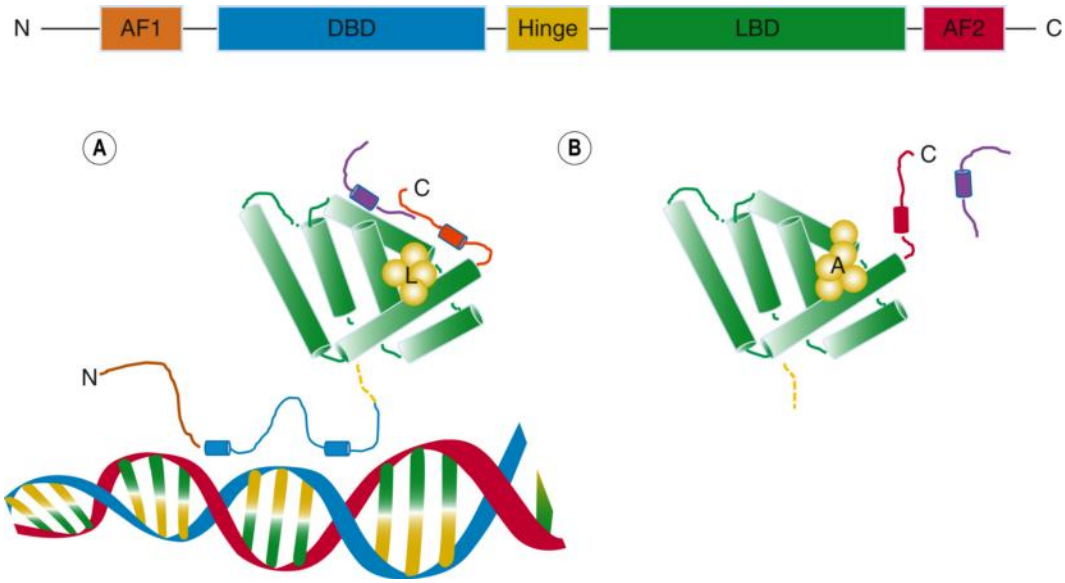

FIG. 3.19 Schematic diagram of a nuclear receptor.A greatly simplified diagram of the functional topology of a nuclear receptor (the oestrogen receptor is picked as an example). A schematic diagram shows the various regions of the receptor including the DNA-binding domain (DBD). *Below* is a diagram illustrating, in the corresponding colours, the configuration of the liganded receptor showing its binding to hormone response elements (HREs) on DNA. In panel A, the ligand (L) is bound in the ligand-binding domain (LBD) and this enables the C-terminal AF2 region to bind to the LBD. In turn, this allows the binding of a co-activator protein at the LBD (only a partial structure shown), which allows gene transcription to proceed. In panel B, an antagonist (A) is bound to the LBD. This sterically inhibits the binding of AF2 and thus the attachment of the co-activator protein. Most nuclear receptors operate as dimers but only a monomer is shown here for clarity. Cylindrical structures represent regions of α-helical protein structure. Based largely

upon Shiau, A.K., Barstad, D., Loria, P.M., et al., 1998. The structural basis of estrogen receptor/coactivator recognition and the antagonism of this interaction by tamoxifen. Cell 95, 927–937.

In addition to agonists, NRs can also be targeted by competitive antagonists, which prevent occupation of the binding site by the endogenous ligand or by inverse agonists (or antagonists), which sterically prevent the binding of co-activator factors, thus reducing the constitutive activity of these receptors. A very interesting development is the identification of selective receptor modulators (e.g. selective ER modulators – SERMs such as **tamoxifen**) which, by altering the binding of co-activator and co-repressor proteins, have agonist activity in some tissues and antagonist activities in others.

Regulation of NR Activity

Many NRs are subject to exquisite post-transcriptional and other regulation. The HSPs play a particularly important part in the functioning of the receptor with HSP90 being essential for GR function (for example) while HSP70 is inhibitory. The dynamic interplay between these HSPs is crucial for the cycling of GR between its active and inactive states (**Noddings et al., 2022**). Differential phosphorylation of GR also plays an important part in behaviour of the receptor with sites such as Ser^{211}, Ser^{203} and others being especially significant. For example, phosphorylation of the former residue is associated with receptor activation and nuclear localisation while phosphorylation of the latter has a down-regulatory influence (**Wang et al., 2002**). Receptor methylation may also be important (**Malbeteau et al., 2022**).

The NR Family in Health and Disease

Given the fact that the NR family of receptors plays a key part in the regulation and coordination of growth, development and organogenesis,

reproduction, the immune system and many other fundamental biological processes, it is not surprising that many illnesses are associated with malfunctioning of the NR system. Such conditions include inflammation, cancer, diabetes, cardiovascular disease, obesity and reproductive disorders (see **Kersten et al., 2000**; **Murphy and Holder, 2000**).

The discussion here must be taken only as a broad guide to the action of NRs, as many other types of interaction have also been discovered. For example, some of these receptors may bring about non-genomic – or even genomic – actions by directly interacting with factors in the cytosol, or they may be covalently modified by phosphorylation or by protein–protein interactions with other transcription factors such that their function is altered (see **Falkenstein et al., 2000**).

Table 3.4 summarises the properties of some common NRs of importance to pharmacologists.

Nuclear receptors

- In humans this protein family comprises 48 soluble intracellular receptors that sense lipid and hormonal signals and modulate gene transcription.
- Their ligands are many and varied, including steroid hormones and drugs, thyroid hormones, vitamins A and D, various lipids and xenobiotics.
- There are two main categories:
  - **Class I** NRs are present in the cytoplasm, form homodimers in the presence of their ligand and migrate to the nucleus. Their ligands are mainly endocrine in nature (e.g. steroid hormones);
  - **Class II** NRs are generally constitutively present in the nucleus and form heterodimers with the RXR. Their ligands are usually lipids (e.g. the fatty acids).

- The liganded receptor complexes initiate changes in gene transcription by binding to HREs in gene promoters and recruiting co-activator or co-repressor factors.
- The receptor family is the target of approximately 10% of prescription drugs, and the enzymes that it regulates affect the pharmacokinetics of some 60% of all prescription drugs.

Ion Channels as Drug Targets

We have discussed ligand-gated ion channels as one of the four main types of drug receptor. There are many other types of ion channel that represent important drug targets, even though they are not generally classified as 'receptors' because they are not the immediate targets of fast neurotransmitters, but drugs can act upon them to alter their ability to open and close. [19]

Table 3.4

Only examples from Classes I and II are included.

HRE, Hormone response element.

Here we discuss the structure and function of ion channels at the molecular level; their role as regulators of cell function is described in **Chapter 4**.

Ions are unable to penetrate the lipid bilayer of the cell membrane and can get across only with the help of membrane-spanning proteins in the form of channels or transporters. The concept of ion channels was developed in the 1950s on the basis of electrophysiological studies on the mechanism of membrane excitation (see **Ch. 4**). Electrophysiology, particularly the *voltage clamp technique*, remains an essential tool for studying the physiological and pharmacological properties of ion channels. Since the mid-1980s, when the first ion channels were cloned by Numa in

Japan, much has been learned about the structure and function of these complex molecules. The use of patch clamp recording, which allows the behaviour of individual channels to be studied in real time, has been particularly valuable in distinguishing channels on the basis of their conductance and gating characteristics. Accounts by **Ashcroft (2000)**, **Catterall (2000)** and **Hille (2001)** give background information.

Ion channels consist of protein molecules designed to form water-filled pores that span the membrane and can switch between open and closed states. The rate and direction of ion movement through the pore are governed by the electrochemical gradient for the ion in question, which is a function of its concentration on either side of the membrane and of the membrane potential. Ion channels are characterised by:

- their selectivity for particular ion species, determined by the size of the pore and the nature of its lining;
- their gating properties (i.e. the nature of the stimulus that controls the transition between open and closed states of the channel);
- their molecular architecture.

Ion Selectivity

Channels are generally either cation selective or anion selective. The main cation-selective channels are selective for Na^+, Ca^{2+} or K^+, or non-selective and permeable to all three. Anion channels are mainly permeable to Cl^-, although other types also occur. The effect of modulation of ion channels on cell function is discussed in **Chapter 4**.

Gating

Voltage-Gated Channels

In the main, these channels open when the cell membrane is depolarised.[20] They form a very important group because they underlie the mechanism of membrane excitability (see **Ch. 4**). The most important

channels in this group are selective sodium, potassium or calcium channels.

Commonly, the channel opening (activation) induced by membrane depolarisation is short lasting, even if the depolarisation is maintained. This is because, with some channels, the initial activation of the channels is followed by a slower process of inactivation.

The role of voltage-gated channels in the generation of action potentials and in controlling other cell functions is described in **Chapter 4**.

Ligand-Gated Channels

These (see **Fig. 3.5**) are activated by binding of a chemical ligand to sites on the channel molecule. Fast neurotransmitters, such as glutamate, acetylcholine, GABA, 5-HT and ATP (see Chs **14**, **16** and **38**), act in this way, binding to sites on the outside of the membrane. In addition, there are also ligand-gated ion channels that do not respond to neurotransmitters but to changes in their local environment. For example, the TRPV1 channel on sensory nerves that mediates the pain-producing effect of the chilli pepper ingredient capsaicin responds to extracellular protons when tissue pH falls, as occurs in inflamed tissue, as well as to the physical stimulus, heat (see **Ch. 43**).

Some ligand-gated channels in the plasma membrane respond to intracellular rather than extracellular signals, the most important being the following:

- Calcium-activated potassium channels, which occur in most cells and open, thus hyperpolarising the cell, when $[Ca^{2+}]_i$ increases.
- Calcium-activated chloride channels, widely expressed in excitable and non-excitable cells where they are involved in diverse functions such as epithelial secretion of electrolytes and water, sensory transduction, regulation of neuronal and cardiac excitability and regulation of vascular tone.

- ATP-sensitive potassium channels, which open when the intracellular ATP concentration falls because the cell is short of energy. These channels, which are quite distinct from those mediating the excitatory effects of extracellular ATP, occur in many nerve and muscle cells, and also in insulin-secreting cells (see **Ch. 31**), where they are part of the mechanism linking insulin secretion to blood glucose concentration.

Other examples of cell membrane channels that respond to intracellular ligands include arachidonic acid-sensitive potassium channels and DAG-sensitive calcium channels, whose functions are not well understood.

Calcium Release Channels

The main ones, IP_3 and **ryanodine** receptors (see **Ch. 4**), are a special class of ligand-gated calcium channels that are present on the endoplasmic or sarcoplasmic reticulum rather than the plasma membrane and control the release of Ca^{2+} from intracellular stores. Ca^{2+} can also be released from lysosomal stores by nicotinic acid adenine dinucleotide phosphate, which activates two-pore domain calcium channels.

Store-Operated Calcium Channels

When the intracellular Ca^{2+} stores are depleted, 'store-operated' channels (SOCs) in the plasma membrane open to allow Ca^{2+} entry. The mechanism by which this linkage occurs involves interaction of a Ca^{2+}-sensor protein in the endoplasmic reticulum membrane with a dedicated Ca^{2+} channel in the plasma membrane (see **Stathopulos and Ikura, 2017**). In response to GPCRs that elicit Ca^{2+} release, the opening of these channels allows the cytosolic free Ca^{2+} concentration, $[Ca^{2+}]_i$, to remain elevated even when the intracellular stores are running low, and also provides a route through which the stores can be replenished (see **Ch. 4**).

Molecular Architecture of Ion Channels

Ion channels are large and elaborate molecules. Their characteristic structural motifs have been revealed as knowledge of their sequence and structure has accumulated since the mid-1980s, when the first voltage-gated sodium channel was cloned. The main structural subtypes are shown in **Fig. 3.20**. All consist of several (often four) domains, which are similar or identical to each other, organised either as an oligomeric array of separate subunits or as one large protein. Each subunit or domain contains a bundle of two to six membrane-spanning helices.

Voltage-gated channels generally include one transmembrane helix that contains an abundance of basic (i.e. positively charged) amino acids. When the membrane is depolarised, so that the interior of the cell becomes less negative, this region – the voltage sensor – moves slightly towards the outer surface of the membrane, which has the effect of opening the channel (see **Bezanilla, 2008**). Many voltage-activated channels also show *inactivation*, which happens when an intracellular appendage of the channel protein moves to plug the channel from the inside. Voltage-gated sodium and calcium channels are remarkable in that the whole structure with four six-helix domains consists of a single huge protein molecule, the domains being linked together by intracellular loops of varying length (see **Fig. 3.20B**). Potassium channels comprise the most numerous and heterogeneous class. [21] Voltage-gated potassium channels resemble sodium channels, except that they are made up of four subunits rather than a single long chain. The class of potassium channels known as 'inward rectifier channels' because of their biophysical properties has the two-helix structure shown in **Fig. 3.20A**, whereas others are classed as 'two-pore domain' channels, because each subunit contains two P loops.

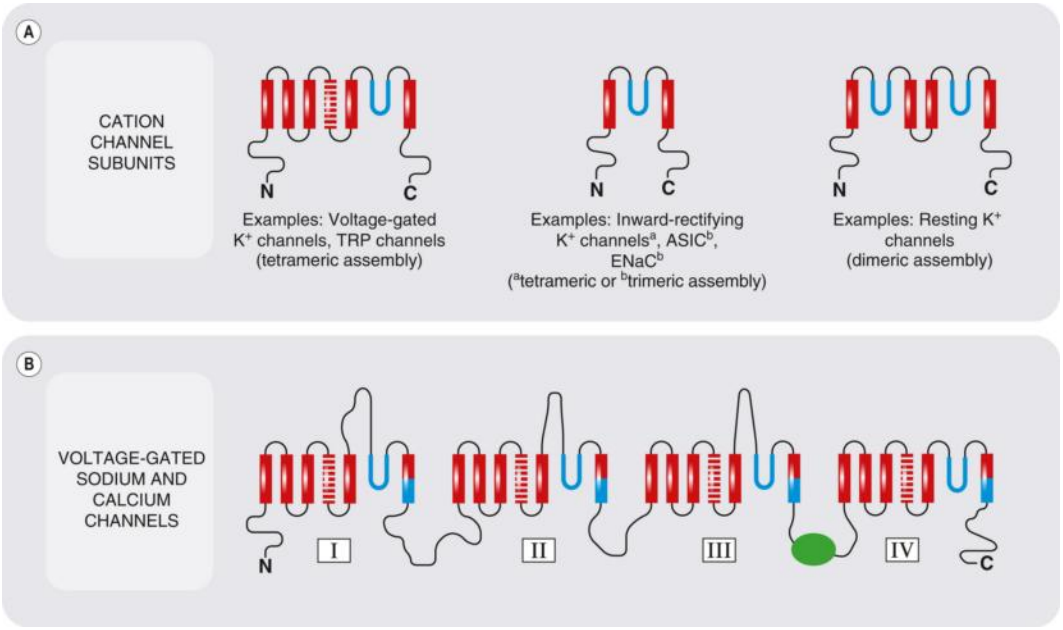

FIG. 3.20 Molecular architecture of ion channels. *Red and blue rectangles* represent membrane-spanning α-helices. *Blue hairpins* are pore loop (P) domains, present in many channels; *blue rectangles* are the pore-forming regions of the membrane-spanning α-helices. *Cross-shaded rectangles* represent the voltage-sensing regions of voltage-gated channels. The *green symbol* represents the inactivating particle of voltage-gated sodium channels. Further information on ion channels is given in **Chapter 4**. *ASIC,* Acid-sensing ion channel; *ENaC,* epithelial sodium channel; *TRP,* transient receptor potential channel.

The various architectural motifs shown in **Fig. 3.20** only scrape the surface of the molecular diversity of ion channels. In all cases, the individual subunits come in several molecular varieties, and these can unite in different combinations to form functional channels as *hetero-oligomers* (as distinct from *homo-oligomers* built from identical subunits). Furthermore, the channel-forming structures described are usually associated with other membrane proteins, which significantly

affect their functional properties. For example, the ATP-gated potassium channel exists in association with the *sulfonylurea receptor* (SUR), and it is through this linkage that various drugs (including antidiabetic drugs of the sulfonylurea class; see **Ch. 31**) regulate the channel. Good progress is being made in understanding the relation between molecular structure and ion channel function, but we still have only a fragmentary understanding of the physiological role of many of these channels. Many important drugs exert their effects by influencing channel function, either directly or indirectly.

Pharmacology of Ion Channels

Many drugs and physiological mediators described in this book exert their effects by altering the behaviour of ion channels.

The gating and permeation of both voltage-gated and ligand-gated ion channels are modulated by many factors, including the following.

- *Ligands that bind directly to various sites on the channel protein*. These include a variety of drugs and toxins that act in different ways, for example by blocking the channel or by affecting the gating process, thereby either facilitating or inhibiting the opening of the channel.
- *Mediators and drugs that act indirectly, mainly by activation of GPCRs*. The latter produce their effects mainly by affecting the state of phosphorylation of individual amino acids located on the intracellular region of the channel protein. As described earlier, this modulation involves the production of second messengers that activate protein kinases. The opening of the channel may be facilitated or inhibited, depending on which residues are phosphorylated. Drugs such as β-adrenoceptor agonists (see **Ch. 15**) affect calcium and potassium channel function in this way, producing a wide variety of cellular effects.

- *Intracellular signals, particularly Ca^{2+} and nucleotides such as ATP and GTP* (see **Ch. 4**). Many ion channels possess binding sites for these intracellular mediators. Increased $[Ca^{2+}]_i$ opens certain types of potassium and chloride channels, and inactivates voltage-gated calcium channels. As described in **Chapter 4**, $[Ca^{2+}]_i$ is itself affected by the function of ion channels and GPCRs. Intracellular ATP binds to and closes a family of potassium channels known as the ATP-gated potassium channels (see **Ch. 31**) that are also sensitive to sulfonylurea drugs. Intracellular cyclic nucleotides, cAMP and cGMP, activate channels permeable to either calcium and sodium ions or potassium ions.

Fig. 3.21 summarises the main sites and mechanisms by which drugs affect voltage-gated sodium channels, a typical example of this type of drug target.

Control of Receptor Expression

Receptor proteins are synthesised by the cells that express them, and the level of expression is itself controlled, via the pathways discussed previously, by receptor-mediated events. We can no longer think of the receptors as the fixed elements in cellular control systems, responding to changes in the concentration of ligands, and initiating effects through the signal transduction pathway – they are themselves subject to regulation. Short-term regulation of receptor function generally occurs through *desensitisation*, as discussed earlier. Long-term regulation occurs through *an increase or decrease of receptor expression*. Examples of this type of control include the proliferation of various postsynaptic receptors after denervation (see **Ch. 13**), the up-regulation of various G protein–coupled and cytokine receptors in response to inflammation (see **Ch. 17**) and the induction of growth factor receptors by certain tumour viruses (see **Ch. 6**). Long-term drug treatment invariably induces adaptive responses,

which, particularly with drugs that act on the central nervous system, can limit their effectiveness as in opioid tolerance (see **Ch. 43**) or can be the basis for therapeutic efficacy. In the latter instance this may take the form of a very slow onset of the therapeutic effect (e.g. with antidepressant drugs; see **Ch. 48**). It is likely that changes in receptor expression, secondary to the immediate action of the drug, are involved in delayed effects of this sort – a kind of 'secondary pharmacology', the importance of which is only now becoming clearer. The same principles apply to drug targets other than receptors (ion channels, enzymes, transporters, etc.) where adaptive changes in expression and function follow long-term drug administration, resulting, for example, in resistance to certain anticancer drugs (see **Ch. 57**).

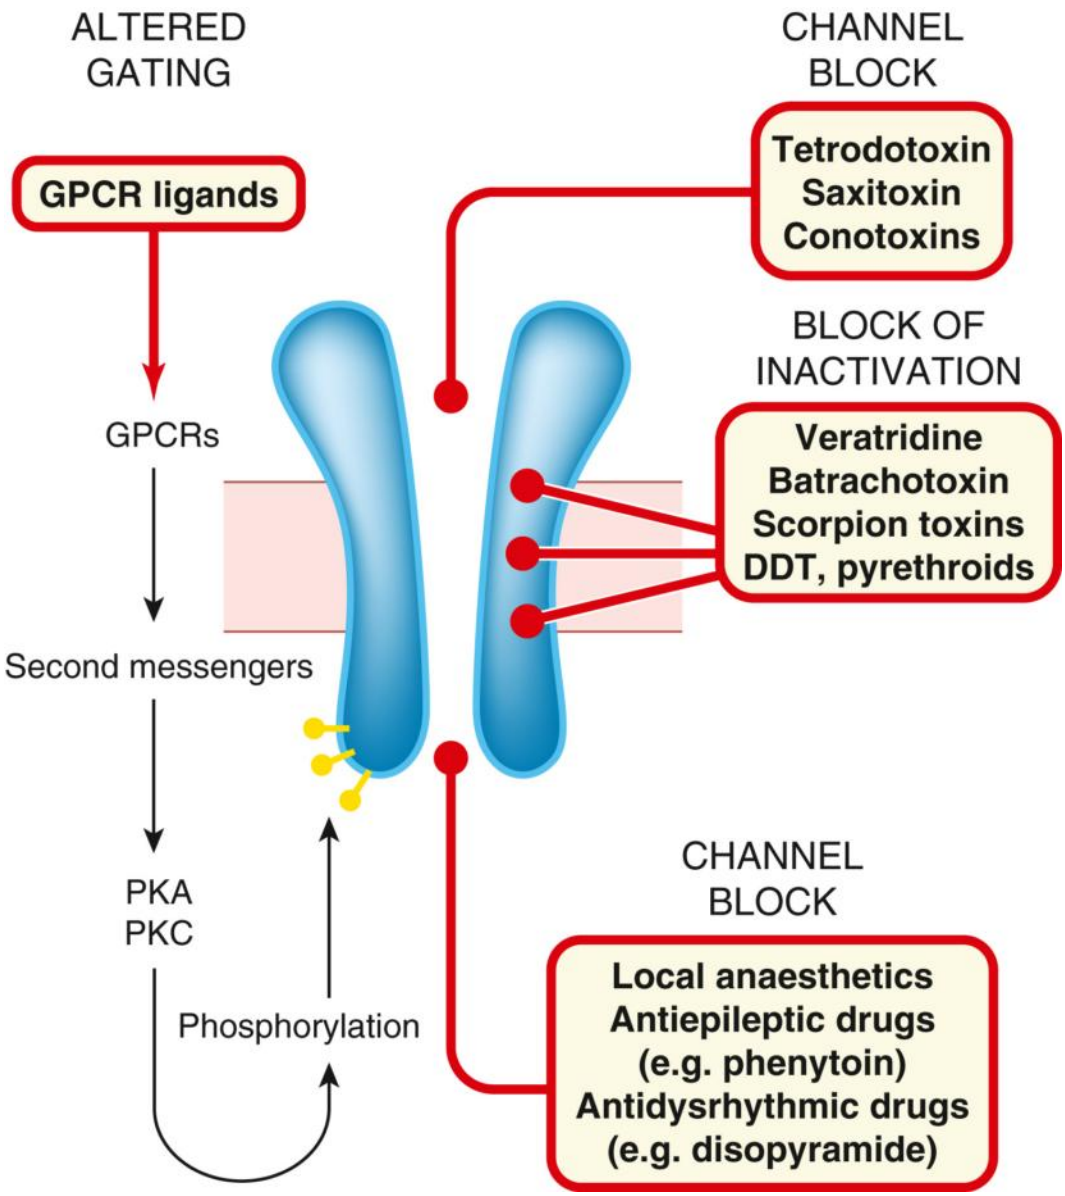

FIG. 3.21 Drug-binding domains of voltage-gated sodium channels (see **Ch. 44**).The multiplicity of different binding sites and effects appears to be typical of many ion channels. *DDT,* Dichlorodiphenyltrichloroethane (dicophane, a well-known insecticide); *GPCR,* G protein–coupled receptor; *PKA,* protein kinase A; *PKC,* protein kinase C.

Receptors and Disease

Increasing understanding of receptor function in molecular terms has revealed a number of disease states directly linked to receptor malfunction. The principal mechanisms involved are:

- autoantibodies directed against receptor proteins;
- mutations in genes encoding receptors, ion channels and proteins involved in signal transduction.

An example of the former is *myasthenia gravis* (see **Ch. 14**), a disease of the neuromuscular junction due to autoantibodies that inactivate nicotinic acetylcholine receptors. Autoantibodies can also mimic the effects of agonists, as in many cases of thyroid hypersecretion, caused by activation of **thyrotropin** receptors (see **Ch. 34**).

Inherited mutations of genes encoding GPCRs account for various disease states (see **Stoy and Gurevich, 2015**). Mutated **vasopressin** and **adrenocorticotrophic hormone** receptors (see Chs **29** and **33**) can result in resistance to these hormones. Receptor mutations can result in activation of effector mechanisms in the absence of agonists. One of these involves the receptor for thyrotropin, producing continuous oversecretion of thyroid hormone; another involves the receptor for luteinising hormone and results in precocious puberty. Adrenoceptor polymorphisms are common in humans, and certain mutations of the β_2 adrenoceptor, although they do not directly cause disease, are associated with a reduced efficacy of β-adrenoceptor agonists in treating asthma (see **Ch. 28**) and a poor prognosis in patients with cardiac failure, potentially through *constitutively active mutations* that render receptors active in the absence of any agonists (see **Ch. 20**). Mutations in G proteins can also cause disease (see **Spiegel and Weinstein, 2004**). For example, mutations of a particular Gα subunit cause one form of *hypoparathyroidism*, while mutations of a Gβ subunit result in

hypertension. Many cancers are associated with mutations of the genes encoding growth factor receptors, kinases and other proteins involved in signal transduction and cell survival (see **Ch. 6**).

Mutations in ligand-gated ion channels ($GABA_A$ and nicotinic) and other ion channels (Na^+ and K^+) that alter their function give rise to some forms of idiopathic epilepsy (see **Ch. 46** and **Thakran et al., 2020**).

Research on genetic polymorphisms affecting receptors, signalling molecules, ion channels and effector enzymes is continuing apace, and it is expected that a clearer understanding of the variability between individuals in their disease susceptibility and response to therapeutic drugs (see **Ch. 12**) will result, in the foreseeable future.

QUESTIONS

QUESTION 3.1

Most drugs act by interacting with target cellular proteins, termed *receptors*, that are grouped into families according to their structure and activation mechanisms.

Which family are not classified as true receptors?

OPTIONS:

A. Ligand gated ion channels

B. Voltage gated channels

C. GPCR (metabotropic)

D. Kinase-linked receptors

E. Nuclear receptors

QUESTION 3.2

G protein–coupled receptors (GPCRs) form the largest family of receptors and are involved in a regulating a wide range of cellular processes.

Which of the following statements about GPCRs is incorrect?

OPTIONS:

A. The α subunit of the G protein binds GDP in the resting state.

B. Both the α and βγ subunits can transmit signals.

C. Regulatory proteins bind to the α subunit to terminate its function.

D. The specificity of the response is largely determined by the α subunit.

E. Pertussis toxin inhibits the Gαs subunit.

QUESTION 3.3

Cyclic AMP (cAMP) is an important second messenger involved in downstream signalling pathways from several receptor families.

Which of the following would not lead to an increase in cAMP?

OPTIONS:

A. β adrenoceptor activation

B. Cholera toxin binding its target

C. Activation of phosphodiesterases

D. Muscarinic M_2 receptor activation

E. Forskolin treatment

ANSWERS

ANSWER 3.1

RATIONALE:

A. These are ionotropic receptors which mediate fast synaptic transmission in the nervous system and are activated by agonist

binding causing opening of the channel.

B.

C. These are membrane receptors activated by agonist ligands that are coupled to intracellular effector systems primarily via a G protein. They constitute the largest receptor family, and include receptors for many hormones and slow transmitters.

D. A large and heterogeneous group of membrane receptors responding mainly to protein ligands which possess either intrinsic enzymatic (kinase) activity or are linked to intracellular kinases.

E. These are receptors that regulate gene transcription and are activated by ligand binding eg steroid hormone receptors.

CORRECT ANSWER WITH EXPLANATION:

B. Voltage gated channels

Technically, these are not true receptors as they are activated (channel opens) in response to changes in membrane potential rather than a ligand binding.

ANSWER 3.2

RATIONALE:

A. In the 'resting' state the G protein exists as an αβγ trimer, which may or may not be precoupled to the receptor, with GDP occupying the site on the α subunit.

B. βγ complexes actually interact with targets of their own, and control effectors in much the same way as the α subunits.

C. Regulators of G protein signalling (RGS) proteins bind specifically to α subunits to increase greatly their GTPase activity, so hastening the hydrolysis of GTP and inactivating the complex. RGS proteins thus exert an inhibitory effect on G protein signalling.

D. Different a subunits (G_s, G_i, G_o and G_q) couple to different second messenger signalling pathways and hence regulate different cellular

function.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Pertussis toxin inhibits the Gαs subunit.

Pertussis toxin specifically blocks G_i and G_o by preventing dissociation of the G protein trimer.

ANSWER 3.3

RATIONALE:

A. β adrenoceptors couple to adenylate cyclase leading to an increase in cAMP.

B. Cholera toxin constitutively activates the Gαs subunit which couples to adenylate cyclase increasing cAMP.

C. Phosphodiesterases are the enzymes responsible for the breakdown of cAMP.

D.

E. Adenylyl cyclase can be activated directly by drugs such as **forskolin**, which is used experimentally to study the role of the cAMP system.

CORRECT ANSWER WITH EXPLANATION:

D. Muscarinic M_2 receptor activation – M_2 cardiac receptors couple to Gαi which inhibits adenylate cyclase.

---

[1] 'Ion channels and the electrical properties they confer on cells are involved in every human characteristic that distinguishes us from the stones in a field' (Armstrong, C.M., 2003. Voltage-gated K channels. Sci. STKE 188, re10).

[2] Including the awarding of the 2021 Nobel Prize for Physiology and Medicine to David Julius and Ardem Patapoutian, for their discovery of mechano-sensitive and ligand-operated ion channel receptors used in temperature, touch and pain sensation.

[3] An oddly Dickensian term that seems inappropriately condescending. Because we can assume that these receptors play defined roles in physiological signalling, their 'orphanhood' reflects our ignorance, not their status. More information on orphan receptors can be found at www.guidetopharmacology.org/GRAC/FamilyDisplayForward?familyId=115#16.

[4] Here, focusing on receptors, we include ligand-gated ion channels as an example of a receptor family. Other types of ion channels are described later; many are also drug targets, although not receptors in the strict sense.

[5] There are 865 human GPCRs comprising 1.6% of the genome (Fredriksson and Schiöth, 2005). Nearly 500 of these are believed to be odorant receptors involved in smell and taste sensations, the remainder being receptors for known or unknown endogenous mediators – enough to keep pharmacologists busy for some time yet.

[6] The term *nuclear receptor* is something of a misnomer, because some are actually located in the cytosol and migrate to the nuclear compartment when a ligand is present.

[7] Receptors for 5-hydroxytryptamine (see Ch. 16) are currently the champions with respect to diversity, with 13 subtypes of GPCR and 1 ligand-gated ion channel all responding to the same endogenous ligand.

[8] In early studies, the Torpedo electric ray was used to isolate and purify the nicotinic receptor as it expresses a very high density of nicotinic receptors on its electroplaques. We now realise that the subunit compositions of the mammalian neuromuscular (Ch. 14) and neuronal (Chs 14 and 39Chapter 14Chapter 39) nicotinic receptors are different from that of the Torpedo but here we focus on the Torpedo receptor to keep it simple.

[9] Examples of promiscuity are increasing, however. Steroid hormones, normally faithful to nuclear receptors, make the occasional pass at ion

channels and GPCRs, and some eicosanoids act on nuclear receptors as well as GPCRs. Nature is quite open minded, although such examples are liable to make pharmacologists frown and students despair.

10 The Ca^{2+}-sensing receptor (see Conigrave et al., 2000) is an unusual GPCR that is activated not by conventional mediators but by extracellular Ca^{2+}in the range of 1–10 mmol/L – an extremely low affinity in comparison with other GPCR agonists. It is expressed by cells of the parathyroid gland, and serves to regulate the extracellular Ca^{2+}concentration by controlling parathyroid hormone secretion (Ch. 36). This homeostatic mechanism is quite distinct from the mechanisms for regulating intracellular Ca^{2+}, discussed in Chapter 4.

11 Hydrophilic small molecules access their ligand-binding domain from the extracellular space down the water-filled cleft, however for highly lipophilic molecules, such as those activating the cannabinoid CB_1 and lysophospholipid $S1P_1$ receptors, access appears to be through a membrane-embedded access fenestration in the side of the receptor.

12 In the past many lead compounds have come from screening huge chemical libraries (see Ch. 60). No inspiration was required, just robust assays, large computers and efficient robotics. Now with the generation of crystal structures we have moved to a more sophisticated age in drug discovery.

13 These receptors were formerly called protease-activated receptors.

14 In humans there are 21 known subtypes of Ga, 6 of Gß and 12 of G?, providing, in theory, about 1500 variants of the trimer. We know little about the role of different a, ß and ? subtypes, but it would be rash to assume that the variations are functionally irrelevant. By now, you will be unsurprised (even if somewhat bemused) by such a display of molecular heterogeneity, for it is the way of evolution.

[15] Alternative abbreviations for these mediators are PtdIns (PI), PtdIns (4,5)-P_2 (PIP_2), Ins (1,4,5)-P_3 (IP_3).

[16] PKCs were originally named as Ca^{2+}-dependent protein kinases (PKC), as opposed to cAMP-dependent PKA. Although later subtypes were found not to be Ca^{2+}-dependent, the PKC name has stuck.

[17] *v-* ***Src*** is a gene found in Rous sarcoma virus that encodes a tyrosine kinase which causes sarcoma (a malignant tumour) in chickens – it was found to have a closely related sequence to the chicken's own gene termed c-Src (for cellular rather than viral Src). This was the first oncogene to be discovered, in 1979.

[18] Protein kinase B was named to fill in the gap between protein kinase A (cAMP-dependent) and protein kinase C (Ca^{2+}-dependent). As you can see, nomenclature is highly imaginative!

[19] In truth, the distinction between ligand-gated channels and other ion channels is an arbitrary one. In grouping ligand-gated channels with other types of receptor in this book, we are respecting the historical tradition established by Langley and others, who first defined receptors in the context of the action of acetylcholine at the neuromuscular junction. The advance of molecular biology may force us to reconsider this semantic issue in the future, but for now we make no apology for upholding the pharmacological tradition.

[20] There is always an exception to the rule! The members of the HCN family of potassium channels found in neurons and cardiac muscle cells are activated by hyperpolarisation.

[21] The human genome encodes more than 70 distinct potassium channel subtypes – either a nightmare or a golden opportunity for the pharmacologist, depending on one's perspective.

4: How drugs act

cellular aspects – excitation, contraction and secretion

OVERVIEW

The link between a drug interacting with a molecular target and its effect at the pathophysiological level, such as a change in blood glucose concentration or the shrinkage of a tumour, involves events at the cellular level. Whatever their specialised physiological function, cells generally share much the same repertoire of signalling mechanisms. In this chapter, we describe excitation, contraction and secretion signalling mechanisms that operate mainly over a short timescale (milliseconds to hours), which account for many physiological responses;

The short-term regulation of cell function depends mainly on the following components and mechanisms, which regulate, or are regulated by, the free concentration of Ca^{2+} in the cytosol, $[Ca^{2+}]_i$:

- ion channels and transporters in the plasma membrane
- the storage and release of Ca^{2+} by intracellular organelles
- Ca^{2+}-dependent regulation of a variety of functional proteins, including enzymes, contractile proteins and vesicle proteins

Because $[Ca^{2+}]_i$ plays such a key role in cell function, a wide variety of drug effects result from interference with one or

more of these Ca^{2+}-dependent mechanisms. Knowledge of the molecular and cellular details is extensive, and here we focus on the aspects that help to explain drug effects. More detailed coverage of the topics presented in this chapter can be found in **Berridge (2014)** and **Kandel et al. (2021)**.

Regulation of Intracellular Calcium

Ever since the famous accident in 1882 by Sidney Ringer's technician, which showed that using tap water rather than distilled water to make up the bathing solution for isolated frog hearts would allow them to carry on contracting, the role of Ca^{2+} as a major regulator of cell function has never been in question. Many drugs and physiological mechanisms operate, directly or indirectly, by influencing $[Ca^{2+}]_i$. Here we consider the main ways in which it is regulated. Details of the molecular components and drug targets are presented in **Chapter 3**, and descriptions of drug effects on integrated physiological function are given in later chapters.

The study of Ca^{2+} regulation was greatly facilitated by the development of optical techniques based on the Ca^{2+}-sensitive photoprotein *aequorin*, and fluorescent dyes such as *Fura-2*, which allow free $[Ca^{2+}]_i$ to be continuously monitored in living cells with a high level of temporal and spatial resolution. Addition of an acetoxymethyl ester (AM) moiety to the dye molecule allows them to diffuse into cells and become 'trapped' inside living cells once intracellular esterases cleave the AM group from the dye. Some (e.g. Fura-2) are ratiometric by nature, allowing greater accuracy of $[Ca^{2+}]_i$ quantitation.

Most of the Ca^{2+} in a resting cell is sequestered in organelles, particularly the *endoplasmic* or *sarcoplasmic reticulum* (ER or SR) and the mitochondria, and the free $[Ca^{2+}]_i$ is kept to a low level, about 100 nmol/L. The Ca^{2+} concentration in extracellular fluid, $[Ca^{2+}]_o$, is about 2.4 mmol/L, so there is a large concentration gradient favouring Ca^{2+} entry. Free $[Ca^{2+}]_i$ is kept low (1) by the operation of active transport mechanisms that eject cytosolic Ca^{2+} through the plasma membrane and pump it into the ER and (2) by the normally low Ca^{2+} permeability of the plasma and ER membranes. Regulation of $[Ca^{2+}]_i$ involves three main mechanisms:

- control of Ca^{2+} entry
- control of Ca^{2+} extrusion
- exchange of Ca^{2+} between the cytosol and the intracellular stores

These mechanisms are described in more detail later and are summarised in **Fig. 4.1**.

Calcium Entry Mechanisms

There are four main routes by which Ca^{2+} enters cells across the plasma membrane:

- voltage-gated calcium channels
- ligand-gated and physically-activated calcium channels
- store-operated calcium entry
- Na^+–Ca^{2+} exchange (which can operate in either direction)

Voltage-Gated Calcium Channels

The pioneering work of Hodgkin and Huxley on the ionic basis of the nerve action potential identified voltage-dependent Na^+ and K^+ conductances as the main participants. It was later found that some invertebrate nerve and muscle cells could produce action potentials that depended on Ca^{2+} rather than Na^+, and it was then found that vertebrate cells also possess voltage-activated calcium channels capable of allowing substantial amounts of Ca^{2+} to enter the cell when the membrane is depolarised. These voltage-gated channels are highly selective for Ca^{2+} and are not permeable to Na^+ or K^+; they are ubiquitous in excitable cells and cause Ca^{2+} to enter the cell whenever the membrane is depolarised, for example by a conducted action potential.

A combination of electrophysiological and pharmacological criteria has revealed five distinct types of voltage-gated calcium channel current: L, T, N, P/Q and R. [1] They vary with respect to their voltage threshold for activation, their activation and inactivation kinetics, their conductance and their sensitivity to blocking agents, as summarised in **Table 4.1**. The molecular basis for this heterogeneity has been worked out in some detail. The main pore-forming subunit (termed α_1, see **Fig. 3.20**) occurs in at least 10 molecular subtypes, and associates with other subunits (β, γ and two subunits from the same gene, $\alpha_2\delta$, linked by a disulfide bond) that also exist in different subtypes to form the functional channel. Different combinations of these subunits give rise to the different physiological subtypes. [2] In general, L channel currents are particularly important in regulating contraction of cardiac and smooth muscle, and N channel currents (and also P/Q) are involved in neurotransmitter and hormone release, while T channel currents

mediate Ca^{2+} entry into neurons around the resting membrane potential and can control the rate of repolarisation of neurons and cardiac cells, as well as various Ca^{2+}-dependent functions such as regulation of other ion channels, enzymes, etc. Clinically used drugs that act directly on some forms of calcium channel include the group of 'Ca^{2+} antagonists' consisting of *dihydropyridines* (e.g. **nifedipine**), **verapamil** and **diltiazem** (used for their cardiovascular effects; see Chs **20** and **21**). Many drugs affect calcium channels indirectly by acting on G protein–coupled receptors (see **Ch. 3**). A number of toxins act selectively on one or other type of calcium channel (see **Table 4.1**), and these are used as experimental tools.

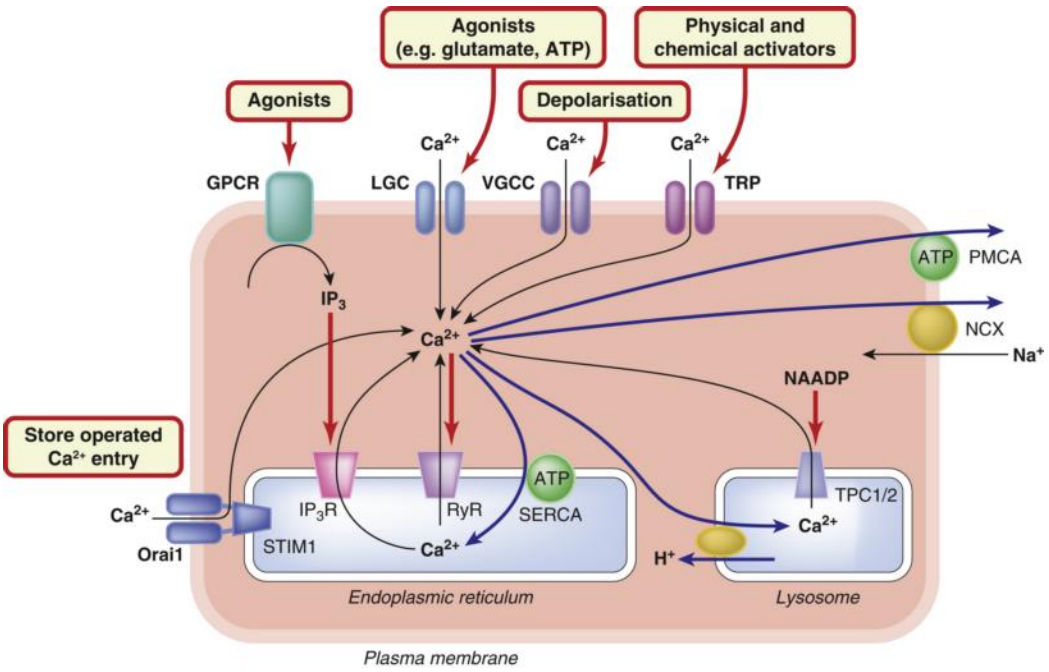

FIG. 4.1 Regulation of intracellular calcium.The main routes of transfer of Ca^{2+} into, and out of, the cytosol, endoplasmic reticulum (ER) and lysosomal structures are shown for a typical cell (see text for details). *Black arrows:* routes into the cytosol. *Blue arrows*: routes out of the cytosol. *Red arrows*: regulatory mechanisms. Ca^{2+} release from the ER activates the sensor protein Stim1, which then interacts directly with Orai1 to promote Ca^{2+} entry when the ER store is depleted. Normally, $[Ca^{2+}]_i$ is regulated to about 10^{-7} mol/L in a 'resting' cell. Mitochondria (not shown) also function as Ca^{2+} storage organelles but release Ca^{2+} only under pathological conditions, such as ischaemia. There is evidence for a lysosomal store of Ca^{2+}, activated by the second messenger nicotinic acid

adenine dinucleotide phosphate (NAADP) through a two-pore domain calcium channel (TPC). *GPCR,* G protein–coupled receptor; IP_3, inositol trisphosphate; IP_3R, inositol trisphosphate receptor; *LGC,* ligand-gated cation channel; *NCX,* Na^+–Ca^{2+} exchange transporter; *PMCA,* plasma membrane Ca^{2+}-ATPase; *RyR,* ryanodine receptor; *SERCA,* sarcoplasmic/endoplasmic reticulum ATPase; *VGCC,* voltage-gated calcium channel.

Ligand-Gated and Physically Activated Channels

Most ligand-gated cation channels (see **Ch. 3**) that are activated by excitatory neurotransmitters are relatively non-selective, and conduct Ca^{2+} ions as well as other cations. Most important in this respect is the glutamate receptor of the *N*-methyl-D-aspartate (NMDA) type (see **Ch. 38**), which has a particularly high permeability to Ca^{2+} and is a major contributor to Ca^{2+} uptake by postsynaptic neurons (and also glial cells) in the central nervous system. Activation of this receptor can readily cause so much Ca^{2+} entry that the cell dies, mainly through activation of Ca^{2+}-dependent proteases but also by triggering *apoptosis* (see **Ch. 6**). This mechanism, termed *excitotoxicity*, probably plays a part in various neurodegenerative disorders (see **Ch. 40**).

Table 4.1

ER, Endoplasmic reticulum; *GPCR,* G protein–coupled receptor; *IP_3,* inositol trisphosphate; *PKA,* protein kinase A.

For many years, there was dispute about the existence of 'receptor-operated channels' in smooth muscle, responding directly to mediators such as adrenaline (epinephrine), acetylcholine and histamine. Now it seems that the P2X receptor (see **Ch. 3**), activated by ATP, is the only example of a true ligand-gated channel in smooth muscle, and this constitutes an important route for Ca^{2+} entry. As mentioned earlier, many mediators acting on G protein–coupled receptors affect Ca^{2+} entry indirectly, mainly by regulating voltage-gated calcium channels or potassium channels.

The TRP channel superfamily [3] comprises six families of ion channels – TRPC, TRPM, TRPV, TRPA, TRPP and TRPML – that exhibit structural homology. They are permeable to Ca^{2+} as well as Na^+ and K^+. Different TRP channels respond to different stimuli and can be chemically activated (e.g. by extracellular protons or by intracellular second messengers such as diacylglycerol) or physically activated (e.g. by cooling or heating and by stretch). Given their widespread distribution in the body in a variety of tissues and their responses to different stimuli it will come as no surprise therefore that these channels are involved in a myriad of physiological and pathological situations (**Blair et al., 2019**). For now all we need to be aware of is their role in allowing Ca^{2+} to enter cells in response to different stimuli.

Store-Operated Calcium Entry

Store-operated calcium entry is through very-low-conductance channels that occur in the plasma membrane and open to allow entry when the ER stores are depleted, but are not sensitive to cytosolic $[Ca^{2+}]_i$. The linkage between the ER and the plasma membrane involves a Ca^{2+}-sensor protein (*Stim1*) in the ER membrane, which connects directly to the channel protein (*Orai1*) in the adjacent plasma membrane (**Fig 4.1**). Ca^{2+} loss from the ER causes Stim1 to accumulate at junctions between the ER and the plasma membrane where it traps and activates Orai1 resulting in Ca^{2+} entry across the plasma membrane (see **Lewis, 2020**).

Like the ER and SR channels, these channels can serve to amplify the rise in $[Ca^{2+}]_i$ resulting from Ca^{2+} release from the stores. So far, only experimental compounds are known to block these channels, but efforts are being made to develop specific blocking agents for therapeutic use as relaxants of smooth muscle.

Calcium Extrusion Mechanisms

Active transport of Ca^{2+} outwards across the plasma membrane, and inwards across the membranes of the ER or SR, depends on the activity of distinct Ca^{2+}-dependent ATPases, [4] similar to the Na^+/K^+-dependent ATPase that pumps Na^+ out of the cell in exchange for K^+. **Thapsigargin** (derived from a Mediterranean plant, *Thapsia garganica*) specifically blocks the ER pump, causing loss of Ca^{2+} from the ER. It is a useful experimental tool but has no therapeutic significance.

Calcium is also extruded from cells in exchange for Na^+, by Na^+–Ca^{2+} exchange. The exchanger transfers three Na^+ ions for one Ca^{2+}, and therefore produces a net depolarising current when it is

extruding Ca^{2+}. The energy for Ca^{2+} extrusion comes from the electrochemical gradient for Na^+, not directly from ATP hydrolysis. This means that a reduction in the Na^+ concentration gradient resulting from Na^+ entry will reduce Ca^{2+} extrusion by the exchanger, causing a secondary rise in $[Ca^{2+}]_i$, a mechanism that is particularly important in cardiac muscle (see **Ch. 20**). **Digoxin** (derived from the *Digitalis* or 'Foxglove' plant), which inhibits Na^+ extrusion, acts on cardiac muscle in this way (see **Ch. 20**), causing $[Ca^{2+}]_i$ to increase.

Calcium Release Mechanisms

There are two main types of calcium channel in the ER and SR membrane, which play an important part in controlling the release of Ca^{2+} from these stores.

- The *inositol trisphosphate receptor* (IP_3R) is activated by inositol trisphosphate (IP_3), a second messenger produced by the action of many ligands on G protein–coupled receptors (see **Ch. 3**). IP_3R is a ligand-gated ion channel, although its molecular structure differs from that of ligand-gated channels in the plasma membrane (see **Berridge, 2016**). This is the main mechanism by which activation of Gq-coupled receptors causes an increase in $[Ca^{2+}]_i$.
- *Ryanodine receptors* (RyRs) are so called because they were first identified through the specific blocking action of the plant alkaloid **ryanodine.** There are three isoforms – RyR1–3 (**Van Petegem, 2012**), which are expressed in many different cell types. RyR1 is highly expressed in skeletal muscle, RyR2 in the heart and RyR3 in brain

neurons. In skeletal muscle, RyRs on the SR are physically coupled to *dihydropyridine receptors (DHPRs)* on the T-tubules (see **Fig. 4.9**); this coupling results in rapid Ca^{2+} release following the action potential in the muscle fibre. In other muscle types, RyRs respond to Ca^{2+} that enters the cell through membrane calcium channels by a mechanism known as *calcium-induced calcium release* (CICR).

The functions of IP_3Rs and RyRs are modulated by a variety of other intracellular signals (see **Berridge, 2016**; **Van Petegem, 2012**), which affect the magnitude and spatiotemporal patterning of Ca^{2+} signals. Fluorescence imaging techniques have revealed a remarkable level of complexity of Ca^{2+} signals, and much remains to be discovered about the importance of this patterning in relation to physiological and pharmacological mechanisms. The Ca^{2+} sensitivity of RyRs is increased by **caffeine**, causing Ca^{2+} release from the SR even at resting levels of $[Ca^{2+}]_i$. This is used experimentally but rarely happens in humans, because the other pharmacological effects of caffeine (see **Ch. 49**) occur at much lower doses. The blocking effect of **dantrolene**, a compound related to ryanodine, is used therapeutically to relieve muscle spasm in the rare condition of *malignant hyperthermia* (see **Ch. 41**), which is associated with inherited abnormalities in the RyR protein.

A typical $[Ca^{2+}]_i$ signal resulting from activation of a Gq–coupled receptor is shown in **Fig. 4.2A**. The response produced in the absence of extracellular Ca^{2+} represents release from intracellular stores. The larger and more prolonged response when extracellular Ca^{2+} is present shows the contribution of store-operated calcium entry. The various positive and negative feedback mechanisms that

regulate $[Ca^{2+}]_i$ give rise to a variety of temporal and spatial oscillatory patterns (**Fig. 4.2B**) that are responsible for spontaneous rhythmic activity in smooth muscle and nerve cells (see **Berridge, 2008**).

Other Second Messengers

Two intracellular metabolites, cyclic ADP-ribose (cADPR) and nicotinic acid adenine dinucleotide phosphate (NAADP) formed from the ubiquitous coenzymes nicotinamide adenine dinucleotide (NAD) and NAD phosphate, also affect Ca^{2+} signalling (see **Morgan et al., 2015**; **Parrington et al., 2015**). cADPR acts by increasing the sensitivity of RyRs to Ca^{2+}, thus increasing the 'gain' of the CICR effect, whereas NAADP has been proposed to release Ca^{2+} from lysosomes by activating two-pore domain calcium channels (**Fig. 4.1**).

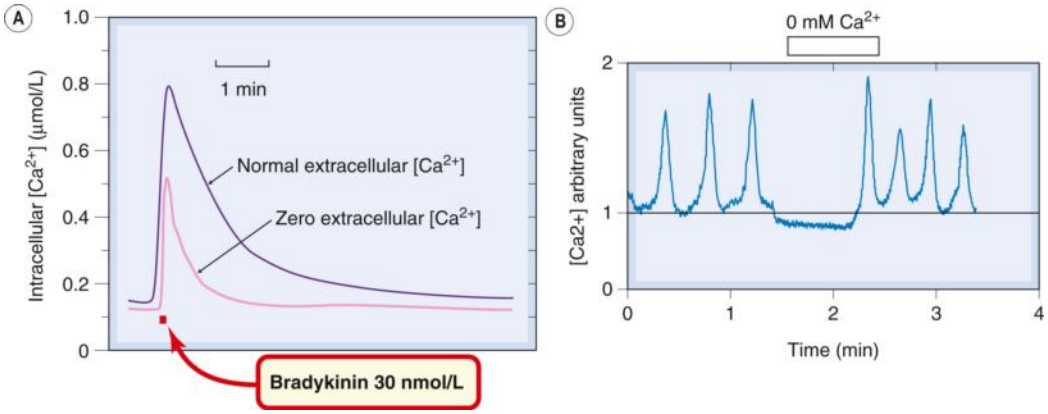

FIG. 4.2 (A) Increase in intracellular free calcium concentration in response to receptor activation. The records were obtained from a single rat sensory neuron grown in tissue culture. The cells were loaded with the fluorescent Ca^{2+} indicator Fura-2, and the signal from a single cell monitored with a fluorescence microscope. A brief exposure to the peptide bradykinin, which causes excitation of sensory neurons (see **Ch. 43**), causes a transient increase in $[Ca^{2+}]_i$ from the resting value of about 150 nmol/L. When Ca^{2+} is removed from the extracellular solution, the bradykinin-induced increase in $[Ca^{2+}]_i$ is still present but is smaller and briefer. The response in the absence of extracellular Ca^{2+} represents the release of stored intracellular Ca^{2+} resulting from the intracellular production of inositol trisphosphate. The difference between this and the larger response when Ca^{2+} is present extracellularly is believed to represent Ca^{2+} entry

through store-operated ion channels in the cell membrane. (B) Spontaneous intracellular calcium oscillations in pacemaker cells from the rabbit urethra that regulate the rhythmic contractions of the smooth muscle. The signals cease when external Ca^{2+} is removed, showing that activation of membrane Ca^{2+} channels is involved in the mechanism. A, Figure kindly provided by G. M. Burgess and A. Forbes, Novartis Institute for Medical Research. B, From McHale, N., Hollywood, M., Sergeant, G., Thornbury, K., 2006. Origin of spontaneous rhythmicity in smooth muscle. J. Physiol. 570, 23–28.

The levels of these messengers in mammalian cells may be regulated mainly in response to changes in the metabolic status of the cell, although the details are still not clear. Abnormal Ca^{2+} signalling is involved in many pathophysiological conditions, such as ischaemic cell death, endocrine disorders and cardiac dysrhythmias, where cADPR and NAADP, and their interaction with other mechanisms that regulate $[Ca^{2+}]_i$, may be important.

The Role of Mitochondria

Under normal conditions, mitochondria accumulate Ca^{2+} passively as a result of the intramitochondrial potential, which is strongly negative with respect to the cytosol. This negativity is maintained by active extrusion of protons, and is lost – thus releasing Ca^{2+} into the cytosol – if the cell runs short of ATP, for example under conditions

of hypoxia. This only happens *in extremis*, and the resulting Ca^{2+} release contributes to the cytotoxicity associated with severe metabolic disturbance. Cell death resulting from brain ischaemia or coronary ischaemia (see Chs **20** and **40**) involves this mechanism, along with others that contribute to an excessive rise in $[Ca^{2+}]_i$.

Calmodulin

Calcium exerts its control over cell functions by virtue of its ability to regulate the activity of many different proteins, including enzymes (particularly kinases and phosphatases), channels, transporters, transcription factors, synaptic vesicle proteins and many others either by binding directly to these proteins or through a Ca^{2+}-binding protein that serves as an intermediate between Ca^{2+} and the regulated functional protein, the best known such binding protein being the ubiquitous *calmodulin*. This regulates at least 40 different functional proteins – indeed a powerful fixer. Calmodulin (short for calcium-modulated protein, often abbreviated further to CaM) is a dumbbell-shaped protein with a globular domain at either end, each with two Ca^{2+} binding sites. When all are occupied, the protein undergoes a conformational change, exposing a 'sticky' hydrophobic domain that lures many proteins into association, thereby affecting their functional properties.

Calcium regulation

Intracellular Ca^{2+} concentration, $[Ca^{2+}]_i$, is critically important as a regulator of cell function.

- Intracellular Ca^{2+} is determined by (a) Ca^{2+} entry; (b) Ca^{2+} extrusion; and (c) Ca^{2+} exchange between the cytosol, endoplasmic or sarcoplasmic reticulum (ER, SR), lysosomes and mitochondria.
- Calcium entry occurs by various routes, including voltage- and ligand-gated calcium channels and Na^{+}–Ca^{2+} exchange.
- Calcium extrusion depends mainly on an ATP-driven Ca^{2+} pump.
- Calcium ions are actively taken up and stored by the ER/SR, from which they are released in response to various stimuli.
- Calcium ions are released from ER/SR stores by (1) the second messenger inositol trisphosphate (IP_3) acting on IP_3receptors; or (2) increased $[Ca^{2+}]_i$ itself acting on ryanodine receptors, a mechanism known as Ca^{2+}-induced Ca^{2+} release.
- Other second messengers, cyclic ADP-ribose and nicotinic acid dinucleotide phosphate, also promote the release of Ca^{2+} from Ca^{2+} stores.
- Depletion of ER/SR Ca^{2+} stores promotes Ca^{2+} entry through the plasma membrane, via store-operated channels.
- Calcium ions affect many aspects of cell function by binding to proteins such as calmodulin, which in turn bind other proteins and regulate their function.

Excitation

Excitability describes the ability of a cell to show a regenerative all-or-nothing electrical response to depolarisation of its membrane, this membrane response being known as an *action potential*. It is a characteristic of most neurons and muscle cells (including skeletal, cardiac and smooth muscle) and of many endocrine gland cells. In neurons and muscle cells, the ability of the action potential, once initiated, to propagate to all parts of the cell membrane, and often to spread to neighbouring cells, explains the importance of membrane excitation in intra- and intercellular signalling. In the nervous system and in skeletal muscle, action potential propagation is the mechanism responsible for communication over long distances at high speed, indispensable for large, fast-moving creatures. In cardiac and smooth muscle, as well as in some central neurons, spontaneous rhythmic activity occurs. In gland cells, the action potential, where it occurs, serves to amplify the signal that causes the cell to secrete. In each type of tissue, the properties of the excitation process reflect the special characteristics of the ion channels that underlie the process. The molecular nature of ion channels, and their importance as drug targets, is considered in **Chapter 3**; here we discuss the cellular processes that depend primarily on ion channel function. For more detail, see **Hille (2001)**.

The 'Resting' Cell

The resting cell is not resting at all but very busy controlling the state of its interior, and it requires a continuous supply of energy to do so. In relation to the topics discussed in this chapter, the following characteristics are especially important:

- membrane potential
- permeability of the plasma membrane to different ions
- intracellular ion concentrations, especially $[Ca^{2+}]_i$

Under resting conditions, all cells maintain a negative internal potential between about −30 and −80 mV, depending on the cell type. This arises because (1) the membrane is relatively impermeable to Na^+ and (2) Na^+ ions are actively extruded from the cell in exchange for K^+ ions by an energy-dependent transporter, the Na^+ pump (or Na^+–K^+-ATPase). The result is that the intracellular K^+ concentration, $[K^+]_i$, is higher, and $[Na^+]_i$ is lower, than the respective extracellular concentrations (**Fig. 4.3**). In many cells, other ions, particularly Cl^-, are also actively transported and unequally distributed across the membrane. In many cases (e.g. in neurons), the membrane permeability to K^+ is relatively high, and the membrane potential settles at a value of −60 to −80 mV, close to the equilibrium potential for K^+ (**Fig. 4.3**). In other cells (e.g. smooth muscle), anions play a larger part, and the membrane potential is generally lower (−30 to −50 mV) and less dependent on K^+.

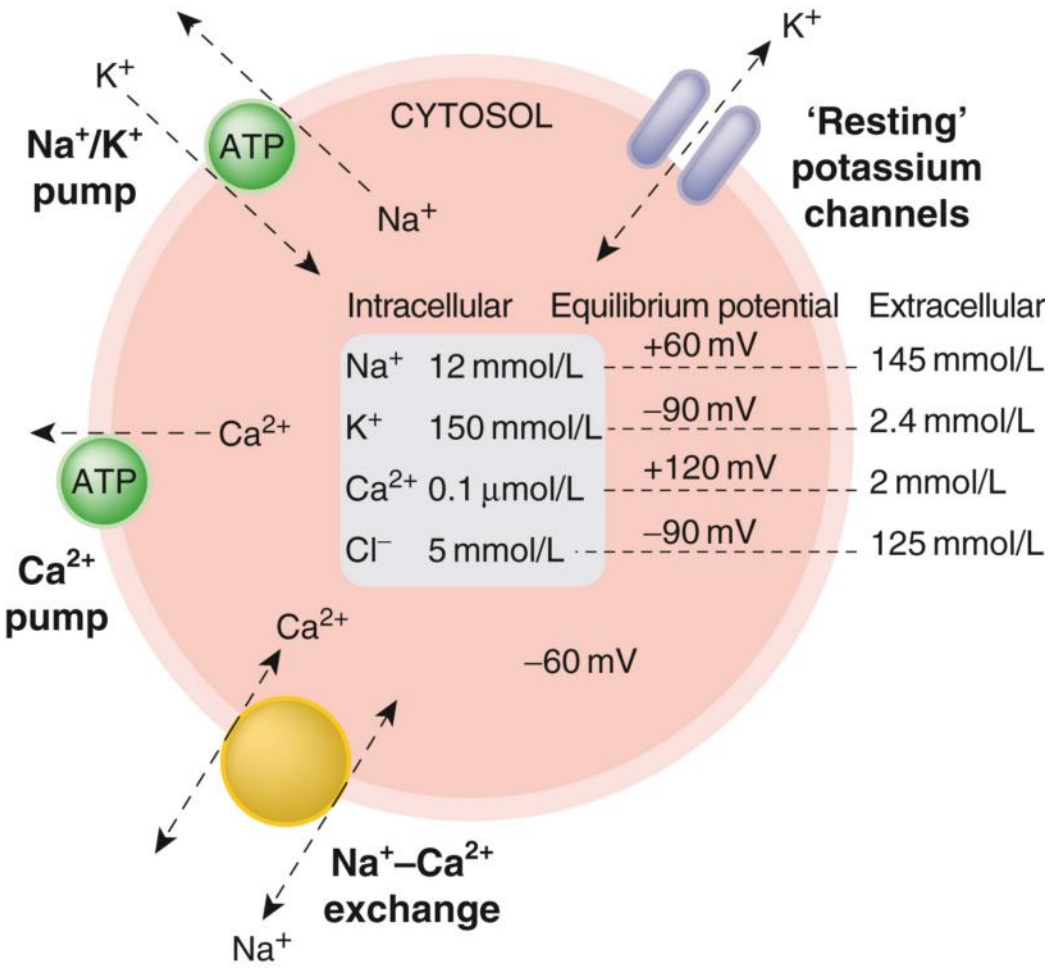

FIG. 4.3 Simplified diagram showing the ionic balance of a typical 'resting' cell.The main transport mechanisms that maintain the ionic gradients across the plasma membrane are the ATP-driven Na^+–K^+ and Ca^{2+} pumps and the Na^+–Ca^{2+} exchange transporter. The membrane is relatively permeable to K^+, because some types of potassium channel are open at rest, but impermeable to other cations. The unequal ion concentrations on either side of the membrane give rise to the 'equilibrium potentials' shown. The resting membrane potential, typically about

−60 mV but differing between different cell types, is determined by the equilibrium potentials and the permeabilities of the various ions involved and by the ‘electrogenic’ effect of the transporters. For simplicity, anions and other ions, such as protons, are not shown, although these play an important role in many cell types.

Electrical and Ionic Events Underlying the Action Potential

Our present understanding of electrical excitability rests firmly on the work of Hodgkin, Huxley and Katz on squid axons, published in 1949–1952. Their experiments (see **Katz, 1966**) revealed the existence of voltage-gated ion channels and showed that the action potential is generated by the interplay of two processes:

1. A rapid, transient increase in Na^+ permeability that occurs when the membrane is depolarised beyond about −50 mV.
2. A slower, sustained increase in K^+ permeability.

Because of the inequality of Na^+ and K^+ concentrations on the two sides of the membrane, an increase in Na^+ permeability causes an inward (depolarising) current of Na^+ ions, whereas an increase in K^+ permeability causes an outward (repolarising) current. The separability of these two currents can be most clearly demonstrated by the use of drugs blocking sodium and potassium channels, as shown in **Fig. 4.4**. During the physiological initiation or propagation of a nerve impulse, the first event is a small

depolarisation of the membrane, produced either by transmitter action or by the approach of an action potential passing along the axon. This opens sodium channels, allowing an inward current of Na^+ ions to flow, which depolarises the membrane still further. The process is thus a regenerative one, and the increase in Na^+ permeability is enough to bring the membrane potential towards E_{Na}. The increased Na^+ conductance is transient, because the channels inactivate rapidly and the membrane returns to its resting state.

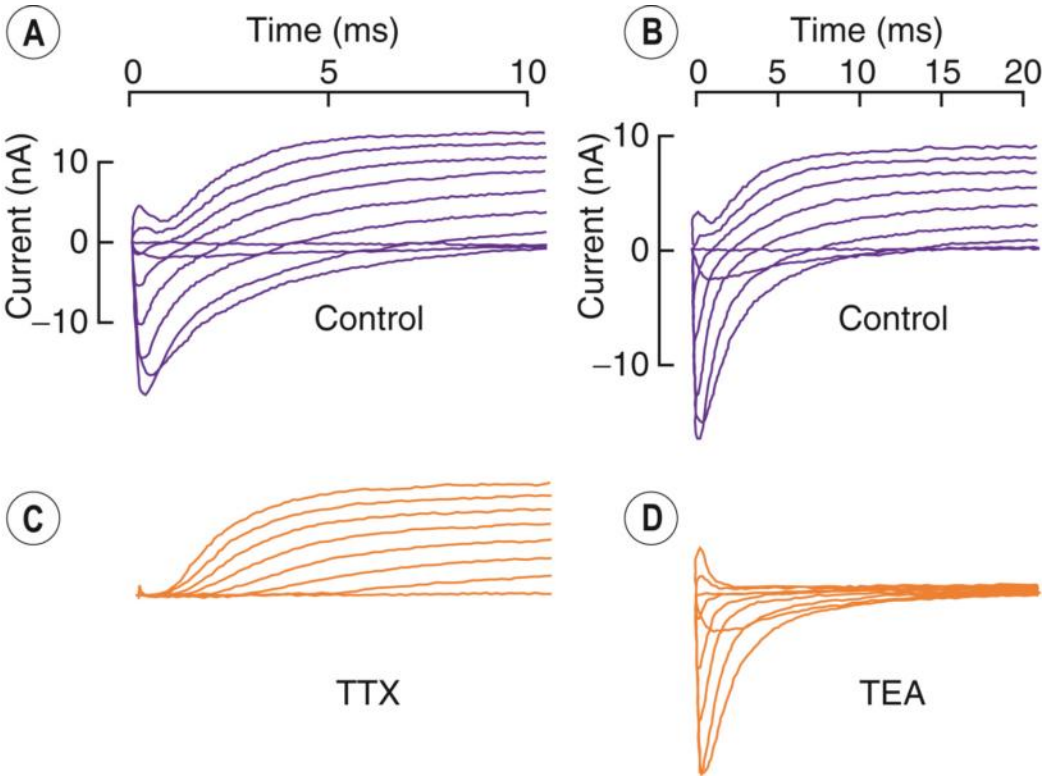

FIG. 4.4 Separation of sodium and potassium currents in the nerve membrane.Voltage clamp records from the node of Ranvier of a single frog nerve fibre. At time 0, the membrane potential was stepped to a depolarised level, ranging from −60 mV (lower trace in each series) to +60 mV (upper trace in each series) in 15-mV steps. (A and B) Control records from two fibres. (C) Effect of tetrodotoxin (TTX), which abolishes Na^+ currents. (D) Effect of tetraethylammonium (TEA), which abolishes K^+ currents. From Hille, B., 1970. Ionic channels in nerve membranes. Prog. Biophys. Mol. Biol. 21, 1–32.

In many types of cell, including most nerve cells, repolarisation is assisted by the opening of voltage-dependent K^+ channels. These function in much the same way as sodium channels, but their activation kinetics are about 10 times slower and they do not inactivate appreciably. This means that the potassium channels open later than the sodium channels, contributing to the rapid termination of the action potential and to the slower after-hyperpolarisation that follows the depolarising phase. The behaviour of the sodium and potassium channels during an action potential is shown in **Fig. 4.5**.

The foregoing account, based on Hodgkin and Huxley's work 70 years ago, involves only Na^+ and K^+ channels. Subsequently, voltage-gated calcium channels (see **Fig. 4.1**) were discovered. These function in basically the same way as sodium channels, if on a slightly slower timescale; they contribute to action potential generation in many cells, particularly cardiac and smooth muscle cells, but also in neurons and secretory cells. Ca^{2+} entry through voltage-gated calcium channels plays a key role in intracellular signalling.

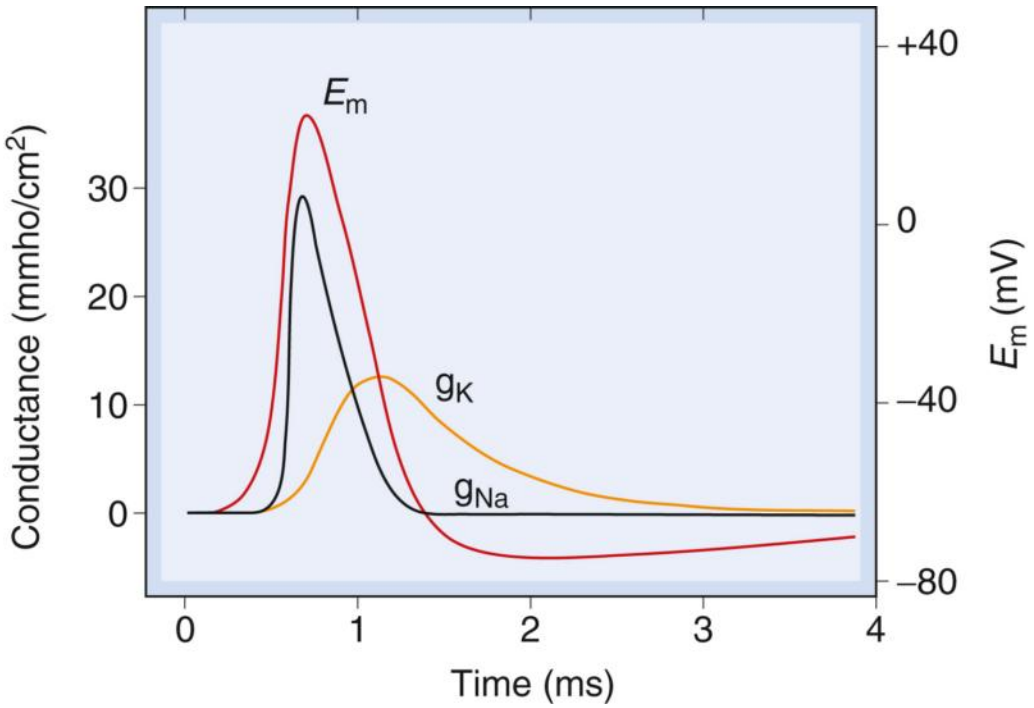

FIG. 4.5 Behaviour of sodium and potassium channels during a conducted action potential.Rapid opening of sodium channels occurs during the action potential upstroke. Delayed opening of potassium channels, and inactivation of sodium channels, causes repolarisation. E_m, Membrane potential; g_K, membrane conductance to K^+; g_{Na}, membrane conductance to Na^+.

Channel Function

The discharge patterns of excitable cells vary greatly. Skeletal muscle fibres are quiescent unless stimulated by the arrival of a nerve impulse at the neuromuscular junction (see **Ch. 14**). Cardiac muscle fibres discharge spontaneously at a regular rate (see **Ch. 20**). Neurons may be normally silent, or they may discharge

spontaneously, either regularly or in bursts; smooth muscle cells show a similar variety of firing patterns. The frequency at which different cells normally discharge action potentials also varies greatly, from 100 Hz or more for fast-conducting neurons, down to about 1 Hz for cardiac muscle cells. These very pronounced functional variations reflect the different characteristics of the ion channels expressed in different cell types. Rhythmic fluctuations of $[Ca^{2+}]_i$ underlie the distinct firing patterns that occur in different types of cell (see **Berridge, 2016**).

Drugs that alter channel characteristics, either by interacting directly with the channel itself or indirectly through second messengers, affect the function of many organ systems, including the nervous, cardiovascular, endocrine, respiratory and reproductive systems, and are a frequent theme in this book. Here we describe some of the key mechanisms involved in the regulation of excitable cells.

In general, action potentials are initiated by membrane currents that cause depolarisation of the cell. These currents may be produced by synaptic activity, by an action potential approaching from another part of the cell, by a sensory stimulus or by spontaneous *pacemaker* activity. The tendency of such currents to initiate an action potential is governed by the *excitability* of the cell, which depends mainly on the state of (1) the voltage-gated sodium and/or calcium channels and (2) the potassium channels of the resting membrane. Anything that increases the number of available sodium or calcium channels, or reduces their activation threshold, will tend to increase excitability, whereas increasing the resting K^+ conductance reduces it. Agents that do the reverse, by blocking

channels or interfering with their opening, will have the opposite effect. Some examples are shown inFigs **4.6** and **4.7**. Inherited mutations of channel proteins are responsible for a wide variety of neurological and other genetic disorders (see **Imbrici et al., 2016**).

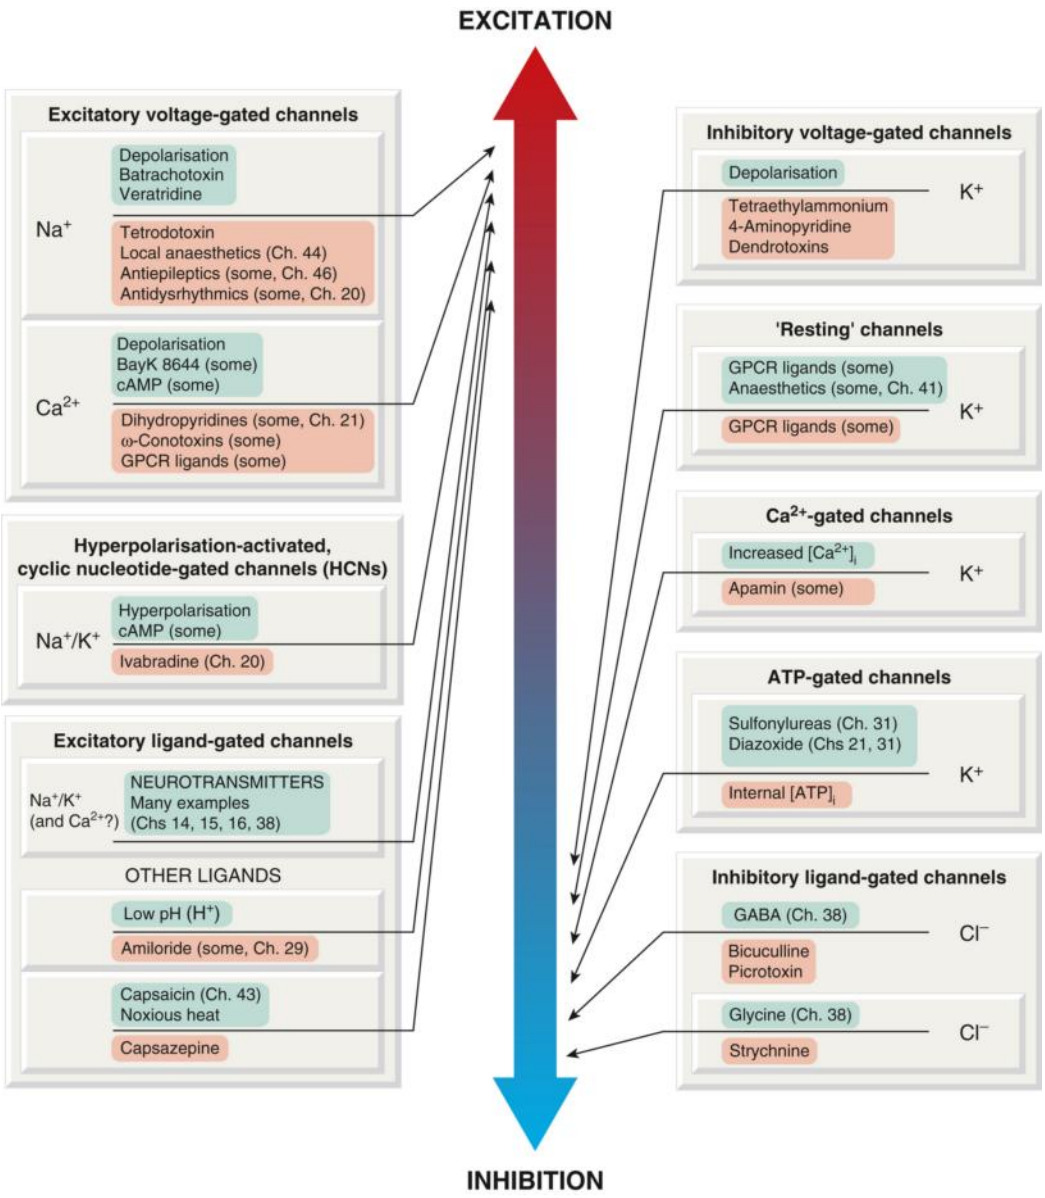

FIG. 4.6 Ion channels associated with excitatory and inhibitory membrane effects, and some of the drugs and other ligands that affect them.Channel openers are shown in *green boxes*, and blocking agents and inhibitors, in *pink boxes*. Hyperpolarisation-activated Na^+/K^+ channels are known as hyperpolarisation-activated, cyclic nucleotide-gated channels

(HCNs); H^+ activated channels are known as acid-sensing ion channels (ASICs). *GPCR,* G protein–coupled receptor.

Use Dependence and Voltage Dependence

Voltage-gated channels can exist in three functional states (**Fig. 4.8**): *resting* (the closed state that prevails at the normal resting potential), *activated* (the open state favoured by brief depolarisation) and *inactivated* (the blocked state resulting from a trapdoor-like occlusion of the open channel by a floppy intracellular appendage of the channel protein). After the action potential has passed, many sodium channels are in the inactivated state; after the membrane potential returns to its resting value, the inactivated channels take time to revert to the resting state and thus become available for activation once more. In the meantime, the membrane is temporarily *refractory*. Each action potential causes the channels to cycle through these states. The duration of the refractory period determines the maximum frequency at which action potentials can occur. Drugs that block sodium channels, such as local anaesthetics (see **Ch. 44**), antidysrhythmic drugs (see **Ch. 20**) and antiepileptic drugs (see **Ch. 46**), commonly show a selective affinity for one or other of these functional states of the channel, and in their presence the proportion of channels in the high-affinity state is increased. Of particular importance are drugs that bind most strongly to the inactivated state of the channel and thus favour the adoption of this state, prolonging the refractory period and reducing the maximum frequency at which action potentials can be generated. This type of block is called *use dependent*, because the binding of such drugs

increases as a function of the rate of action potential discharge, which governs the rate at which inactivated – and therefore drug-sensitive – channels are generated. This is important for some antidysrhythmic drugs (see **Ch. 20**) and for antiepileptic drugs (see **Ch. 46**), because high-frequency discharges can be inhibited without affecting excitability at normal frequencies. Drugs that readily block sodium channels in their resting state (e.g. some local anaesthetics, see **Ch. 44**) prevent excitation at low as well as high frequencies.

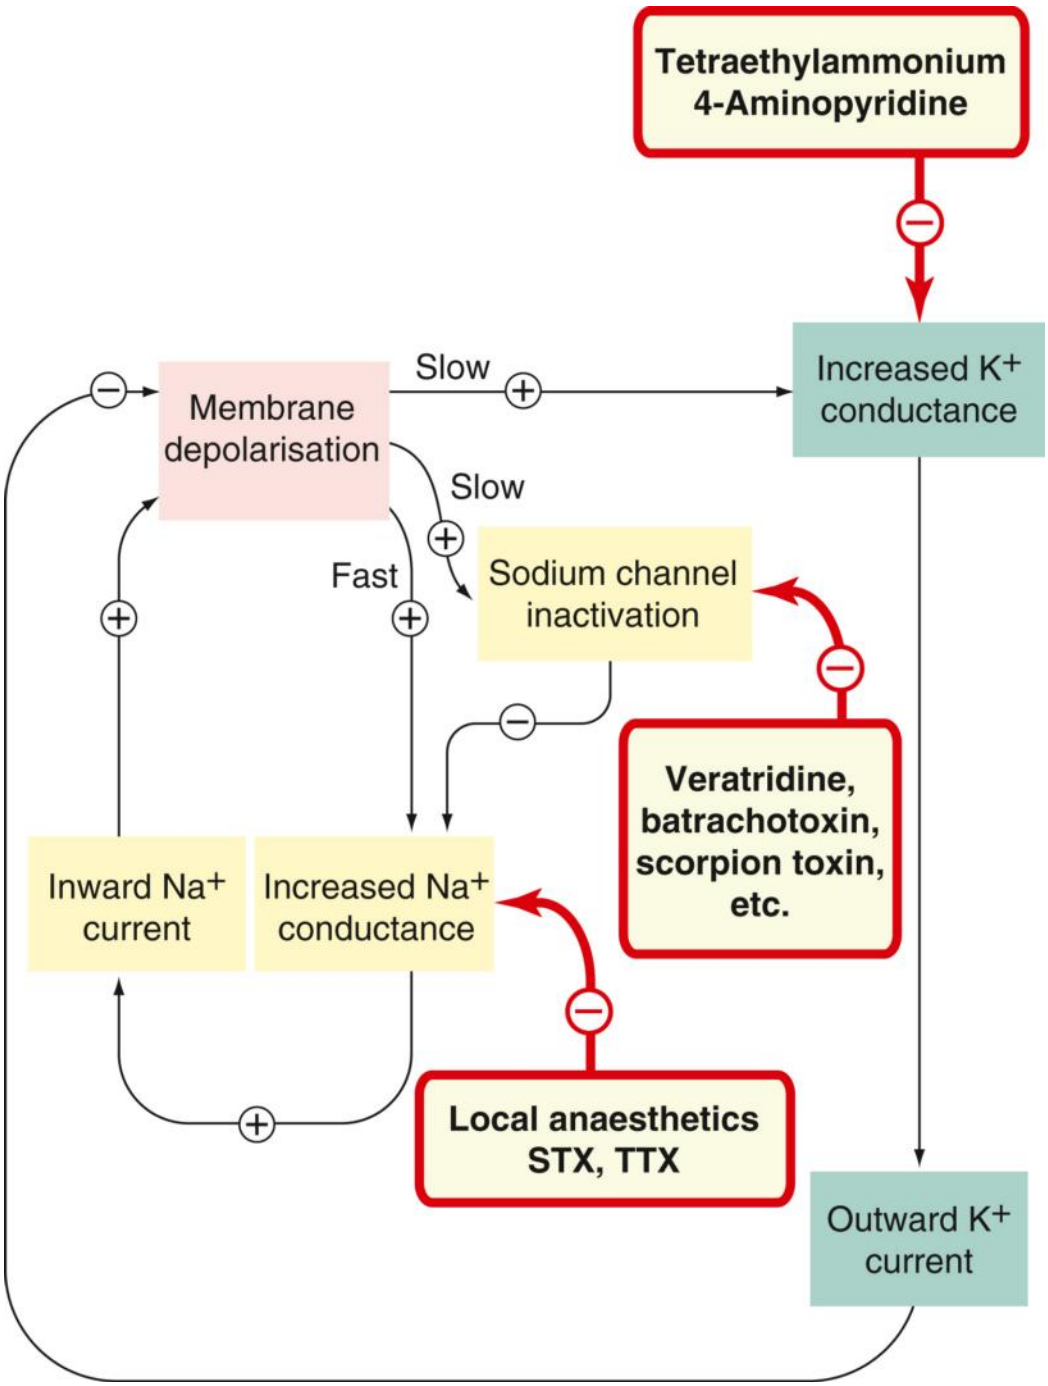

FIG. 4.7 Sites of action of drugs and toxins that affect channels involved in action potential generation.Many other mediators affect these channels indirectly via membrane receptors,

through phosphorylation or altered expression.
STX, Saxitoxin; *TTX,* tetrodotoxin.

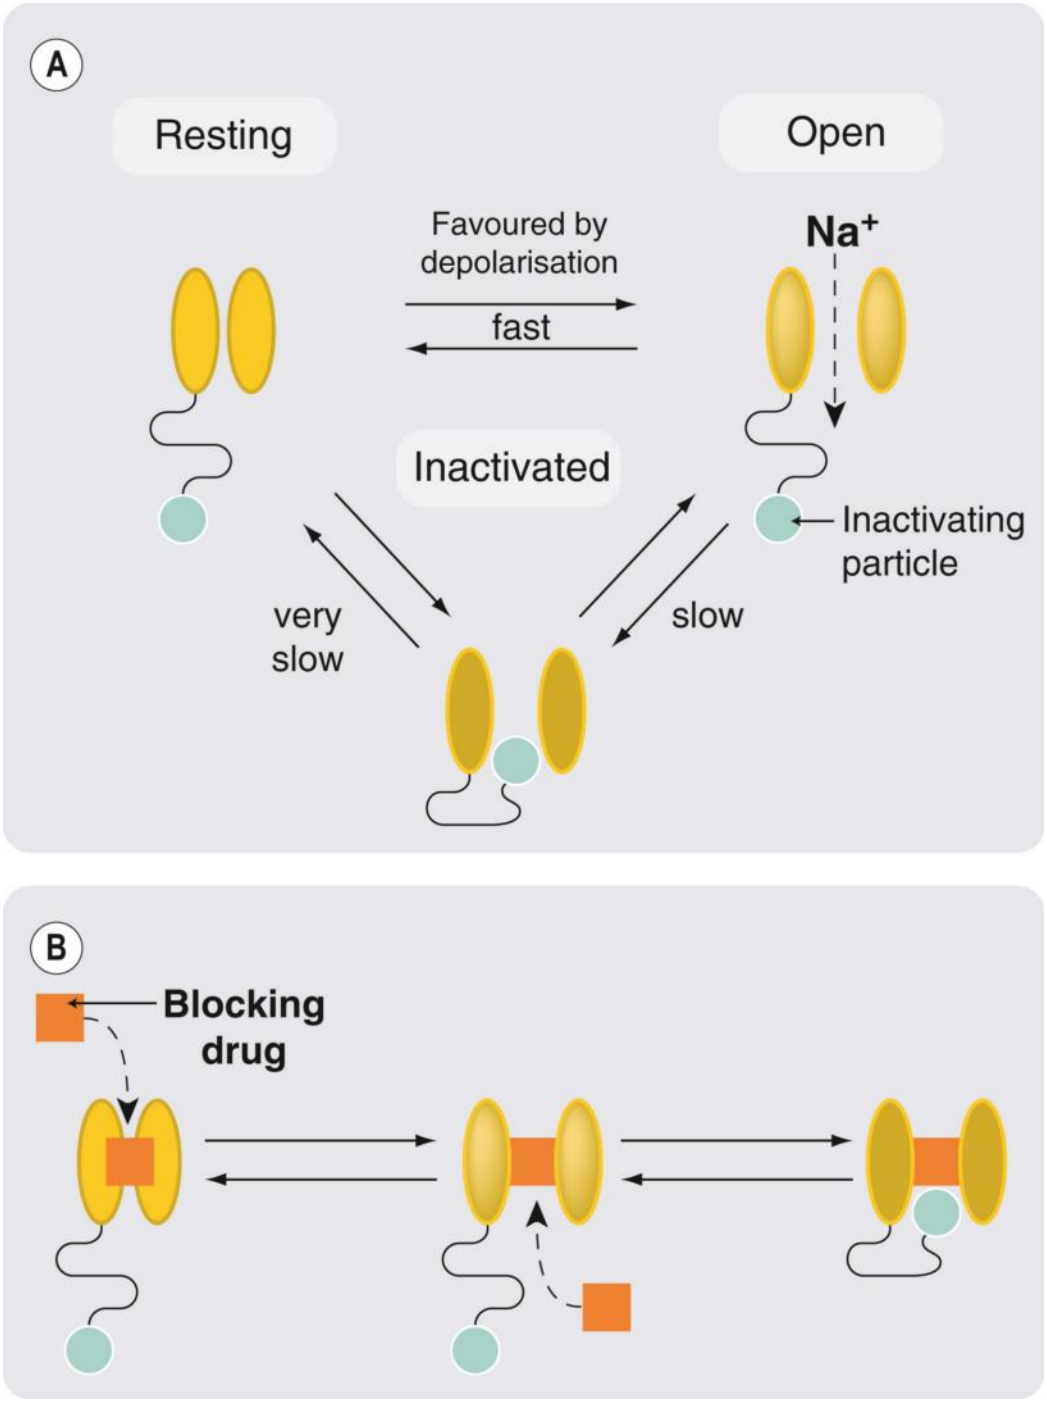

FIG. 4.8 Resting, activated and inactivated states of voltage-gated channels, exemplified by the sodium channel.(A) Membrane depolarisation causes a rapid transition from the resting (closed) state to the open state. The

inactivating particle (part of the intracellular domain of the channel protein) is then able to block the channel. With prolonged depolarisation below the threshold for opening, channels can go directly from resting to inactivated without opening. (B) Some blocking drugs (such as tetrodotoxin) block the channel from the outside like a plug, whereas others (such as local anaesthetics and antiepileptic drugs) enter from the inside of the cell and often show preference for the open or inactivated states, and thus affect the kinetic behaviour of the channels, with implications for their clinical application.

Most sodium channel-blocking drugs are cationic at physiological pH and are therefore affected by the voltage gradient across the cell membrane. Some drugs block the channel from the inside, so that their blocking action is favoured by depolarisation. This phenomenon, known as *voltage dependence*, is also of relevance to the action of antidysrhythmic and antiepileptic drugs, because the cells that are the seat of dysrhythmias or seizure activity are generally somewhat depolarised and therefore more strongly blocked than healthy cells. Similar considerations apply also to drugs that block potassium or calcium channels, but we know less about the importance of use and voltage dependence for these than we do for sodium channels.

Sodium Channels

In most excitable cells, the regenerative inward current that initiates the action potential results from activation of voltage-gated sodium channels. The early voltage clamp studies by Hodgkin and Huxley on the squid giant axon revealed the essential functional properties of these channels. Later, advantage was taken of the potent and highly selective blocking action of **tetrodotoxin** (TTX, see **Ch. 44**) to label and purify the channel proteins, and subsequently to clone them. Sodium channels consist of a central, pore-forming α subunit (shown in **Fig. 3.20**) and two auxiliary β subunits. Nine α-subunits ($Na_v1.1$ through $Na_v1.9$) and four β subunits have been identified in mammals. The α subunits contain four similar domains, each comprising six membrane-spanning helices (see **Catterall et al., 2020**). One of these helices, S4, which contains several basic amino acids and forms the voltage sensor, moves outwards, thus opening the channel, when the membrane is depolarised. One of the intracellular loops is designed to swing across and block the channel when S4 is displaced, thus inactivating the channel.

It was known from physiological studies that the sodium channels of heart and skeletal muscle differ in various ways from those of neurons. In particular, cardiac sodium channels (and those of some sensory neurons) are relatively insensitive to TTX and slower in their kinetics, compared with most neuronal sodium channels. This is explained by the relative insensitivity of some α subunits ($Na_v1.5$, $Na_v1.8$ and $Na_v1.9$) to TTX. Changes in the level of expression of some sodium channel subunits is thought to underlie the hyperexcitability of sensory neurons in different types of neuropathic pain (see **Ch. 43**).

In addition to channel-blocking compounds such as TTX, other compounds affect sodium channel gating. For example, the plant alkaloid **veratridine** and the frog skin poison **batrachotoxin** cause persistent activation, while various scorpion toxins prevent inactivation, mechanisms resulting in enhanced neuronal excitability.

Potassium Channels

In a typical resting cell (**Fig. 4.3**), the membrane is selectively permeable to K^+ and the membrane potential (about −60 mV) is somewhat positive to the K^+ equilibrium (about −90 mV). This resting permeability comes about because some potassium channels are open. If more potassium channels open, the membrane hyperpolarises and the cell is inhibited, whereas the opposite happens if potassium channels close. As well as affecting excitability in this way, potassium channels also play an important role in regulating the duration of the action potential and the temporal patterning of action potential discharges; altogether, these channels play a central role in regulating cell function. As mentioned in **Chapter 3**, the number and variety of potassium channel subtypes are extraordinary, implying that evolution has been driven by the scope for biological advantage to be gained from subtle variations in the functional properties of these channels. There are over 60 different pore-forming subunits, plus another 20 or so auxiliary subunits. An impressive evolutionary display, maybe, but hard going for most of us.

Potassium channels fall into three main classes (**Table 4.2**), [5] of which the structures are shown in **Fig. 3.20**.

- *Voltage-gated potassium channels*, which possess six membrane-spanning helices, one of which serves as the voltage sensor, causing the channel to open when the membrane is depolarised. Included in this group are channels responsible for most of the voltage-gated K^+ currents familiar to electrophysiologists, and others such as Ca^{2+}-activated potassium channels, and HERG channels important in the heart. Many of these channels are blocked by drugs such as **tetraethylammonium** and **4-aminopyridine.**
- *Inwardly rectifying potassium channels*, so called because they allow K^+ to pass inwards much more readily than outwards. These have two membrane-spanning helices and a single pore-forming loop (P loop). These channels are regulated by interaction with G proteins (see **Ch. 3**) and mediate the inhibitory effects of many agonists acting on G protein–coupled receptors. Certain types are important in the heart, particularly in regulating the duration of the cardiac action potential (see **Ch. 20**); others are the target for the action of **sulfonylureas** (antidiabetic drugs that stimulate insulin secretion by blocking them; see **Ch. 31**) and smooth muscle relaxant drugs, such as **minoxidil** and **diazoxide**, which open them (see **Ch. 21**).
- *Two-pore domain potassium channels*, with four helices and two P loops. These show outward rectification and therefore exert a strong repolarising influence, opposing any tendency to excitation. They may contribute to the resting K^+ conductance in many cells and are susceptible to regulation

via G proteins; certain subtypes have been implicated in the action of volatile anaesthetics such as **isoflurane** (see **Ch. 41**).

For more details, and information on potassium channels and the various drugs and toxins that affect them, see **Jenkinson (2006)** and **Alexander et al. (2021)**.

Inherited abnormalities of potassium channels (channelopathies) contribute to a rapidly growing number of cardiac, neurological and other diseases. These include the *long QT syndrome* associated with mutations in cardiac voltage-gated potassium channels, causing episodes of ventricular arrest that can result in sudden death. Drug-induced prolongation of the *QT* interval is an unwanted side effect of several drugs (see Chs **20** and **58**), including **methadone** and various antipsychotic agents. Nowadays, new drugs are screened for this property at an early stage in the development process (see **Ch. 60**). Certain familial types of deafness and epilepsy are associated with mutations in voltage-gated potassium channels (**Imbrici et al., 2016**).

Ion channels and electrical excitability

- Excitable cells generate an all-or-nothing action potential in response to membrane depolarisation. This occurs in most neurons and muscle cells, and in some gland cells. The ionic basis and time course of the response varies between tissues.
- The regenerative response results from the depolarising current associated with opening of voltage-gated cation

channels (mainly Na^+ and Ca^{2+}). It is terminated by inactivation of these channels accompanied by opening of K^+ channels.

- These voltage-gated channels exist in many molecular varieties, with specific functions in different types of cell.
- The membrane of the 'resting' cell is relatively permeable to K^+ but impermeable to Na^+ and Ca^{2+}. Drugs or mediators that open K^+ channels reduce membrane excitability, as do inhibitors of Na^+ or Ca^{2+} channel function. Blocking K^+ channels or activating Na^+ or Ca^{2+} channels increases excitability.
- Cardiac muscle cells, some neurons and some smooth muscle cells generate spontaneous action potentials whose amplitude, rate and rhythm are affected by drugs that affect ion channel function.

Table 4.2

GPCR, G protein–coupled receptor; HERG, human ether-a-go-go related gene; *LQT,* longQT syndrome.

[a] K^+ channel structures (see **Fig. 3.20**) are defined according to the number of transmembrane helices (T) and the number of pore-forming loops (P) in each α subunit. Functional channels contain several subunits (often four) which may be identical or different, and they are often associated with accessory (β) subunits.

[b] Within each functional subtype, several molecular variants have been identified, often restricted to particular cells and tissues. The physiological and pharmacological significance of this heterogeneity is not yet understood.

Muscle Contraction

The effects of drugs on the contractile machinery of smooth muscle are the basis of many therapeutic applications, for smooth muscle is an important component of most physiological systems, including blood vessels and the gastrointestinal, respiratory and urinary tracts. For many decades, smooth muscle pharmacology with its trademark technology – the isolated organ bath – held the centre of the pharmacological stage, and neither the subject nor the technology shows any sign of flagging, even though the stage has become much more crowded. Cardiac and skeletal muscle contractility is also the target of important drug effects.

Although in each case the basic molecular basis of contraction is similar, namely an interaction between actin and myosin, fuelled by

ATP and initiated by an increase in $[Ca^{2+}]_i$, there are differences among these three kinds of muscle that account for their different responsiveness to drugs and chemical mediators.

These differences (**Fig. 4.9**) involve (1) the linkage between membrane events and increase in $[Ca^{2+}]_i$ and (2) the mechanism by which $[Ca^{2+}]_i$ regulates contraction.

Skeletal Muscle

Skeletal muscle possesses an array of transverse T-tubules extending into the cell from the plasma membrane. The action potential of the plasma membrane depends on voltage-gated sodium channels, as in most nerve cells, and propagates rapidly from its site of origin, the motor endplate (see **Ch. 14**), to the rest of the fibre. The T-tubule membrane contains voltage-gated calcium channels termed *dihydropyridine receptors* (DHPRs), [6] that respond to membrane depolarisation conducted passively along the T-tubule when the plasma membrane is invaded by an action potential. DHPRs are located extremely close to *RyRs* (see **Ch. 3**) in the adjacent SR membrane and activation of these RyRs causes release of Ca^{2+} from the SR. Direct coupling between the DHPRs of the T-tubule and the RyRs of the SR (as shown in **Fig. 4.9**) causes the opening of the RyRs on membrane depolarisation. Through this link, depolarisation rapidly activates the RyRs, releasing a short puff of Ca^{2+} from the SR into the sarcoplasm. The Ca^{2+} binds to troponin, a protein that normally blocks the interaction between actin and myosin. When Ca^{2+} binds, troponin moves out of the way and allows the contractile machinery to operate. Ca^{2+} release is rapid and brief, and the muscle responds with a short-lasting

'twitch' response. This is a relatively fast and direct mechanism compared with the arrangement in cardiac and smooth muscle (see later), and consequently less susceptible to pharmacological modulation.

Cardiac Muscle

Cardiac muscle differs from skeletal muscle in several important respects. The nature of the cardiac action potential, the ionic mechanisms underlying its inherent rhythmicity and the effects of drugs on the rate and rhythm of the heart are described in **Chapter 20**. The cardiac action potential varies in its configuration in different parts of the heart, but commonly shows a plateau lasting several hundred milliseconds following the initial rapid depolarisation. T-tubules in cardiac muscle contain L-type calcium channels, which open during this plateau and allow Ca^{2+} to enter. This Ca^{2+} entry acts on RyRs (a different molecular type from those of skeletal muscle) to release Ca^{2+} from the SR (see **Fig. 4.9**). With minor differences, the subsequent mechanism by which Ca^{2+} activates the contractile machinery is the same as in skeletal muscle. Ca^{2+}-induced Ca^{2+} release via RyRs may play a role in some forms of cardiac arrhythmia. Mutations of RyRs are implicated in various disorders of skeletal and cardiac muscle function (see **Priori and Napolitano, 2005**).

Smooth Muscle

The properties of smooth muscle vary considerably in different organs, and the mechanisms linking membrane events and contraction are correspondingly variable and more complex than in

other kinds of muscle. Spontaneous rhythmic activity occurs in many organs, by mechanisms producing oscillations of $[Ca^{2+}]_i$ (see **Fig. 4.2B**). The action potential of smooth muscle is generally a rather lazy and vague affair compared with the more military behaviour of skeletal and cardiac muscle, and it propagates through the tissue much more slowly and uncertainly. The action potential is, in most cases, generated by L-type calcium channels rather than by voltage-gated sodium channels, and this is one important route of Ca^{2+} entry. In addition, many smooth muscle cells possess P2X receptors, ligand-gated cation channels, which allow Ca^{2+} entry when activated by ATP released from autonomic nerves (see **Ch. 13**). Smooth muscle cells also store Ca^{2+} in the ER, from which it can be released when the IP_3R is activated (see **Ch. 3**). IP_3 is generated by activation of many types of G protein–coupled receptor. Thus in contrast to skeletal and cardiac muscle, Ca^{2+} release and contraction can occur in smooth muscle when such receptors are activated without necessarily involving depolarisation and Ca^{2+} entry through the plasma membrane. RyRs are also present in many smooth muscle cells, and calcium-induced Ca^{2+} release via these channels may play a role in generating muscle contraction (see **Fig. 4.9**) or couple to plasma membrane calcium-activated K^+ channels resulting in cell hyperpolarisation, thereby reducing Ca^{2+} entry through voltage-gated calcium channels (**Fig. 4.10**).

The contractile machinery of smooth muscle is activated when the *myosin light chain* undergoes phosphorylation, causing it to become detached from the actin filaments. This phosphorylation is catalysed by a kinase, *myosin light-chain kinase* (MLCK), which is

activated when it binds to Ca^{2+}–calmodulin (**Fig. 4.9**). A second enzyme, *myosin phosphatase*, reverses the phosphorylation and causes relaxation. The activity of MLCK and myosin phosphatase thus exerts a balanced effect, promoting contraction and relaxation, respectively. Both enzymes are regulated by cyclic nucleotides (cAMP and cGMP; see **Ch. 3**), and many drugs that cause smooth muscle contraction or relaxation mediated through G protein–coupled receptors or through guanylyl cyclase-linked receptors act in this way. **Fig. 4.10** summarises the main mechanisms by which drugs control smooth muscle contraction. The complexity of these control mechanisms and interactions explains why pharmacologists have been entranced for so long by smooth muscle. Many therapeutic drugs work by contracting or relaxing smooth muscle, particularly those affecting the cardiovascular, respiratory and gastrointestinal systems, as discussed in later chapters, where details of specific drugs and their physiological effects are given.

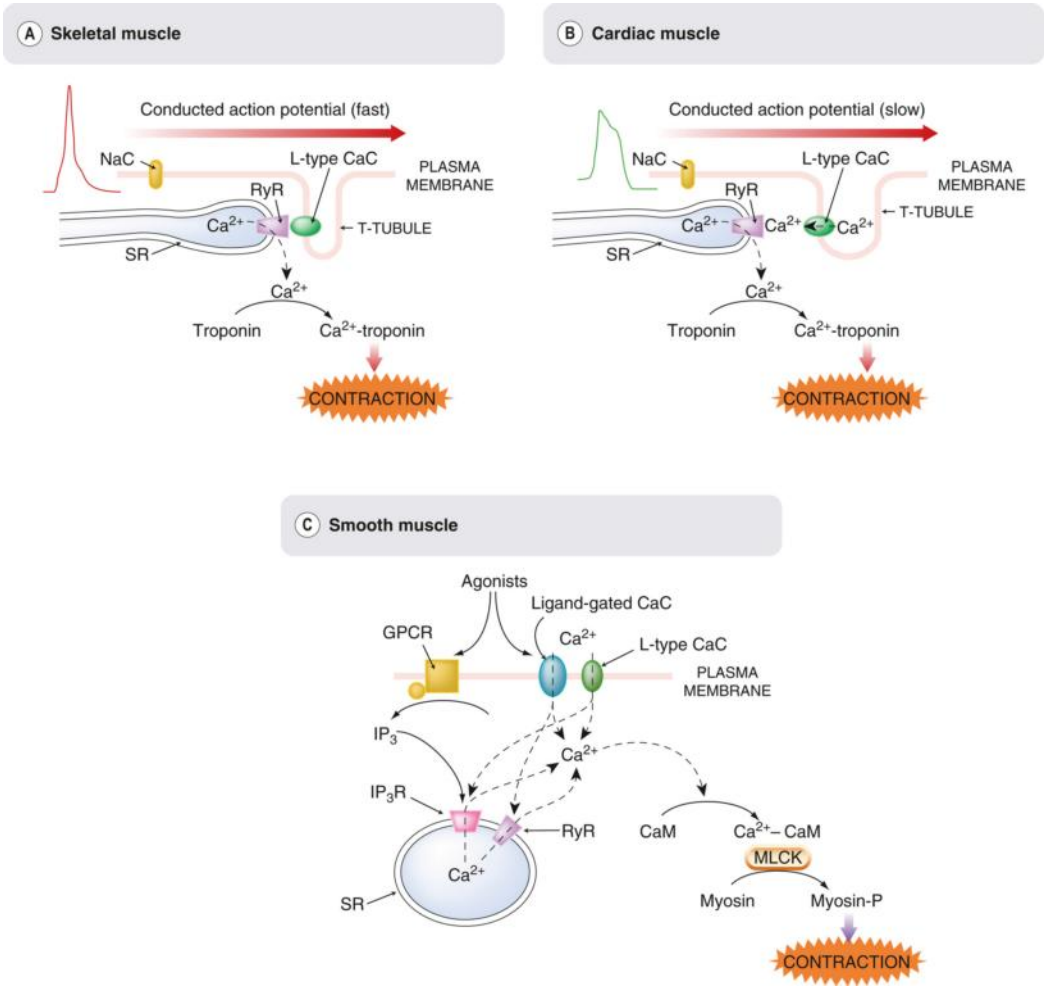

FIG. 4.9 Comparison of excitation–contraction coupling in (A) skeletal muscle, (B) cardiac muscle and (C) smooth muscle.Skeletal and cardiac muscle differ mainly in the mechanism by which membrane depolarisation is coupled to Ca^{2+} release. The calcium channel (CaC) and ryanodine receptor (RyR) are very closely positioned in both types of muscle. In cardiac muscle, Ca^{2+} entry via voltage-gated calcium channels initiates Ca^{2+} release through activation of the Ca^{2+}-sensitive RyRs, whereas in skeletal muscle the sarcolemmal calcium

channels activate the RyRs through a voltage-dependent physical interaction. The control of intracellular Ca^{2+} in smooth muscle cells may vary depending upon the type of smooth muscle. In general terms, smooth muscle contraction is largely dependent upon inositol trisphosphate (IP_3)-induced Ca^{2+} release from SR stores through IP_3 receptors (IP_3R). Smooth muscle contraction can also be produced either by Ca^{2+} entry through voltage- or ligand-gated calcium channels. The mechanism by which Ca^{2+} activates contraction is different, and operates more slowly, in smooth muscle compared with in skeletal or cardiac muscle. *CaM,* Calmodulin; *GPCR,* G protein–coupled receptor; *MLCK,* myosin light-chain kinase; *NaC,* voltage-gated sodium channel; *SR,* sarcoplasmic reticulum.

Muscle contraction

- Muscle contraction occurs in response to a rise in $[Ca^{2+}]_i$.
- In skeletal muscle, depolarisation causes rapid Ca^{2+} release from the sarcoplasmic reticulum (SR); in cardiac muscle, Ca^{2+} enters through voltage-gated channels, and this initial entry triggers further release from the SR; in smooth muscle, the Ca^{2+} signal is due partly to Ca^{2+} entry and partly to inositol trisphosphate (IP_3)-mediated release from the SR.

- In smooth muscle, contraction can occur without action potentials, for example, when agonists at G protein–coupled receptors lead to IP_3 formation.
- Activation of the contractile machinery in smooth muscle involves phosphorylation of the myosin light chain, a mechanism that is regulated by a variety of second messenger systems.

Release of Chemical Mediators

Much of pharmacology is based on interference with the body's own chemical mediators, particularly neurotransmitters, hormones and inflammatory mediators. Here we discuss some of the common mechanisms involved in the release of such mediators, and it will come as no surprise that Ca^{2+} plays a central role. Drugs and other agents that affect the various control mechanisms that regulate $[Ca^{2+}]_i$ will therefore also affect mediator release, and this accounts for many of the physiological effects that they produce.

Chemical mediators that are released from cells fall into two main groups (**Fig. 4.11**):

- Mediators that are preformed and packaged in storage vesicles – sometimes called storage granules – from which they are released by *exocytosis*. This large group comprises all the conventional neurotransmitters and neuromodulators (see Chs **13** and **37**), and many hormones. It also includes secreted proteins such as cytokines and various growth factors (see **Ch. 17**).
- Mediators that are produced on demand and are released by diffusion or by membrane carriers. [7] This group includes nitric oxide (see **Ch. 19**) and many lipid mediators (e.g. prostanoids, see **Ch. 17**) and endocannabinoids (see **Ch. 18**), which are released from the postsynaptic cell to act on nerve terminals in a retrograde manner.

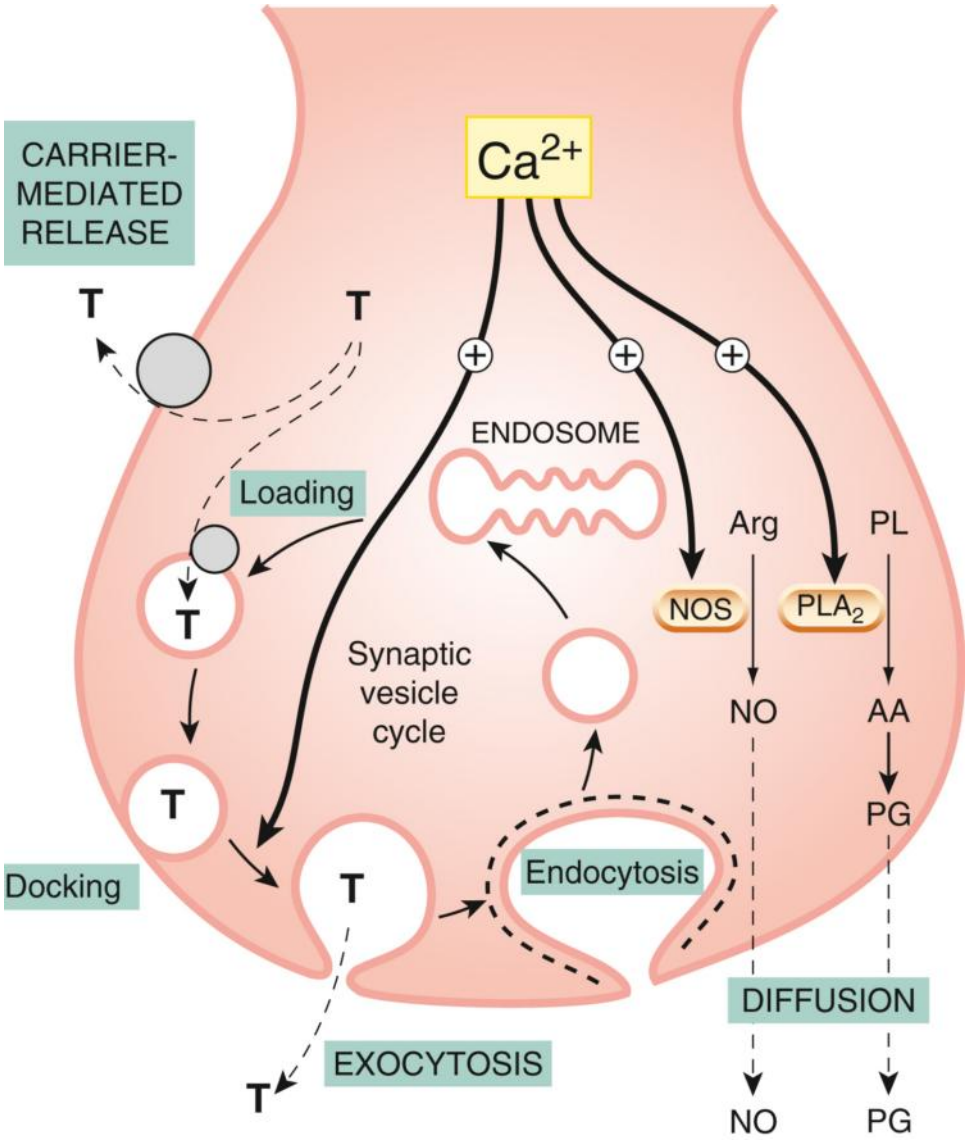

FIG. 4.11 Role of exocytosis, carrier-mediated transport and diffusion in mediator release.The main mechanism of release of monoamine and peptide mediators is Ca^{2+}-mediated exocytosis, but carrier-mediated release from the cytosol also occurs. T represents a typical amine transmitter, such as noradrenaline (norepinephrine) or 5-hydroxytryptamine.

Nitric oxide (NO) and prostaglandins (PGs) are released by diffusion as soon as they are formed, from arginine (Arg) and arachidonic acid (AA), respectively, through the action of Ca^{2+}-activated enzymes, nitric oxide synthase (NOS) and phospholipase A_2 (PLA_2) (see Chs **17** and **19** for more details).

Calcium ions play a key role in both cases, because a rise in $[Ca^{2+}]_i$ initiates exocytosis and is also the main activator of the enzymes responsible for the synthesis of diffusible mediators.

In addition to mediators that are released from cells, some are formed from precursors in the plasma, two important examples being *kinins* (see **Ch. 17**) and *angiotensin* (see **Ch. 21**), which are peptides produced by protease-mediated cleavage of circulating proteins.

Exocytosis

Exocytosis, occurring in response to an increase of $[Ca^{2+}]_i$, is the principal mechanism of transmitter release (see **Fig. 4.11**) in the peripheral and central nervous systems, as well as in endocrine cells and mast cells. The secretion of enzymes and other proteins by gastrointestinal and exocrine glands and by vascular endothelial cells is also basically similar. Exocytosis (see **Thorn et al., 2016**) involves fusion between the membrane of synaptic vesicles and the inner surface of the plasma membrane. The vesicles are preloaded with stored transmitter, and release occurs in discrete packets, or quanta, each representing release from a single vesicle. The first

evidence for this came from the work of Katz and his colleagues in the 1950s, who recorded spontaneous 'miniature endplate potentials' at the frog neuromuscular junction and showed that each resulted from the spontaneous release of a packet of the transmitter, acetylcholine. [8] They also showed that release evoked by nerve stimulation occurred by the synchronous release of several hundred such quanta and was highly dependent on the presence of Ca^{2+} in the bathing solution. Unequivocal evidence that the quanta represented vesicles releasing their contents by exocytosis came from electron microscopic studies, in which the tissue was rapidly frozen in mid-release, revealing vesicles in the process of extrusion, and from elegant electrophysiological measurements showing that membrane capacitance (reflecting the area of the presynaptic membrane) increased in a stepwise manner as each vesicle fused and then gradually returned as the vesicle membrane was recovered from the surface. There is also biochemical evidence showing that, in addition to the transmitter, other constituents of the vesicles are released at the same time.

In nerve terminals specialised for fast synaptic transmission, Ca^{2+} enters through voltage-gated calcium channels, mainly of the N and P/Q type (**Table 4.1**), and the synaptic vesicles are 'docked' at active zones – specialised regions of the presynaptic membrane from which exocytosis occurs, situated close to the relevant calcium channels and opposite receptor-rich zones of the postsynaptic membrane. Elsewhere, where speed is less critical, Ca^{2+} may come from intracellular stores and the spatial organisation of active zones is less clear. It is common for secretory cells, including neurons, to release more than one mediator (for example, a 'fast' transmitter

such as glutamate and a ‘slow’ transmitter such as a neuropeptide) from different vesicle pools (see **Ch. 13**). The fast transmitter vesicles are located close to active zones, while the slow transmitter vesicles are further away. Release of the fast transmitter, because of the tight spatial organisation, occurs as soon as the neighbouring calcium channels open, before the Ca^{2+} has a chance to diffuse throughout the terminal, whereas release of the slow transmitter requires the Ca^{2+} to diffuse more widely. As a result, release of fast transmitters occurs impulse by impulse, even at low stimulation frequencies, whereas release of slow transmitters builds up only at higher stimulation frequencies. The release rates of the two therefore depend critically on the frequency and patterning of firing of the presynaptic neuron (**Fig. 4.12**). In non-excitable cells (e.g. most exocrine and endocrine glands), the slow mechanism predominates and is activated mainly by Ca^{2+} release from intracellular stores.

Calcium causes exocytosis by binding to the vesicle-bound protein synaptotagmin, and this favours association between a second vesicle-bound protein, *synaptobrevin*, and a related protein, *syntaxin*, on the inner surface of the plasma membrane. This association brings the vesicle membrane into close apposition with the plasma membrane, causing membrane fusion. This group of proteins, known collectively as SNAREs, plays a key role in exocytosis.

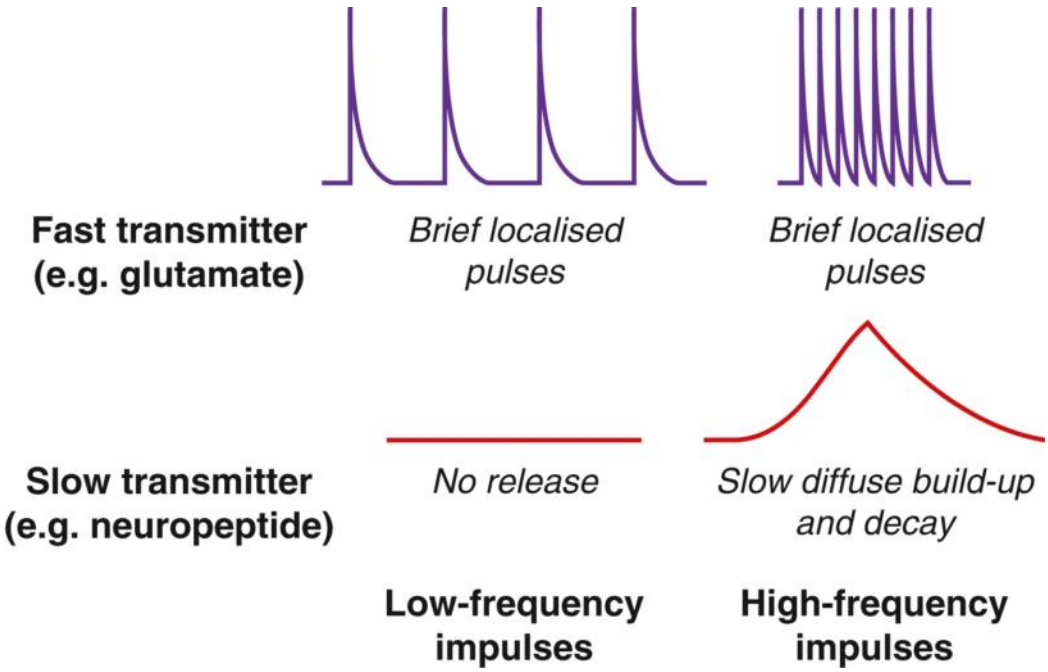

FIG. 4.12 Time course and frequency dependence of the release of 'fast' and 'slow' transmitters.Fast transmitters (e.g. glutamate) are stored in synaptic vesicles that are 'docked' close to voltage-gated calcium channels in the membrane of the nerve terminal and are released in a short burst when the membrane is depolarised (e.g. by an action potential). Slow transmitters (e.g. neuropeptides) are stored in separate vesicles further from the membrane. Release is slower, because they must first migrate to the membrane, and occurs only when $[Ca^{2+}]_i$ builds up sufficiently.

Having undergone exocytosis, the empty vesicle [9] is recaptured by endocytosis and returns to the interior of the terminal, where it fuses with the larger endosomal membrane. The endosome buds off

new vesicles, which take up transmitter from the cytosol by means of specific transport proteins and are again docked on the presynaptic membrane. This sequence, which typically takes several minutes, is controlled by various trafficking proteins associated with the plasma membrane and the vesicles, as well as cytosolic proteins. So far, there are few examples of drugs that affect transmitter release by interacting with synaptic proteins, although the botulinum neurotoxins (see **Ch. 14**) produce their effects by proteolytic cleavage of SNARE proteins.

Non-Vesicular Release Mechanisms

If this neat and tidy picture of transmitter packets ready and waiting to pop obediently out of the cell in response to a puff of Ca^{2+} seems a little too good to be true, rest assured that the picture is not quite so simple. Acetylcholine, noradrenaline (norepinephrine) and other mediators can leak out of nerve endings from the cytosolic compartment, independently of vesicle fusion, by utilising carriers in the plasma membrane (see **Fig. 4.11**). Drugs such as **amphetamines**, which release amines from central and peripheral nerve terminals (see Chs **15** and **39**), do so by displacing the endogenous amine from storage vesicles into the cytosol, whence it escapes via the monoamine transporter in the plasma membrane, a mechanism that does not depend on Ca^{2+}. [10]

Nitric oxide (see **Ch. 19**), arachidonic acid metabolites (e.g. prostaglandins; see **Ch. 17**) and endocannabinoids (see **Ch. 18**) are important examples of mediators that are released from the cytosol by diffusion across the membrane or by carrier-mediated extrusion, rather than by exocytosis. The mediators are not stored but escape

from the cell as soon as they are synthesised. In each case, the synthetic enzyme(s) is activated by Ca^{2+}, and the moment-to-moment control of the rate of synthesis depends on $[Ca^{2+}]_i$. This kind of release is necessarily slower than the classic exocytotic mechanism, but in the case of nitric oxide is fast enough for it to function as a true transmitter (see **Fig. 13.5** and **Ch. 19**).

Mediator release

- Most chemical mediators are packaged into storage vesicles and released by exocytosis. Some are not stored but synthesised on demand and released by diffusion or the operation of membrane carriers.
- Exocytosis occurs in response to increased $[Ca^{2+}]_i$ as a result of a Ca^{2+}-mediated interaction between proteins of the synaptic vesicle and the plasma membrane, causing the membranes to fuse.
- After releasing their contents, vesicles are recycled and reloaded with transmitter.
- Many secretory cells contain more than one type of vesicle, loaded with different mediators and secreted independently.
- Stored mediators (e.g. neurotransmitters) may be released directly from the cytosol independently of Ca^{2+} and exocytosis, by drugs that interact with membrane transport mechanisms.
- Non-stored mediators, such as prostanoids, nitric oxide and endocannabinoids, are released by increased $[Ca^{2+}]_i$, which activates the enzymes responsible for their synthesis.

Epithelial Ion Transport

Fluid-secreting epithelia include the renal tubule, salivary glands, gastrointestinal tract and airways epithelia. In each case, epithelial cells are arranged in sheets separating the interior (blood-perfused) compartment from the exterior lumen compartment, into which, or from which, secretion takes place. Fluid secretion involves two main mechanisms, which often co-exist in the same cell and indeed interact with each other. The two mechanisms (**Fig. 4.13**) are concerned, respectively, with Na^+ transport and Cl^- transport.

In the case of Na^+ transport, secretion occurs because Na^+ enters the cell passively at one end and is pumped out actively at the other, with water following passively. Critical to this mechanism is a class of highly regulated epithelial sodium channels (ENaCs) that allow Na^+ entry.

ENaCs (see **Hanukoglu, 2021**) are widely expressed, not only in epithelial cells but also in neurons and other excitable cells, where their function is largely unknown. They are regulated mainly by aldosterone, a hormone produced by the adrenal cortex that enhances Na^+ reabsorption by the kidney (see **Ch. 29**). Aldosterone, like other steroid hormones, exerts its effects by regulating gene expression (see **Ch. 3**), and causes an increase in ENaC expression, thereby increasing the rate of Na^+ and fluid transport. ENaCs are selectively blocked by certain diuretic drugs, notably **amiloride** (see **Ch. 29**), a compound that is widely used to study the functioning of ENaCs in other situations.

FIG. 4.13 Generalised mechanisms of epithelial ion transport.Such mechanisms are important in renal tubules (see **Ch. 29** for more details) and in many other situations, such as the gastrointestinal and respiratory tracts. The exact mechanism may vary from tissue to tissue depending upon channel and pump expression and location. (A) Sodium transport. A special type of epithelial sodium channel (ENaC) controls entry of Na^+ into the cell from the lumenal surface, the Na^+ being actively pumped out at the apical surface by the Na^+–K^+ exchange pump. K^+ moves passively via potassium channels. (B) Chloride transport. Cl^- leaves the cell via a special membrane channel, the cystic fibrosis transmembrane conductance regulator (CFTR), after entering the cell either from the apical surface via the Na^+/Cl^- co-transporter, or at the lumenal surface via the Cl^-/HCO_3^- co-transporter.

Chloride transport is particularly important in the airways and gastrointestinal tract. In the airways it is essential for fluid secretion, whereas in the colon it mediates fluid reabsorption, the difference being due to the different arrangement of various transporters and channels with respect to the polarity of the cells. The simplified diagram in **Fig. 4.13B** represents the situation in the pancreas, where secretion depends on Cl^- transport. The key

molecule in Cl^- transport is the *cystic fibrosis transmembrane conductance regulator* (CFTR), so named because early studies on the inherited disorder cystic fibrosis showed it to be associated with impaired Cl^- conductance in the membrane of secretory epithelial cells, and the CFTR gene, identified through painstaking genetic linkage studies and isolated in 1989, was found to encode a Cl^--conducting ion channel. Severe physiological consequences follow from CFTR mutations and the resulting impairment of secretion, particularly in the airways but also in many other systems, such as sweat glands and pancreas. Studies on the disease-associated mutations of the CFTR gene (see **Ch. 28**) have revealed much about the molecular mechanisms involved in Cl^- transport (**Wang et al., 2014**).

Both Na^+ and Cl^- transport is regulated by intracellular messengers, notably by Ca^{2+} and cAMP, the latter exerting its effects by activating protein kinases and thereby causing phosphorylation of channels and transporters. CFTR itself is activated by cAMP. In the gastrointestinal tract, increased cAMP formation causes a large increase in the rate of fluid secretion, an effect that leads to the copious diarrhoea produced by cholera infection (see **Ch. 3**) and by inflammatory conditions in which prostaglandin formation is increased (see **Ch. 17**). Activation of G protein–coupled receptors, which causes release of Ca^{2+}, also stimulates secretion, possibly also by activating CFTR. Many examples of therapeutic drugs that affect epithelial secretion by activating or blocking G protein–coupled receptors appear in later chapters.

Epithelial ion transport

- Many epithelia (e.g. renal tubules, exocrine glands and airways) are specialised to transport specific ions.
- This type of transport depends on a special class of ENaCs which allow Na^+ entry into the cell at one surface, coupled to active extrusion of Na^+, or exchange for another ion, from the opposite surface.
- Anion transport depends on a specific chloride channel (the CFTR), mutations of which result in cystic fibrosis.
- The activity of channels, pumps and exchange transporters is regulated by various second messengers and nuclear receptors, which control the transport of ions in specific ways.

QUESTIONS

QUESTION 4.1

Calcium (Ca^{2+}) is a major regulator of cell function and many drugs and physiological mechanisms operate, directly or indirectly, by influencing intracellular calcium concentrations $[Ca^{2+}]_i$.

Which of the following statements about physiological calcium concentrations is correct?

OPTIONS:

A. The Ca^{2+} concentration in extracellular fluid, $[Ca^{2+}]_o$, is about 2.4 nmol/L, the free intracellular $[Ca^{2+}]_i$ is about 100 nmol/L.

B. The Ca^{2+} concentration in extracellular fluid, $[Ca^{2+}]_o$, is about 2.4 mmol/L, the free intracellular $[Ca^{2+}]_i$ is about 100 mmol/L.

C. The Ca^{2+} concentration in extracellular fluid, $[Ca^{2+}]_o$, is about 100 mmol/L, the free intracellular $[Ca^{2+}]_i$ is about 2.4 nmol/L.

D. The Ca^{2+} concentration in extracellular fluid, $[Ca^{2+}]_o$, is about 100 nmol/L, the free intracellular $[Ca^{2+}]_i$ is about 2.4 mmol/L.

E. The Ca^{2+} concentration in extracellular fluid, $[Ca^{2+}]_o$, is about 2.4 mmol/L, the free intracellular $[Ca^{2+}]_i$ is about 100 nmol/L.

QUESTION 4.2

Free intracellular concentrations of calcium are kept low by tight regulation of calcium entry and calcium release from intracellular stores.

Activation of which of the following receptors triggers calcium release from intracellular stores?

OPTIONS:

A. N-methyl-d-aspartate (NMDA) receptors

B. P2X receptors

C. T channels

D. Gq coupled receptors

E. Transient receptor potential (TRP) channels

QUESTION 4.3

Which of the following statements about the involvement of Na^+ channels in the action potential is incorrect?

OPTIONS:

A. Resting membrane potential in most cell types lies between about −30 and −80 mV.

B. An action potential is initiated by a rapid, transient increase in Na^+ permeability followed by a slower, sustained increase in K^+ permeability.

C. After the action potential has passed, many sodium channels are in the resting state and are refractory to further activation.

D. Use-dependent drugs prolong the refractory period.

E. Local anaesthetics block the resting state.

QUESTION 4.4

Calcium plays a central role in the release of many endogenous chemical mediators.

Which of the following mechanisms is not calcium dependent?

OPTIONS:

A. Fast synaptic transmission in nerve terminals

B. Amphetamine-mediated neurotransmitter release

C. Mediator release from endocrine and exocrine glands

D. Nitric oxide transmitter function

E. Chloride transport in the lung epithelia

ANSWERS

ANSWER 4.1

RATIONALE:

A. The Ca^{2+} concentration in extracellular fluid, $[Ca^{2+}]_o$, is about 2.4 mmol/L, so there is a large concentration gradient favouring Ca^{2+} entry.

B. Most of the Ca^{2+} in a resting cell is sequestered in organelles, particularly the *endoplasmic* or *sarcoplasmic reticulum* (ER or SR) and the mitochondria, and the free $[Ca^{2+}]_i$ is kept to a low level, about 100 nmol/L.

C. Most of the Ca^{2+} in a resting cell is sequestered in organelles, particularly the *endoplasmic* or *sarcoplasmic reticulum* (ER or SR) and the mitochondria, and the free $[Ca^{2+}]_i$ is kept to a low level, about 100 nmol/L. The Ca^{2+} concentration in extracellular fluid, $[Ca^{2+}]_o$, is about 2.4 mmol/L, so there is a large concentration gradient favouring Ca^{2+} entry.

D. Most of the Ca^{2+} in a resting cell is sequestered in organelles and the free $[Ca^{2+}]_i$ is kept to a low level, about 100 nmol/L. The Ca^{2+} concentration in extracellular fluid, $[Ca^{2+}]_o$, is about 2.4 mmol/L, so there is a large concentration gradient favouring Ca^{2+} entry.

E.

CORRECT ANSWER WITH EXPLANATION:

E. The Ca^{2+} concentration in extracellular fluid, $[Ca^{2+}]_o$, is about 2.4 mmol/L, the free intracellular $[Ca^{2+}]_i$ is about 100 nmol/L.

Free $[Ca^{2+}]_i$ is kept low (a) by the operation of active transport mechanisms that eject cytosolic Ca^{2+} through the plasma membrane and pump it into the ER and (b) by the normally low Ca^{2+} permeability of the plasma and ER membranes.

ANSWER 4.2

RATIONALE:

A. NMDA (glutamate) receptors have a particularly high permeability to Ca^{2+} and are a major contributor to Ca^{2+} uptake by postsynaptic neurons in the central nervous system. Activation of this receptor can readily cause so much Ca^{2+} entry that the cell dies, mainly through activation of Ca^{2+}-dependent proteases but also by triggering *apoptosis*.

B. The P_2X receptor activated by ATP is the only example of a true ligand-gated channel in smooth muscle, and this constitutes an important route for Ca^{2+} entry.

C. T-channel currents mediate Ca^{2+} entry into neurons around the resting membrane potential and can control the rate of repolarisation of neurons and cardiac cells, as well as various

Ca^{2+}-dependent functions such as regulation of other ion channels, enzymes.

D.

E. TRP channels are permeable to Ca^{2+} as well as Na^+ and K^+. Different TRP channels respond to different stimuli and can be chemically or physically activated.

CORRECT ANSWER WITH EXPLANATION:

D. Gq coupled receptors

Gq coupled receptors increase calcium levels indirectly by the generation of IP_3 which triggers activation of IP_3 receptors on the ER and SR to release stored calcium.

ANSWER 4.3

RATIONALE:

A. This arises because the membrane is relatively impermeable to Na^+, and Na^+ ions are actively extruded from the cell in exchange for K^+ ions by an energy-dependent transporter, the Na^+ pump (or Na^+–K^+-ATPase).

B. Because of the inequality of Na^+ and K^+ concentrations on the two sides of the membrane, an increase in Na^+ permeability causes an inward (depolarising) current of Na^+ ions, whereas an increase in K^+ permeability causes an outward (repolarising) current.

C.

D. Use-dependent block involves drugs that bind most strongly to the inactivated state of the channel prolonging the refractory period and reducing the maximum frequency at which action potentials can be generated. The binding of such drugs

increases as a function of the rate of action potential discharge, which governs the rate at which inactivated channels are generated. This is important for some antidysrhythmic drugs and for antiepileptic drugs because high-frequency discharges can be inhibited without affecting excitability at normal frequencies.

E. Local anaesthetics readily block sodium channels in their resting state and prevent excitation at low as well as high frequencies.

CORRECT ANSWER WITH EXPLANATION:

C. After the action potential has passed, many sodium channels are in the resting state and are refractory to further activation.

Voltage-gated channels can exist in three functional states: resting (the closed state that prevails at the normal resting potential), activated (the open state favoured by brief depolarisation) and inactivated (the blocked state). After the action potential has passed, many sodium channels are in the inactivated state; after the membrane potential returns to its resting value, the inactivated channels take time to revert to the resting state (refractory) and thus become available for activation once more.

ANSWER 4.4

RATIONALE:

A. Fast synaptic transmission in nerve terminals is mediated by Ca^{2+} -dependent exocytosis.

B.

C. In non-excitable cells (e.g. most exocrine and endocrine glands), the slow mechanism of release predominates and is

activated mainly by Ca^{2+} release from intracellular stores.

D. Nitric oxide is not stored but is released from the cytosol by diffusion across the membrane as it is synthesised by a Ca^{2+}-dependent enzyme.

E. Activation of G protein–coupled receptors, which cause release of Ca^{2+}, also stimulates Cl- transport, by activating the cystic fibrosis transmembrane conductance regulator (CFTR).

CORRECT ANSWER WITH EXPLANATION:

B. Amphetamine-mediated neurotransmitter release

Amphetamines displace the endogenous amine from storage vesicles into the cytosol, whence it escapes via the monoamine transporter in the plasma membrane, a mechanism that does not depend on Ca^{2+}.

[1] P and Q are so similar that they usually get lumped together. The terminology is less than poetic: L stands for *long-lasting*; T stands for *transient*; N stands for *neither long-lasting nor transient*. Although P stands for *Purkinje* – this type of channel current was first observed in cerebellar Purkinje cells – it continued the alphabetical sequence (missing out O of course) and so the next discovered were termed Q and R.

[2] Readers interested in knowing more about the subunit composition of different voltage-gated calcium channels should consult the Guide to Pharmacology at http://www.guidetopharmacology.org/GRAC/FamilyDisplayForward?familyId=80.

[1] 'TRP' is an abbreviation of 'Transient Receptor Potential' which was the term applied to the first such channel observed in the

drosophila retina. Although channels in the TRP superfamily have vastly different biophysical and pharmacological characteristics the term has stuck despite its relevance being questionable. In 2021 David Julius and Ardem Patapoutian were awarded the Nobel Prize in Physiology or Medicine for their work on TRP channels.

[3] These pumps have been likened to Sisyphus, condemned endlessly to push a stone up a hill (also consuming ATP, no doubt), only for it to roll downhill again.

[4] Potassium channel terminology is confusing, to put it mildly. Electrophysiologists have named K^+currents prosaically on the basis of their functional properties (I_{KV}, I_{KCa}, I_{KATP}, I_{KIR}, etc.); geneticists have named genes somewhat fancifully according to the phenotypes associated with mutations ('shaker', 'ether-a-go-go', etc.), while molecular biologists have introduced a rational but unmemorable nomenclature on the basis of sequence data (KCNK, KCNQ, etc., with numerical suffixes). The rest of us must make what we can of the unpoetic jargon of labels such as HERG (which – don't blink – stands for 'Human Ether-a-go-go Related Gene'), TWIK, TREK and TASK.

[5] Although these are, to all intents and purposes, just a form of L-type calcium channel the term *dihydropyridine receptor* (DHPR) is used to reflect that they are not identical to the L-type channels in neurons and cardiac muscle.

[7] Carrier-mediated release can also occur with neurotransmitters that are stored in vesicles but is quantitatively less significant than exocytosis.

[8] For this work Sir Bernard Katz was awarded the Nobel Prize in Physiology or Medicine in 1970. He shared the prize with Ulf Von Euler and Julius Axelrod, who worked on aspects of noradrenergic transmission.

[9] The vesicle contents may not always discharge completely. Instead, vesicles may fuse transiently with the cell membrane and release only part of their contents before becoming disconnected (termed *kiss-and-run exocytosis*).

[10] Some cheeses may have high levels of the trace amino acid tyramine, which can act akin to amphetamines and release noradrenaline (particularly in those being treated with monoamine oxidase (MAO) inhibitors, see Ch. 48), giving a dramatic sympathomimetic episode known as a ‘cheese effect’.

5: How drugs act

biopharmaceuticals and gene therapy

OVERVIEW

In this chapter, we discuss the properties of a group of therapeutic agents known collectively as *biopharmaceuticals*. These are relatively recent additions to our therapeutic armoury, but they have already made a major impact on the treatment of rare genetic conditions as well as chronic diseases such as rheumatoid arthritis. The number of biopharmaceuticals approved for clinical use is growing rapidly and the sector will assume even more significance in the future. We first introduce protein- and oligonucleotide-based (largely RNA derived) biopharmaceuticals, highlight the major differences with 'conventional' small molecule drugs and explain how they are manufactured, how they work and how they are metabolised. We then introduce the central concepts of *gene therapy*, discuss the promise and problems associated with this therapeutic modality and highlight some recent successes.

INTRODUCTION

This chapter deals with the general pharmacological characteristics of protein and nucleic acid-based drugs produced using either 'genetic engineering' techniques or synthetic chemistry. Many of

these drugs have filled therapeutic niches which other more conventional 'small molecule' drugs have been unable to occupy. Some idea of the vigour of the biopharmaceutical sector may be gained from the total market size which is estimated to be worth over US$320 billion by 2026.

The drugs described in this chapter are termed biopharmaceuticals but, annoyingly for authors of textbooks and their readers, there is no consensus on what actually constitutes a 'biopharmaceutical' as opposed to a conventional drug. An apparently obvious distinguishing feature is whether the drug is predominately 'chemical' in nature (like almost all the small molecule drugs in this book) or of 'biological' origin or manufacture (like insulin or growth hormone, for example). Unfortunately, this simplistic distinction breaks down rather quickly when we consider that 'small molecule' drugs (such as **morphine** or **penicillin**) are plant or fungal products whilst other 'biological molecules' such as short peptides or antisense oligonucleotides (ASOs) can be synthesised using organic chemistry techniques.

A further problem is the stance adopted by the main drug regulatory agencies. Historically, the US Food and Drug Administration (FDA) and their European counterparts have used slightly different definitions when classifying 'biopharmaceuticals' and this has profound effects on the companies that manufacture them, affecting their regulatory obligations, business models, patent filings, investment funding and even public relations. As one commentator (**Rader, 2008**) put it, 'The result is a Babel-like situation with terminological chaos and anarchy confounding

communication, comparative and industry analyses, understanding and regulation'.

There is also another tiresome semantic issue here which should be noted: such drugs are often referred to by the diminutive 'biologics' in academic discussions and papers for the sake of convenience, but this term is also used to refer to *any* biological reagents (e.g. antibody-based laboratory tests, blood products and so on). For reasons of clarity therefore, we will adhere to the term *biopharmaceutical* in this chapter. We will begin with a discussion of protein and oligonucleotide biopharmaceuticals.

PROTEIN AND PEPTIDE BIOPHARMACEUTICALS

The use of proteins as therapeutic agents is not a novel idea; insulin, extracted from animal pancreas tissue (see **Ch. 31**), and human growth hormone (extracted at one time from human cadaver pituitary glands; see **Ch. 33**) were among the first therapeutic proteins to be used and, for many years, such purified extracts provided the only option for treating protein hormone deficiency disorders. However, there were problems. Technical difficulties in extraction of the hormone from tissue often led to disappointing yields. Administration of animal hormones (e.g. pig insulin) to humans did not offer an easy solution. These could evoke an immune response and there was also another insidious danger – transmission of infectious agents across species or between people. This was highlighted in the 1970s, when cases of the neurodegenerative *Creutzfeldt–Jakob disease* (see **Ch. 40**) were seen in patients who had been treated, sometimes decades

earlier, with human growth hormone obtained from cadavers,. This serious, and sometimes life-threatening, problem was traced to contamination of the donor pituitary glands with infectious *prions* (see **Ch. 40**). Fortunately, the advent of 'genetic engineering' techniques offered a new way to deal with these troublesome issues.

The protein biopharmaceuticals in use today are sometimes classified as first- or second-generation agents. *First-generation* biopharmaceuticals are usually straightforward copies of human hormones or other proteins, prepared by *transfecting* the human gene into a suitable *expression system* (a cell line that produces the protein in good yield), then harvesting and purifying the *recombinant protein* for use as a drug. The first agent to be produced in this way was recombinant human insulin in 1982. *Second-generation* biopharmaceuticals are those that have been *engineered* in some way; that is to say, either the gene has been deliberately altered prior to transfection such that the structure of the recombinant protein is changed, or some alteration is made to the purified end product. Such changes are generally made to improve some aspect of the protein's activity profile. Human recombinant insulins designed to act faster or last longer were among the first in this class to be marketed; **Table 5.1** contains other examples.

Table 5.1

AA, Amino acid.

Production methods

There are several technical and other challenges associated with the manufacture of any type of recombinant protein, and one of the most pressing is the choice of expression system. Recombinant proteins can be conveniently expressed in bacterial systems (*Escherichia coli*, for example), which grow quickly and are generally easy to manipulate. Disadvantages of this approach include the fact that the final product may contain bacterial endotoxins, which must be removed before administration to patients, and also that bacterial cells differ from mammalian cells in patterns of *post-translational processing* (e.g. glycosylation) of proteins, which may affect their biological action. To circumvent these problems, mammalian (e.g. Chinese hamster ovary (CHO)) cells can also be used as expression systems, although such cells require more careful culture, grow more slowly than bacteria and produce less product, all of which contributes to the cost of the final medicine.

A number of emergent technologies are set to transform the production process in the future. The use of plants (see **Huebbers and Buyel, 2021**; **Moon et al., 2019**) or algae (see **Rosales-Mendoza et al., 2020**; **Taunt et al., 2018**) to produce recombinant proteins obviously has considerable potential. The associated concept of 'therapeutic food' in which biopharmaceuticals or vaccines are incorporated within the plant such that the foodstuff itself becomes the therapeutic agent (see **Cebadera Miranda et al., 2020**) is one which would have obvious advantages in the treatment of large populations particularly in developing countries if the legislative and ethical challenges, as well as the pharmaceutical problems of delivering

such drugs by an oral route, can be surmounted (see **Homayun et al., 2019**). Looking forward, some biopharmaceutical drugs could be produced in the future using 3D printing technology (**Evans et al., 2021**) streamlining production considerably.

Engineered proteins

There are several ways in which proteins can be altered prior to expression. Changing the nucleotide sequence of the coding gene can be used to alter single amino acids or, indeed, entire segments of the polypeptide chain. Reasons for modifying proteins in this way include:

- improving pharmacokinetic properties
- creation of novel *fusion* or other proteins
- reducing immunogenicity, for example, by *humanising* the protein

It is often useful to modify the pharmacokinetic properties of recombinant proteins. Changes in the structure of human insulin, for example, provided a form of the hormone that does not self-associate (i.e. 'clump' together) during storage and is therefore faster acting and easier to manage. The half-life of proteins in the blood can often be extended by *PEGylation* (see **Ch. 11**), that is, the addition of polyethylene glycol (PEG) to the molecule. This *post-translational engineering* approach has been applied to human hormones, such as recombinant growth hormone, interferons and others. This is not merely a convenience to patients; it also reduces the overall cost of the treatment, which is an important factor in the adoption of any type of therapy.

Fusion proteins comprise two or more proteins engineered (by modification of their genes) so as to be expressed as one single polypeptide chain, sometimes joined by a short linker. An example is **etanercept**, an anti-inflammatory drug used in the treatment of rheumatoid arthritis and other conditions (see **Ch. 25**). Etanercept consists of the ligand-binding domain taken from the tumour necrosis factor (TNF) receptor, joined to the *constant* (Fc) domain of a human immunoglobulin G antibody. The receptor moiety sequesters endogenous TNF, complexing it in an inactive form, while the immunoglobulin fragment increases persistence of the drug in the blood. Reduction of immunogenicity through bioengineering is discussed later.

Perhaps the most exciting idea in protein engineering is the notion that use of a 'modified' genetic code will permit the inclusion of noncanonical amino acids into biopharmaceuticals. This would provide multiple opportunities for novel drug discovery (**Kang et al., 2018**). Such an approach has already yielded at least one approved veterinary drug (***Pegbovigrastim*** , a modified form of granulocyte colony stimulating factor (G-CSF) used to treat mastitis in cattle) and several other agents are already in the developmental pipeline.

MONOCLONAL ANTIBODIES

As with early hormones, the initial use of monoclonal antibodies (mAbs) as therapeutics was achieved via their transfer from humans or animals to patients as 'antisera'. Conventionally, antisera are produced from the blood of humans or animals who have recovered from an infection or have been immunised.

Antiserum containing high levels of specific antibodies (e.g. to tetanus toxin, snake venom or, more recently, spike proteins of SARS-CoV-2) is prepared from this serum and this can then be used therapeutically to neutralise pathogens or other dangerous substances in the blood of the recipient patient. While preparations can thus confer *passive immunity*, they suffer from a number of inherent disadvantages that limit their utility.

The endogenous immune response produces a mixture of *polyclonal antibodies* – that is, a *polyvalent* mixture of antibodies from all the plasma cell clones that reacted to that particular antigen. The actual composition and efficacy of this vary over time, and obviously there is a limit to how much immune plasma can be collected on any one occasion. However, in 1975, Milstein and Köhler [1] discovered a method of producing from immunised mice an immortalised *hybridoma*, a fusion of one selected lymphocytic clone with an immortalised tumour cell. The hybridoma cell line could be retained and expanded indefinitely while preserving the integrity of its product. This consequently provided a versatile method of producing *mAbs* – a single species of *monovalent* antibody – at high abundance in vitro against virtually any antigen.

Therapeutic mAbs can be classified into first- or second-generation reagents along similar lines to the other therapeutic proteins discussed earlier. First-generation mAbs were simply murine monoclonals (or fragments thereof) but these encountered several problems in the clinic. As mouse proteins, they provoked an immune response in 50%–75% of all human recipients, had a short half-life in the human circulation and were unable to activate human complement.

Most of these problems have been surmounted by using either *chimeric* or *humanised* mAbs. These two terms refer to the degree to which the immunoglobulin has been modified (see **Fig. 5.1**); the IgG molecule consists of an Fc domain and the antibody-binding domain (Fab), with *hypervariable* regions that recognise and bind to the antigen in question. The genes for chimeric mAbs are engineered to contain the cDNA of the *murine* Fab domain coupled with the *human* Fc domain sequences. This greatly (around five-fold) extends the plasma half-life because whilst most plasma proteins turn over quite rapidly, immunoglobulins are an exception (it is easy to see why this provides a selective advantage to the host). Incorporation of human Fc sequences also improves the functionality of the antibody in human medicine. A further development (and now the preferred approach) is to replace the *entire* Fc and Fab region with the human equivalent with the exception of the hypervariable regions, giving a molecule which, while essentially human in nature, contains just the minimal segment of murine antibody-binding sites. The anticancer monoclonal **trastuzumab (Herceptin**; see **Ch. 57**) is an example of such an antibody.

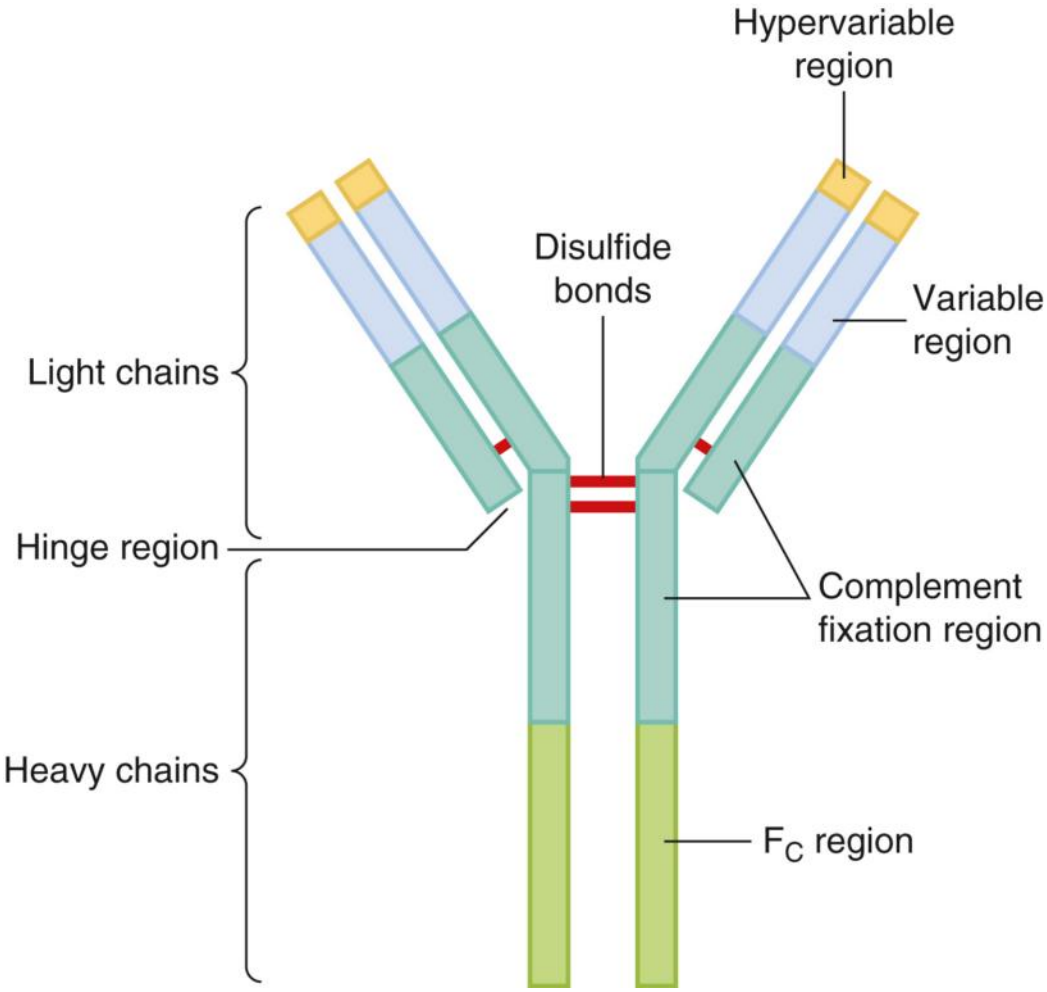

FIG. 5.1 Production of engineered 'chimeric' and 'humanised' monoclonal antibodies.The Y-shaped antibody molecule consists of two main domains: the Fc (constant) domain and the Fab (antigen-binding) domain. At the tip of the Fab regions (on the arms of the 'Y') are the hypervariable regions that actually bind the antigen. Chimeric antibodies are produced by replacing the murine Fc region with its human equivalent by altering and splicing the gene. For humanised antibodies, only the murine

hypervariable regions are retained, the remainder of the molecule being human in origin. After Walsh, G., 2004. Second-generation biopharmaceuticals. Eur. J. Pharm. Biopharm. 58, 185–196.

It is now also possible to produce a *wholly human* mAb. The techniques for doing this include using genetically modified (GM) 'humanised' mice which bear human immunoglobulin genes or by using antibody engineering techniques. Such proteins are usually referred to as 'human' mAbs, but it is important to realise that they may still be immunogenic despite being predominantly human proteins (see **Harding et al., 2010**).

mAb preparations now form by far the largest sector of the biopharmaceutical market and represent the majority of the highest grossing drugs in recent years (quoted in **Evans et al., 2021**). At the time of writing there are some 80 such preparations on the market (**Lu et al., 2020**). **Table 5.2** contains some examples of these together with an explanation of the tongue-twisting nomenclature system by which they are known.

Table 5.2

Therapeutic monoclonal antibody names all end in '-mab', prefixed by an indication of their species nature: *-umab* (human), *-omab* (mouse), *-ximab* (chimera), *-zumab* (humanised).

HER2, Human epidermal growth factor receptor 2; *IgE,* immunoglobulin E; *IL*, interleukin; *mAb,* monoclonal antibody; *PD-1*, programmed cell death protein-1; *TNF-α*, tumour necrosis factor α; *VEGF-A*, vascular endothelial growth factor A.

In the future, antibodies from other animals may be a useful addition to our armoury. Those from *Camelids* (camels, lamas, etc.) have a simpler molecular structure than human antibodies and are thus easier to manufacture and 'engineer' (see **Wrapp et al., 2020**).

PHARMACOLOGY OF PROTEIN BIOPHARMACEUTICALS

There are important differences between the pharmacological properties of protein (and oligonucleotide biopharmaceuticals) and those of conventional small molecule drugs (Tables **5.3** and **5.4**), which are in part attributable to their difference in molecular mass. Most conventional drugs have molecular masses of less than 1000 and are usually less than 500 – in fact, it is thought that this factor is important in achieving optimal distribution in the body and the biological activity of the drug. In contrast, even the smallest protein biopharmaceutical, insulin, has a molecular mass of almost 6 kDa, while antibodies usually weigh in at about 150 kDa. Roughly, 1 kDa

equates to 1000 g/mole. Their size obviously affects the absorption and bioavailability of biopharmaceuticals.

Another distinguishing factor between the two types of drugs is a consequence of their production. 'Conventional' drugs (and short peptides and oligonucleotides) are produced by total (occasionally partial) chemical synthesis, with identical characteristics wherever the compound is made. However, this is not the case with many protein-based biopharmaceuticals. The gene expression system used to produce therapeutically active proteins differs from one company or laboratory to another – deliberately so in most cases because, unlike genes themselves, proprietary constructs and expression systems can be patented, enabling pharma to protect its intellectual property. Each expression system produces a slightly different product in terms of its purity, post-translational modifications and protein 'fingerprint'. [2] This has important consequences for drug regulation, because unlike synthetic small molecule drugs, each biopharmaceutical is unique and a common saying in the biotech industry is that 'the product is the process'. Compared to the first-in-the-field drug, *subsequent entry biologics* (SEBs) or *follow-on biologics* (FOBs) may be *bioequivalents* (i.e. drugs that are interchangeable with, and therapeutically equivalent to, the original preparation); but more often, while still therapeutically effective, they have different clinical properties. [3] However, each preparation requires separate regulatory approval.

Another manufacturing issue concerns the number of steps required to prepare biopharmaceuticals. With chemical synthesis, one can easily assess the exact purity of the final product, but preparations of biopharmaceuticals may not be homogenous and

could contain mixtures of different glycoforms of the protein or possibly traces of bacterial proteins or endotoxins. This means that there is a requirement for greatly enhanced quality control which obviously has profound implications for ease of manufacture and final unit cost (**Revers and Furczon, 2010**).

T_{max}, Time to maximum plasma concentration; $t_{1/2}$, half-life; *V,* volume of distribution.

[a] Route of administration: *i.m.,* intramuscular; *p.o.,* by mouth. All data approximated from manufacturer's information.

Some actions of biopharmaceuticals resemble those of conventional drugs: for example, insulin or growth hormone has identical actions to the native hormone. But others are different. Some mAbs immunoneutralise unwanted substances: for example, **infliximab** directly neutralises the cytokine TNF to produce its therapeutic effect. However, another mAb, **rituximab**, binds to CD20 on lymphocytes, causing actual destruction of the cells to diminish an unwanted immune response. **Ibritumomab tiuxetan** also binds CD20 but delivers ^{90}Y to kill the cells.

Because of these different modes of action, the relationship between dose and effect, so beloved of pharmacologists, is much less clear cut. **Agoram (2009)** highlights some of the problems. In the case of mAbs for example, high-affinity binding is usual

(sometimes a mixture of specific and non-specific binding), slow on- and off-rates are common and the mAb may be internalised, thus modifying the properties of its target cell. Dose–response relationships are sometimes bell shaped or U shaped. Human recombinant erythropoietin has a bell-shaped dose–response and, in the case of many mAbs, there is a single optimal dose at which effective immunoneutralisation occurs, instead of the proportional effects that we are more accustomed to when dealing with small molecule drugs.

The differences in the nature and size of most biopharmaceuticals when compared with conventional drugs also have implications for their pharmacokinetic properties. Because proteins do not usually survive oral administration, most must be administered parenterally and so bioavailability is typically high compared with many small molecule drugs – often in the region of 80%–100%. However, except in the case of intravenous administration, absorption from the injection site is usually slow and the time to attain C_{max} (i.e. the T_{max}) reflects this. Once in the circulation, however, the half-life is typically long. Because antibodies bind to their target with high affinity, the volume of distribution is often small, but transcellular and unusual trafficking may redistribute the drug to other tissues (**Zhao et al., 2012**). A comparison of the pharmacokinetics of conventional small molecule drugs with several biopharmaceuticals is shown in **Table 5.4**.

Protein biopharmaceuticals are not removed from the body following metabolic transformation and excretion of the type described for conventional drugs in **Chapter 10** and some antibodies can persist in the circulation for weeks. Instead, uptake

of large biopharmaceuticals by the lymphatic system is the usual first step, followed by lysosomal degradation. However, some 'small' (<69 kDa) mAbs may be eliminated directly by the kidney. Immunogenicity is an issue that plagued early development of proteins as drugs, and whilst this has been largely overcome by 'humanisation' of antibodies and proteins, it is still important because it may alter the pharmacokinetic properties of the drug (**Richter et al., 1999**) by increasing its clearance from the circulation.

Drug interactions are less of an issue with protein biopharmaceuticals, as are general toxicity problems and adverse effects (although unwanted biological side effects can be severe), an advantage that is reflected in their relatively rapid approval by regulatory agencies. In part, this is due to their extraordinary specificity. In fact, few drugs currently come closer to the idea of a 'magic bullet' [4] than mAbs which, because of the specificity of the immune system, can inactivate single targets with an extraordinary degree of precision.

Ironically, this latter property can cause major problems when testing these drugs. In 2006, for example, a UK 'first-in-man' phase 1 clinical trial of a new mAb (TGN 1412) designed to activate T cells (see **Ch. 7**) and thus treat B-cell lymphocytic leukaemia went badly wrong. All six participants became severely ill following a 'cytokine storm' and suffered lasting damage. The incident provoked wide media publicity [5] and, while the subsequent investigation blamed an 'unpredictable' biological reaction for the disaster, it caused many to think hard about how such trials should be conducted in the future (see **Muller and Brennan, 2009**). Highly specific reagents, such

as monoclonals intended for human use, pose particular problems as they may not cross-react with the corresponding proteins of other species, thus evading detection in the usual preclinical animal safety screens. It may be the case that 'surrogate' mAbs which are species specific will have to be developed to test in animal models of the disease prior to testing in humans.

OLIGONUCLEOTIDES

At the time of writing, the most notable advances in this category are the RNA-based biopharmaceuticals. While RNA was discovered just a few years after the ground-breaking publication of the structure of DNA, it was, until the early 1990s, regarded solely as a sort of molecular shuttle which moved genetic information from the genome to the ribosomes where it could be translated into the appropriate protein. The discovery in 1990 that injection of mRNA into muscle tissue could produce an increased synthesis of the corresponding protein was a major conceptual breakthrough in the field and ignited an interest in using RNA therapeutically.

Some 30 years on, we are reaping the harvest of this insight. The use of RNA-based drugs is set to have an enormous impact on pharmacology, greatly enlarging its reach and scope (see **Yu et al., 2020**). Part of the reason is that RNA molecules are hugely versatile and can be used to target not just other RNA species but also proteins and even DNA itself, in other words, not just the *proteome* but also the *transcriptome* and the *genome* of the cell. Only some 2% of the genome codes for functional proteins; the remainder (previously known arrogantly as 'junk DNA') comprises *pseudogenes*, the molecular remains of ancient viral infections,

some (presumably) non-functional or redundant genetic information but significantly, it also includes a huge amount of *long non-coding RNA*. The function of which is only just emerging. The prospect of deploying RNA drugs (or more usually modified analogues) in this part of the transcriptome vastly increases the number of potential drug targets, many of which can now be addressed for the first time. In addition, when used in conjunction with other molecular techniques such as the clustered regulatory interspersed short palindromic repeats (CRISPR)-Cas gene editing system (discussed later), RNA can extend the reach of pharmacology directly into the genome to edit particular genes. It is an astonishing prospect.

In practice we can conveniently divide RNA drugs into four general categories:

- RNA drugs that target proteins
- RNA drugs that target other nucleotides (either RNA or DNA)
- RNA drugs that are actually used to encode proteins
- Miscellaneous other RNA species with pharmacological potential.

The main properties of these species are listed in **Table 5.5**. We will consider each category separately.

RNA DRUGS THAT TARGET PROTEINS

Aptamers are single-stranded structures of RNA (or DNA). These probably exist naturally in some organisms (e.g. viruses and bacteria) where they fulfil various cellular functions. Because of the

ease by which they can be (chemically) synthesised and their ability to adopt many different structures through intramolecular bonding between their constituent nucleotide bases, aptamers can be used to target proteins (and other structures) in much the same way as conventional small molecule drugs, and thus can act at cell surface receptors and other 'pharmacological' targets.

In 2004, the first RNA aptamer approved for clinical use was licensed by the FDA. **Pegaptanid** is a 28-nucleotide structure with an added PEG group. The therapeutic target was age-related macular degeneration (see **Ch. 27**) and the drug specifically binds to and inhibits the action of an isoform of vascular endothelial growth factor (VEGF) blocking the VEGF receptor thus preventing it from stimulating the growth of new blood vessels.

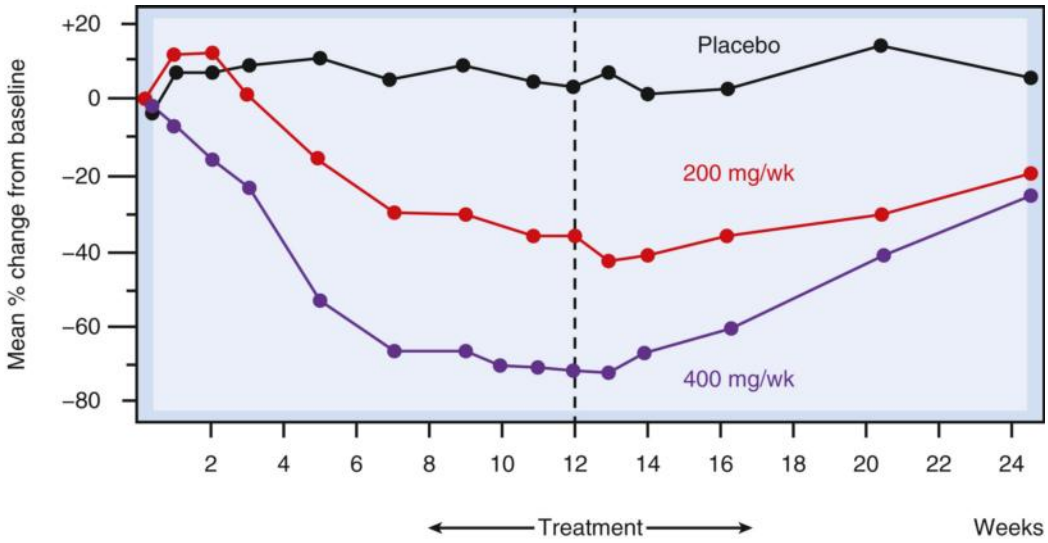

FIG. 5.2 Using antisense oligonucleotides to correct mild-moderate hyperlipidaemia.The antisense oligonucleotide **mipomersen** was administered to 50 patients for 13 weeks. The data show the mean reduction in low-density lipoprotein (LDL) cholesterol expressed in percentage terms from the baseline readings at day 1 with doses of 200 mg/week *(red)* and 400 mg/week *(blue)* compared with a placebo *(black)*. The reduction in expression of apolipoprotein B caused by the drug exactly paralleled the LDL cholesterol data. After discontinuation of the treatment (indicated by *dotted line*) the blood levels showed signs of returning to baseline values but were still depressed by 20%–30% at the conclusion of the study at these doses Redrawn from **Geary, R.S., Baker, B.F., Crooke, S.T., 2015**. Clinical and preclinical pharmacokinetics and

pharmacodynamics of mipomersen (Kynamro^{R}): a second-generation antisense oligonucleotide inhibitor of apolipoprotein B. Clin. Pharmacokinet. 54, 133–146.

RNA DRUGS THAT TARGET OTHER NUCLEOTIDES

ANTISENSE OLIGONUCLEOTIDES

Discovered in 1978 and long a staple of laboratory research where they were used with great success to 'knock down' the expression of genes of interest, 'ASOs' have now found their place in the clinic. They are generally chemically modified single-strand oligonucleotides which hybridise to the complementary mRNA (which itself needs to be single stranded to partcipate in translation) for particular proteins and prevent transcription or translation either directly (as the two strands are now duplexed) or because the target mRNA is then degraded by RNAses. They typically have molecular masses in the region of 7–15 kDa.

ASOs can act in several ways: for example, the anti-cytomegalovirus drug **fomiversin** (the first such agent to be introduced but now withdrawn because of lack of demand) halts the progress of cytomegalovirus retinitis by blocking transcription of a key viral protein. **Mipomersin** reduces the expression of apolipoprotein B and has been used for treating hypercholesteraemia (**Fig. 5.2**), whereas drugs such as **eteplirsen** and **golodirsen** act to mitigate the progress of Duchenne muscular dystrophy in a more complex fashion. The problem here is a mutation (a premature stop codon) in the dystrophin gene which leads to the synthesis of a non-functional protein; this results in gradual atrophy of muscle mass with progressive weakness and eventually paralysis and death. Since it is an X-linked gene, the victims are young boys. **Eteplirsen** and **golodirsen** can interfere with the transcription of the defective gene and reintroduce a new open reading frame resulting in the transcription of a truncated but still functional protein. There are several common mutations (and thus variants of this disease) with different regions of the dystrophin gene being affected. Thus several drugs have been developed which target different exons of the dystrophin gene. **Eteplirsen** targets exon 51, **golodirsen** and **vitolarsen** target exon 53 and a further antisense drug **casimersin** targets exon 45.

SMALL INTERFERING RNAs

Discovered in 1998, [6] and similarly to antisense agents, small interfering RNAs (siRNAs) also target mRNA but through a more complex process. These are double-stranded RNA molecules which comprise a *guide strand* and a *passenger strand*. Following rather

complex enzymatic processing, the passenger strand is removed, and the guide strand complexes with the target mRNA to form an *siRNA-induced silencing complex* (RISC). This enhances breakdown of mRNA coding for one specific protein, potentially for long periods (several months). Generally speaking, siRNAs are more effective in silencing cytoplasmic mRNA targets whereas antisense RNAs are more effective in the nuclear compartment. They are highly unstable in plasma, and their use as therapeutic agents depends on chemical modification of the 2' position of the ribose ring which greatly improves their stability (see **Ch. 60**). A further hurdle is access to their site of action in the cytoplasm. One method of achieving this is formulation in lipid nanoparticles (see **Ch. 9**). More recently, for drugs acting on hepatocytes this problem has been addressed by conjugating the chemically modified siRNA with tris-*N*-acetylgalactosamine (Gal-Nac). This binds to asialoglycoprotein (ASGP) receptors expressed by hepatocytes. Binding to ASGP leads rapidly to endocytosis and efficient delivery to a hepatic site of action.

One approved siRNA drug formulated in lipid nanoparticles, **patisiran**, is used to treat the neuropathy caused by the misfolded copies of transthyretin in patients with hereditary transthyretin-mediated amyloidosis. Two other, more recently licensed siRNA drugs are Gal-Nac conjugates, namely **givosiran** (illustrated on our front cover in combination in its RISC complex) and **inclisiran**. **Givosiran** is used to treat patients with hepatic porphyria caused by a disruption of heme biosynthesis in the liver. It works by causing breakdown of mRNA coding for aminolevulinic acid synthase 1 thereby suppressing synthesis of this inducible hepatic

enzyme toward normal. **Inclisiran** (see **Ch. 22**) reduces low-density lipoprotein (LDL)-cholesterol by destabilising mRNA coding for PCSK9 and hence suppressing the synthesis of PSCK9 in hepatocytes. It is administered subcutaneously twice a year, so is potentially useful in primary care. The therapeutic potential of this extraordinarily versatile class of agent for treatment of both rare and common disorders is further discussed in **Chapter 60**.

MICRO-RNAs

Micro-RNAs (miRNAs) are single-stranded structures with a molecular weight of about 10–12 kDa. They are derived from non-coding RNA involved in post-transcriptional gene regulation. Their mechanism of action is complex but, like the siRNAs, they can form a 'silencing complex' with their target mRNA. Unlike siRNAs, however, they can simultaneously alter the expression of multiple transcripts, making them a versatile experimental (and possibly therapeutic) drug. At the time of writing, there are no miRNA drugs in the clinic but there are several being trialled for, for example, Huntingdon's disease. They also hold out especial promise as possible replacements for tumour suppressing miRNAs (as opposed to pro-tumoural 'oncomiRs') which are lost in some types of cancer.

RNA DRUGS THAT ARE USED TO ENCODE PROTEINS

Since the transcription of (single-stranded) mRNA copies of genes is the usual way in which cells generate proteins, it is obvious that this species could have great therapeutic potential as a form of 'replacement therapy'. If a particular protein is not produced, or at least not in sufficient quantities, administration of the appropriate

mRNA to the target cell could provide a very attractive way forward, certainly easier than using DNA or plasmid constructs to do the same job.

One particular application which has achieved recent success (as well as grabbing the headlines) has been its use in vaccines. In the widely used Pfizer-BioNTech COVID-19 vaccine used to prevent infection with SARS-CoV-2 for example, the mRNA for a version of the full-length 'spike' protein of the virus is delivered intramuscularly in nanolipid particles. This mRNA is then translated in the host's muscle to produce copies of the coronavirus spike protein which is then recognised by the immune system which responds with an appropriate antibody and T-cell response. The Moderna COVID-19 vaccine relies on a similar mechanism. [7]

Table 5.6

[a] Not yet available in the UK.

Data chiefly from **Yu, A.M., Choi, Y.H., Tu, M.J., 2020**. RNA drugs and RNA targets for small molecules: principles, progress, and challenges. Pharmacol. Rev. 72, 862–898.

In order to function as mRNA in the cell, the synthetic construct must contain the requisite molecular signals enabling it to be recognised by the protein synthesising machinery. These include the presence of an open reading frame as well as appropriate 5'- and 3'-untranslated groups and a poly(A) tail. Because of this, mRNA constructs tend to be larger than the other RNA-derived drugs in

this section. In addition, and like almost all the other species, they must be modified in some way to prevent destruction by RNAses.

MISCELLANEOUS OTHER RNA SPECIES WITH PHARMACOLOGICAL POTENTIAL

This group comprises several other types of RNA species which hold out promise for future use, but which whose current state of development are not yet sufficiently mature to have realised this potential. The group includes *guide RNAs* (gRNAs), small fragments of complementary RNA which can be used in conjunction with the CRISPR-Cas gene editing technique, as well as *ribozymes*, catalytically active RNA.

Table 5.6 shows some examples of RNA-based drugs already in the clinic.

PROBLEMS WITH RNA BIOPHARMACEUTICALS

There are a number of constitutive problems with all types of RNA biopharmaceuticals. One especially troublesome feature of RNA drugs is the fact that the immune system recognises RNA through Toll receptors (particularly TLR 7; see **Ch. 7**) as being an indicator of the presence of a pathogenic virus and this may trigger an aberrant immune reaction and possibly a cytokine storm.

As is the case with proteins, RNA drugs cannot be administered orally and so must be given by other routes such as intramuscular injection or infusion. Some can be administered topically (see **Table 5.6**). Polynucleotides have a negative charge and are hydrophilic in nature, making it difficult for them to cross cell membranes, so the development of suitable delivery systems is

another hurdle which must be surmounted before any type of RNA is useful in the clinic. Lipid carriers of various compositions have been trialled as delivery systems often with some success, but other possibilities include the construction of hybrid molecules in which the RNA is conjugated to other ligands to achieve a more targeted approach. In the case of **givosiran** for example, a conjugated *N*-acetylgalactosamine residue promotes uptake by the target organ, the liver.

Table 5.7

GM-CSF, Granulocyte-macrophage colony stimulating factor; *IV*, intravenous.

As one might also anticipate, as well as cold-storage requirements of RNA therapeutics, the stability of the RNA is itself a major issue. Cells and tissues contain abundant RNAses which could rapidly destroy any administered RNA. RNAses are found in fingerprints, on every surface and even in the air we breathe. To circumvent this, various strategies have been devised by which chemical modification of the nucleotide structure, often using *methylphosphonate* or *phosphorothioate* derivatives, can offer protection against these enzymes. Such modifications may also improve the pharmacokinetic properties of these drugs too although there is the risk of enhanced immunogenicity and possibly toxicity also. The eventual clearance of RNA drugs (or metabolic fragments) from the body is mainly through renal excretion.

GENE THERAPY

Astonishingly, the first study to demonstrate the theoretical feasibility of gene transfer took place in 1944 when Avery and his colleagues showed that a virulence factor could be transferred between two strains of pneumococcus and identified the factor as (what we now call) DNA, which was not even recognised at that time as the genetic material. Following the molecular biology revolution in the 1980s, however, the significance of this experiment became clear and the notion that one could replace faulty or missing genes became a distant – if thrilling – prospect. It is easy to see why; first, it is a (deceptively) simple approach to a radical cure of the literally thousands of rare genetic and other monogenic diseases such as *cystic fibrosis* and the *haemoglobinopathies*, which are collectively responsible for much misery throughout the world. Second, many other more common conditions, including malignant, neurodegenerative and infectious diseases, have a large genetic component. Conventional treatment of such disorders is (as readers of later chapters will appreciate) far from ideal, so the promise of a completely new approach had enormous allure. The field, which had a rather shaky beginning, has now achieved some notable success (see **Table 5.7**) and despite the fact that only a few gene therapies have so far been approved for clinical use, some experts estimate the sector will be worth US$10–20 billion by 2028.

There are two main gene therapy strategies. Using the *in vivo technique*, the vector containing the therapeutic gene is injected into the patient, either intravenously (in which case some form of organ or tissue targeting is required) or directly into the target tissue (e.g. the retina). When using the *ex vivo strategy* (**Figs.**

5.3 and 5.4), cells are removed from the patient (e.g. stem cells from bone marrow, cells from the circulating blood or myoblasts from a biopsy of striated muscle) and treated with the vector in the laboratory. The genetically altered autologous cells are injected back into the patient they came from (usually sometime later), thus avoiding any immune rejection.

While many difficulties have been overcome, the technology is still rife with technical and other problems. These include:

- *pharmacokinetics*: delivery of the gene to the interior of appropriate target cells either in vivo (especially those in the central nervous system (CNS)) or in vitro;

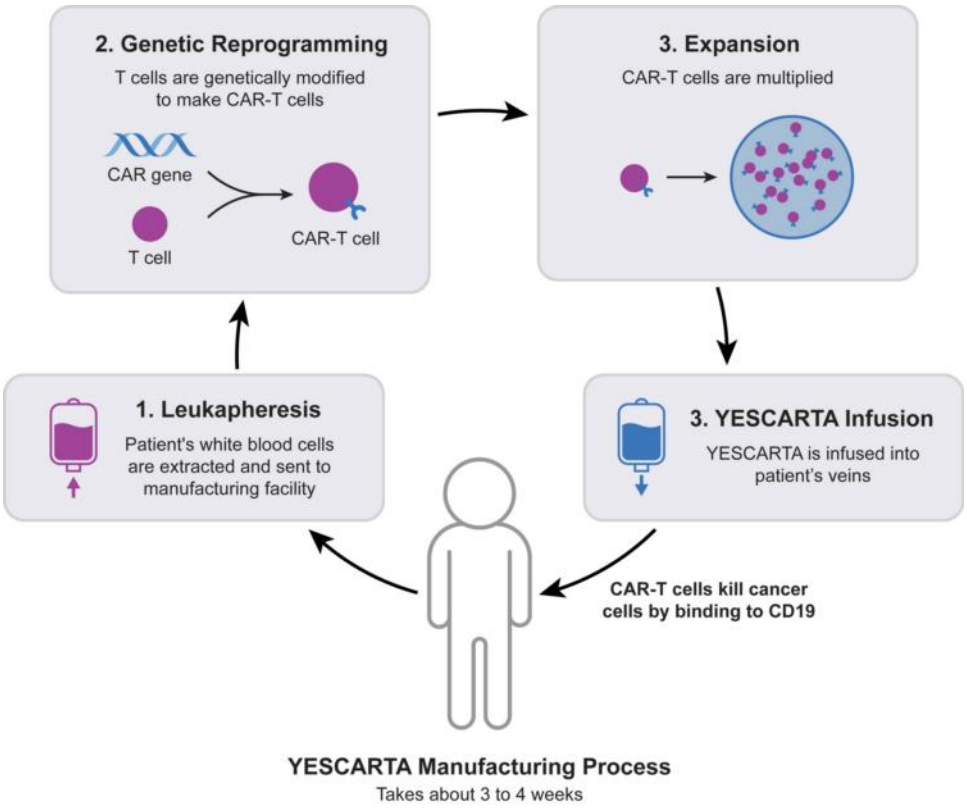

FIG. 5.3 An example of ex vivo gene therapy. **Yescarta** (Axicabtagene ciloleucel) is a gene therapy for treating large B-cell lymphoma. T cells are removed for the patient and, in the laboratory, transfected with the gene for a specific T-cell (chimeric antigen) receptor (CAR-T). After expanding the population, the preparation of autologous T cells is reinfused into the patient who has been prepared with a suitable chemotherapy regime. The modified T cells bind to the CD19 receptor on lymphoma cells and kill the cell. Note that the preparation procedure takes 3–4 weeks to accomplish.

- *pharmacodynamics*: the controlled expression of the gene in question;
- *safety;*
- *clinical efficacy* and *long-term practicability*.

GENE DELIVERY

The transfer of large stretches of recombinant nucleic acid into target cells is critical to the success of gene therapy. In the words of one commentator (Galun, quoted in **Bender, 2016**), 'Gene therapy is actually three things: delivery, delivery and delivery'. To achieve their therapeutic effects, the constructs must pass from the extracellular space across the plasma and nuclear membranes and be incorporated into the chromosomes. Because DNA is negatively charged and single genes have molecular weights around 10^4 times greater than conventional drugs, the problem is of a different order from the equivalent stage of routine drug development.

There are several important considerations in choosing a gene delivery system; these include:

- the *capacity* of the system (e.g. how much DNA it can carry);
- the *transfection efficiency* (its ability to enter and become utilised by the cell's own machinery);
- the *lifespan* of the transfected material (usually determined by the lifetime of the targeted cells);
- the *safety issue*, especially important in the case of viral delivery systems.

An ideal vector should be safe, highly efficient (i.e. insert the therapeutic gene into a high proportion of target cells and under control of the appropriate promoter) and selective in that it should lead to expression of the therapeutic protein in the target cells but not to the expression of other (e.g. viral proteins). Ideally, and provided that the cell into which it is inserted is itself long lived, the vector should cause persistent expression, avoiding the need for repeated treatment. The latter consideration can be a problem in some tissues. In the autosomal recessive disorder cystic fibrosis, for example, the airway epithelium malfunctions because it lacks a membrane Cl^- transporter known as the cystic fibrosis transport regulator (CFTR). Epithelial cells in the airways are continuously dying and being replaced, so even if the unmutated CFTR gene could be stably transfected into the epithelium, there would still be a periodic need for further treatment unless the gene could be inserted into the progenitor (stem) cells. Similar problems are anticipated in other cells that turn over continuously, such as gastrointestinal epithelium and skin.

VIRAL VECTORS

To overcome this first and most fundamental hurdle of gene delivery, techniques borrowed from viruses, which are masters of the sort of molecular hijacking that is required to introduce functional genes into mammalian cells, are often used in gene therapy research.

While seemingly straightforward, there remain substantial practical problems with this *viral vector* approach. As viruses have evolved the means to invade human cells, so humans have evolved

immune responses and other protective countermeasures. Although limiting in some respects, this is not all bad news from the point of view of safety. As many of the viruses used for vectors are pathogenic, they are usually modified such that they are 'replication defective' to avoid toxicity.

Retroviruses

If introduced into stem cells, most *retroviral vectors* have long-lasting effects because they are incorporated into, and replicate along with, host genomic DNA, and so the 'therapeutic' gene is passed down to each daughter cell during division. Against this, the *retroviral integrase* inserts the construct into chromosomes randomly, so it may also cause damage. Also, retroviruses could infect germ or non-target cells and produce undesired effects if administered in vivo. For this reason, they have been used mainly for ex vivo gene therapy.

Many viruses are equipped to infect specific cell types, but these are not necessarily the target cell of interest. It is however possible to change the retroviral envelope to alter specificity, such that the vector could be administered systemically but would target only the desired cell population. An example of this approach with a *lentivirus* (a type of retrovirus) is the substitution of the envelope protein of a non-pathogenic vector (e.g. mouse leukaemia virus) with the envelope protein of human vesicular stomatitis virus, to specifically target human epithelial cells.

Most retrovirus vectors are unable to penetrate the nuclear envelope, and because this dissolves during cell division, they only

infect dividing cells rather than non-dividing cells (such as adult neurons).

Adenovirus vectors

Adenovirus vectors are popular because of the high transgene expression that can be achieved. They transfer genes to the nucleus of the host cell, but (unlike retroviruses) these are not inserted into the host genome and so do not produce effects that outlast the lifetime of the transfected cell. This property also obviates the risk of disturbing the function of other cellular genes and the theoretical risks of carcinogenicity and germ cell transfection. Because of these favourable properties, adenovirus vectors have been used extensively for in vivo gene therapy. Engineered deletions in the viral genome render it unable to replicate or cause widespread infection in the host while at the same time creating space in the viral genome for the therapeutic transgene to be inserted.

One of the first adenoviral vectors lacked part of a growth-controlling region called E_1 , while incorporating the desired transgene. This vector gave excellent results, demonstrating gene transfer to cell lines and animal models of disease, but it proved disappointing as a treatment for cystic fibrosis in human trials. Low doses (administered by aerosol to patients with this disease) produced only a very low-efficiency transfer, whereas higher doses caused inflammation, a host immune response and short-lived gene expression. Furthermore, treatment could not be repeated because of the appearance, in the circulation, of neutralising antibodies. This led to attempts to manipulate adenoviral vectors to mutate or remove the genes that are most strongly immunogenic.

Other viral vectors

Other potential viral vectors used in gene therapy preparations include *adeno-associated virus*, *herpes virus* and disabled versions of *human immunodeficiency virus* (HIV). Adeno-associated virus associates with host DNA but is not activated unless the cell is infected with an adenovirus. It is less immunogenic than other vectors but is difficult to mass produce and cannot be used to carry large transgenes. Herpes virus does not associate with host DNA but is very long lived in nervous tissue (so might have a specific application in treating neurological disease). HIV, unlike most other retroviruses, can infect non-dividing cells such as neurons. It is possible to remove the genes that control replication from HIV and substitute other genes. Alternatively, it may prove possible to transfer to other non-pathogenic retroviruses those genes that permit HIV to penetrate the nuclear envelope.

NON-VIRAL VECTORS

To reduce the potential problems associated with viral vectors, a variety of other substances have been used to deliver genes and other material. These are often collectively known as *nanocarriers*. The list includes the following (but see also **Xu et al., 2014**).

Liposomes

Non-viral vectors include a variant of liposomes (see **Ch. 9**). Plasmids (diameter up to approximately 2 μm) are too big to package in regular liposomes (diameter 0.025–0.1 μm), but larger particles can be made from positively charged lipids (‘lipoplexes’), which interact with both negatively charged cell membranes and

DNA, improving delivery into the cell nucleus and incorporation into the host chromosome. Such particles have been used to deliver the genes for HLA-B7, interleukin-2 and CFTR (as well as COVID-19 vaccines) to cells. They are much less efficient than viruses, and attempts are currently under way to improve this by incorporating various viral signal proteins (membrane fusion proteins, for example) in their outer coat. Direct injection of these complexes into solid tumours (e.g. melanoma, breast, kidney and colon cancers) can, however, achieve high local concentrations within the tumour.

Microspheres

Biodegradable microspheres made from polyanhydride co-polymers of fumaric and sebacic acids can be loaded with plasmid DNA. A plasmid with bacterial β-galactosidase activity formulated in this way and given by mouth to rats has resulted, surprisingly, in systemic absorption and expression of the bacterial enzyme in the rat liver, raising the eventual possibility of oral gene therapy (**Kutzler and Weiner, 2008**).

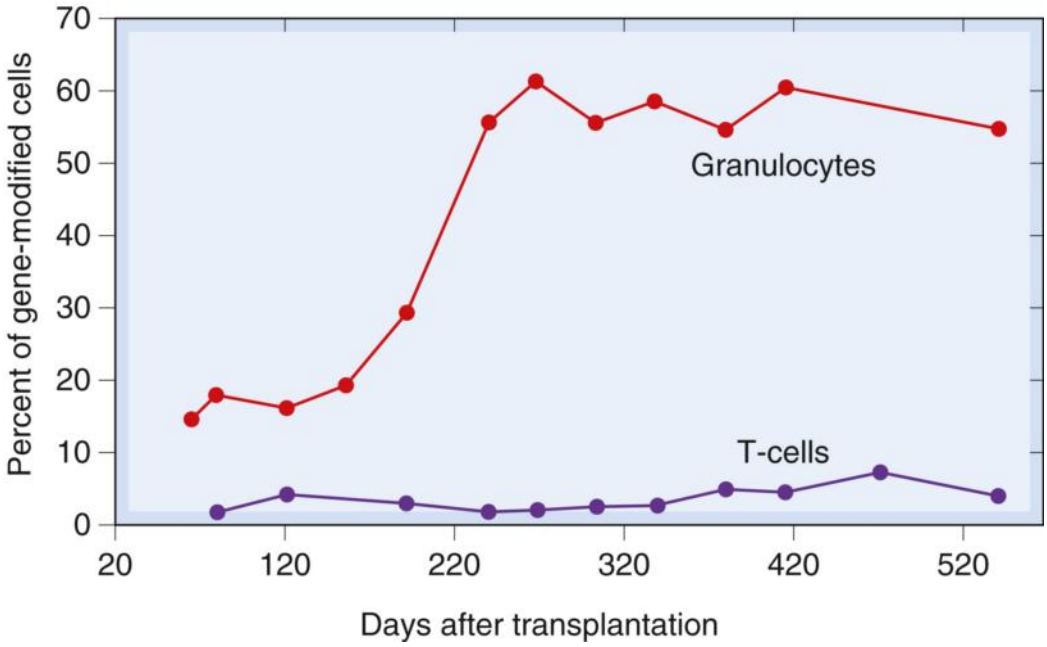

FIG. 5.4 Correcting an inherited defect using gene therapy.In this clinical trial, two patients with X-linked chronic granulomatous disease were transfused with GM-CSF (granulocyte-macrophage colony stimulating factor)-treated peripheral blood cells that had been genetically modified with a retroviral vector bearing the intact *gp91phox* gene ('in vitro protocol' – see text). The graph shows that the number of gene-modified peripheral blood leukocytes remained high for well over a year and this was accompanied by good levels of superoxide production in these cells – a clinical 'cure'. Data redrawn from **Ott, M.G., Schmidt, M., Schwarzwaelder, K., et al., 2006**. Correction of X-linked chronic granulomatous disease by gene therapy, augmented by insertional

activation of MDS1-EVI1, PRDM16 or SETBP1.
Nat. Med. 12, 401–409.

Plasmid DNA

Surprisingly, plasmid DNA itself ('naked DNA', obtained from bacterial cultures) enters the nucleus of some cells and is expressed, albeit much less efficiently than when it is packaged in a vector. Such DNA carries no risk of viral replication and is not usually immunogenic, but it cannot be targeted precisely. Nevertheless, there is considerable interest in the use of naked DNA in vaccines, as the technique has several theoretical advantages (**Kutzler and Weiner, 2008**; **Liu, 2011**). At the time of writing the first DNA vaccine, **ZyCoV-D** (for prophylactic treatment of COVID-19 infection), developed by the Indian pharmaceutical company Zydus Cadilla, has been approved for global usage. Many others are in development.

CONTROLLING GENE EXPRESSION

To realise the full potential of gene therapy, it is not enough to transfer the gene selectively to the desired target cells and maintain acceptable expression of its product – difficult though these goals are. It is also essential that the activity of the gene can be controlled. Historically, it was the realisation of the magnitude of this task that diverted attention from the haemoglobinopathies (which were among the first projected targets of gene therapy). Correction of these disorders demands an appropriate balance of normal α- and β-globin chain synthesis to be effective, and for this, and many other

potential applications, precisely controlled gene expression, are essential.

It has not yet proved routinely possible to control transgenes precisely in human recipients, but there are techniques that may eventually enable us to achieve this goal. One hinges upon the use of an *inducible expression system*. This is a fairly standard laboratory technique whereby the inserted gene also includes, for example, a **doxycycline**-inducible promoter such that expression of the gene can be switched on or off by treatment with, or withdrawal of, the antibiotic.

The control of transfected genes is important in gene targeting as well. By splicing the gene of interest with a tissue-specific promoter, it should be possible to restrict expression of the gene to the target tissue. Such an approach has been used in the design of gene therapy constructs for use in ovarian cancer, the cells of which express several proteins at high abundance, including the proteinase inhibitor SLP1. In combination with the SLP1 promoter, plasmids carrying various genes were successfully and selectively expressed in ovarian cancer cell lines (**Wolf and Jenkins, 2002**).

SAFETY AND SOCIETAL ISSUES

Experiments or protocols involving the transfer of genetic material tend to provoke deep unease in some sectors of society – witness the GM crop debate (see **Freire et al., 2014**), the 'vaccine hesitancy' that we have seen during the recent COVID-19 pandemic as well as the controversy surrounding the MMR vaccine and autism. While this may be traced partly to ignorance or prejudice (not helped by society's politicisation of science and health

matters), it is nevertheless a problem that can hinder the introduction of new agents. There is a broad consensus that the *Weismann barrier* [8] should not be breached and so a moratorium has been agreed on making alterations to the DNA of germ cells (which could influence future generations) and gene therapy trials have focused on somatic cells only.

Societal issues aside, the technique does raise a number of specific concerns that generally relate to the use of viral vectors. These are usually selected because they are non-pathogenic, or modified to render them innocuous, but there is a concern that such agents might still acquire virulence during use. Retroviruses, which insert randomly into host DNA, may damage the genome and interfere with the protective mechanisms that normally regulate the cell cycle (see **Ch. 6**), and if they happen to disrupt essential cellular functions, this could increase the risk of malignancy. [9]

Another problem is that immunogenic viral proteins may elicit an inflammatory response. Initial clinical experience was reassuring, but the death of Jesse Gelsinger, an 18-year-old volunteer in a gene therapy trial for the non-fatal disease *ornithine decarboxylase deficiency* (which can be controlled, albeit tediously, by diet and drugs anyway), led to the appreciation that such safety concerns are very real (see **Marshall, 1999**).

THERAPEUTIC APPLICATIONS

Despite the plethora of technical problems and safety concerns, there have been some encouraging successes and continuing interest in the sector as evidenced by the huge number of papers describing, or proposing, gene therapy solutions for a variety of

clinical conditions, ranging from overactive bladder and defective colour vision to life-threatening cancers and neurological conditions. Even so, there are at present only a handful of gene therapies actually approved. Some of these are listed in **Table 5.7**.

The first to be approved was **Gendicine**, a treatment which aimed to replace the faulty p53 protein that caused head and neck cancer, which was licensed in China in 2003. The European Medicines Agency granted its first license for a gene therapy product, **Alipogene tiparvovec (Glybera),** in 2012. [10] This is an adeno-associated virus construct that delivers a correct copy of lipoprotein lipase to patients lacking this enzyme (a very rare disorder that causes severe pancreatitis), and in 2016, **Strimvelis** was also approved in Europe. This is an ex vivo gene therapy approach to replace adenosine deaminase which is absent from children with a rare (~15 patients per year in Europe) type of severe compromised immunodeficiency (SCID). In the United States, the first gene therapy was approved in 2017: **Kymriah (tisagenlecleucel)**, a treatment for acute lymphoblastic leukaemia. This is also based upon an ex vivo technique whereby T cells from the patient are genetically modified to contain a chimeric antigen receptor (CAR-T) cell, which, when reinfused into the patient, destroys leukaemia cells. Currently, gene therapies for spinal muscular atrophy (one of the common fatal inherited diseases of infancy) and large B-cell lymphoma command the highest market share of this sector.

FUTURE DIRECTIONS

This biopharmaceutical sector of the market is growing rapidly and major advances appear with bewildering speed.

One field which is especially promising is *gene editing*. Rather than replacing a gene in its entirety, this technique, which is similar in scope to the RNA pharmaceuticals, actually aims to 'edit' the faulty gene in the cell. The mechanism for accomplishing this is a system of gene editing originally discovered in bacteria. Bearing the rather daunting name ***c*** *lustered* ***r*** *egulatory* ***i*** *nterspersed* ***s*** *hort* ***p*** *alindromic* ***r*** *epeats (CRISPR)* it can selectively target nucleases (notably *Cas9*) to precisely edit genes of interest. [11] Viruses can deliver the CRISPR-Cas9 components, thereby acting as delivery vehicles for the biochemical machinery required to repair faulty genes in humans (see for example, **Gori et al., 2015**; **Gee et al., 2017**). gRNAs can be used in conjunction with this technique to provide selectivity and specificity. At the time of writing, several studies are underway around the world to use this technique for the treatment of haemoglobinopathies. This new field, together with an assessment of the likely problems and hurdles to overcome, is reviewed by **Cornel et al. (2019)**.

Also worth mentioning is the fact that some small molecule drugs have, rather surprisingly, been discovered to produce their effects through an action on RNA or DNA targets. These include the naturally occurring antibiotics which act on the ribozymes which catalyse the synthesis of growing protein chains at the ribosomes (see **Ch. 52**) and **ataluren**, a drug which despite being undoubtedly in the small molecule class (m.w. 284.25 kDa) can actually reduce the probability of premature 'stop codons' (such as occur in dystrophin) by interfering with the synthesis of full-length

proteins at the ribosomes. Because of this action, it can be used to treat Duchenne muscular dystrophy. Even more extraordinary was the discovery (**Jones and Taylor, 1980**) that the drug **5'-azacytidine** (see **Ch. 57**), used for years as an anticancer drug, actually inhibits DNA methylation, in other words it can influence the *epigenetic modification* of genes (see **Ghasemi, 2020**, for a comprehensive overview of drugs that act through various epigenetic mechanisms). The idea that drugs can work – or can even be designed to work through epigenetic mechanisms – is revolutionary and could open the way to all sorts of useful pharmacology. It would be possible for example to cause fully differentiated cells to revert to stem cells. While this is possible now, this is a technically difficult procedure.

While oligonucleotide and even protein biopharmaceuticals share some of the characteristics of other drugs described in this book, the same cannot be said for gene therapy and this raises some important questions. Is a gene a 'drug'? Is a virus a 'drug'? Is a GM stem cell a 'drug'? You could argue that they satisfy the broad definition that we posited at the start of this book in that 'administration to a living organism produces a biological effect', but it does not seem sensible to discuss the 'pharmacology' of gene therapy as such and most would consider it beyond the scope of our subject at present. They are therapies nonetheless. A gene has no inherent pharmacodynamic or pharmacokinetic properties; most of the toxicity and adverse effects mentioned here are due to the vector or carrier and not the gene itself. And how do you assess the optimal dose of a 'drug' that is self-replicating? Having said that, we make no apologies for including gene therapy in this section. It is

becoming a major therapeutic modality and physicians and pharmacologists alike will be called on to assess and comment on the biological effects it produces.

QUESTIONS

QUESTION 5.1

The use of protein-based biopharmaceuticals such as monoclonal antibodies has had a significant impact on the efficacy of treatment for a wide range of disease states.

Which of the following statements about therapeutic monoclonal antibodies is correct?

OPTIONS:

A. Humanising the Fc region extends the half-life.

B. Humanising the antibody increases its affinity for antigen.

C. Chimeric antibodies contain human hypervariable regions.

D. Humanised antibodies are more immunogenic than chimeric antibodies.

E. Humanised antibodies are generated using transgenic mice.

QUESTION 5.2

The production methods and properties of biopharmaceutical agents are very different from that of conventional small molecule drugs.

Which of the following is least likely to be an issue with biopharmaceuticals compared to conventional drugs?

OPTIONS:

A. Purity

B. Immunogenicity

C. Batch variability

D. Toxicity

E. Bioavailability

QUESTION 5.3

Harnessing the ability of viruses to infect mammalian cells has become a useful tool for gene therapy delivery.

Which of the following statements about retroviral vector-mediated delivery is incorrect?

OPTIONS:

A. Most retroviral vectors have long-lasting effects because they are incorporated into, and replicate along with, host genomic DNA.

B. Repeated administration is limited by their immunogenicity.

C. The retroviral envelope can be altered to target only the desired cell population.

D. The retroviral integrase inserts the construct into chromosomes randomly, so it may also cause damage.

E. Most retrovirus vectors only infect dividing cells.

ANSWERS

ANSWER 5.1

RATIONALE:

A.

B. The murine hypervariable regions which determine the specificity and affinity for the antigen are not altered in the 'humanising' process.

C. The hypervariable regions remain as murine sequences as these determine the specificity and affinity for the antigen.

D. Humanised antibodies contain fewer murine regions/sequences than chimeric antibodies and less likely to trigger an immune response in the patient.

E. Wholly human antibodies are generated using genetically modified 'humanised' mice which bear human immunoglobulin genes.

CORRECT ANSWER WITH EXPLANATION:

A. Humanising the Fc region extends the half-life.

Replacing murine Fc regions with human Fc domain sequences greatly (around five-fold) extends the plasma half-life because whilst most plasma proteins turn over quite rapidly, immunoglobulins are an exception as this provides a selective advantage to the host.

ANSWER 5.2

RATIONALE:

A. Preparations of biopharmaceuticals may not be homogenous and could contain mixtures of different glycoforms of the protein or possibly bacterial proteins or endotoxins.

B. Immunogenicity is an issue that plagued early development of proteins as drugs and whilst this has been largely overcome by 'humanisation' of antibodies and proteins, it is still important

because it may alter the pharmacokinetic properties of the drug.

C. Biopharmaceuticals are often produced by different systems in different companies and therefore have considerable variation in terms of its purity, post-translational modifications.

D.

E. The bioavailability of biopharmaceutics is typically high compared with many small molecule drugs – often in the region of 80%–100%. But, except in the case of intravenous administration, absorption from the injection site is usually slow and the time taken to achieve the T_{max} reflects this. Also due to their large size they cannot penetrate cells and so volume of distribution is often lower than for conventional drugs.

CORRECT ANSWER WITH EXPLANATION:

D. Toxicity

Drug interactions are less of an issue with protein biopharmaceuticals, as are general toxicity problems and adverse side effects (although unwanted biological side effects can be severe). In part, this is due to their extraordinary specificity.

ANSWER 5.3

RATIONALE:

A. Insertion of the retroviral genetic material into the host genome allows for long-lasting, stable gene expression.

B.

C. Although some retroviruses naturally target specific cell types, docking proteins such as antibodies can be incorporated into

the viral membrane to enhance uptake into specific cell types.

D. The site of insertion of the genetic material is random and has the potential to disrupt essential genes or cause mutations in the host genome.

E. Most retrovirus vectors are unable to penetrate the nuclear envelope, and because this dissolves during cell division, they only infect dividing cells rather than non-dividing cells.

CORRECT ANSWER WITH EXPLANATION:

B. Repeated administration is limited by their immunogenicity.

Retroviruses tend to have lower immunogenicity than adenoviruses as patients have not usually had previous exposure to the virus and the long-lasting nature of the retrovirally inserted gene means that repeat administration, resulting in a build-up of immunogenicity, is usually not required.

[1] They won the 1984 Nobel Prize for Physiology or Medicine for this work.

[2] The 'biological variation' encountered when using living cells to produce a drug is obviously not present in the more precise medicinal chemistry processes. The activity of conventional 'chemical' drugs relates directly to their physicochemical properties such as weight and purity, whereas the activity of biopharmaceuticals can only be measured in activity 'units'.

[3] More bewildering terminology: *biosimilars* are generic drugs with a similar function to the original but with different pharmacology or toxicology; *biobetters* are generic drugs with a similar function to the original but with superior pharmacology or toxicology.

[4] It was Weber's opera, *Der Freischütz* (The Sharpshooter, 1821), that introduced the idea of a 'magic bullet' which, once fired, always found its mark. Ehrlich liked the idea and thought that it was a good description of a highly specific drug. The term, and the associated aspirational concept, has haunted our discipline ever since.

[5] One tabloid headline read: 'We saw human guinea pigs explode' (quoted by Stobbart et al., 2007).

[6] Discovered initially when plant scientists found, to their surprise, that introducing RNA which encoded the colour-producing enzyme in petunias made the flowers *less* colourful, not more so – a process they termed 'gene quelling'. Subsequently siRNA has emerged as an important physiological mechanism for controlling gene expression and was recognised by the award in 2006 of the Nobel Prize to Craig Mello and Andrew Fire for their seminal discoveries in *Caenorhabditis elegans*.

[7] At the start of 2022, Pfizer and Moderna combined are reportedly making ~$100 million profit per day from these two vaccines alone.

[8] Named after August Weismann (1834–1914), who formulated the concept that inheritance utilises only germ, and not somatic, cells.

[9] This risk is more than a theoretical possibility; several children treated for *severe combined immunodeficiency* (SCID) with a retrovirus vector developed a leukaemia-like illness (Woods et al., 2006). The retroviral vector was shown to have inserted itself into a gene called *LMO-2*, mutations of which are associated with childhood cancers.

[10] With an annual cost of at least US$1 million per treatment, Glybera was at that time dubbed ‘the most expensive medicine in the world’. This dubious honour has now passed to Zolgensma at £1.79 million per treatment.

[11] Emmanuelle Charpentier and Jennifer Doudna won the 2020 Nobel Prize for Chemistry for this extraordinary discovery.

6: Cell proliferation, apoptosis, repair and regeneration

OVERVIEW

About 10 billion new cells are created daily in us through cell division and this must be counterbalanced by the elimination of a similar number from the body in an ordered manner. This chapter explains how this homeostasis is managed. We deal with the life and death of the cell – the processes of replication, proliferation, apoptosis, repair and regeneration and how these relate to the actions of drugs. We begin with cell replication. We explain how stimulation by growth factors causes cells to divide and then consider the interaction of how these cells may interact with the extracellular matrix (ECM) which regulates further cell proliferation and development. We describe the crucial phenomenon of apoptosis (the programmed series of events that lead to cell's controlled death), outlining the changes that occur in a cell that is preparing to die and the intracellular pathways that culminate in its demise. We explain how these processes relate to the repair of damaged tissue, to the possibility of its regeneration and whether there is scope for modulating this using novel drugs.

Cell Proliferation

Cell proliferation is, of course, a fundamental biological event. It is integral to many physiological and pathological processes including growth, healing, repair, hypertrophy, hyperplasia and the development of tumours. Because cells need oxygen and nutrients to survive, *angiogenesis* (the development of new blood vessels) is necessary before many of these processes can occur.

Proliferating cells go through what is termed *the cell cycle*, during which they replicate all their components and then divide into two identical daughter cells. [1] The process is tightly regulated by signalling pathways, including receptor tyrosine kinases or receptor-linked kinases and the mitogen-activated protein kinase (MAP kinase) cascade (see **Ch. 3**). In all cases, the pathways eventually lead to transcription of the genes that control the cell cycle.

The Cell Cycle

In the adult, few cells divide repeatedly and most remain in a quiescent phase outside the cycle in the phase termed G_0 (**Fig. 6.1**). Some cells such as neurons and skeletal muscle cells (considered to be 'terminally differentiated') spend all their lifetime in G_0, whereas others being more stem cell–like in phenotype, including bone marrow cells and the epithelium of the gastrointestinal tract, divide daily.

The cell cycle is an ordered sequential series of phases (see **Fig. 6.1**). These are known as S (Synthesis), M (Mitosis) and G (Gap between S or M phases), and they always occur in this order:

- G_1: (Gap1) preparation for DNA synthesis

- S: (Synthesis) DNA synthesis and chromosome duplication of the parental cell
- G_2: (Gap2) preparation for division
- M: (Mitosis) division into two identical daughter cells.

In cells that are dividing continuously, G_1, S and G_2 comprise the *interphase* – the phase between one mitosis and the next.

Cell division requires the controlled timing of the critical S phase and M phases. Entry into each of these phases is tightly regulated at *check points* (restriction points) at the start of the S and M phases. Any DNA damage stops the cycle at one or other of these check points to allow repair and thus maintain the integrity of our DNA sequence in each subsequent cell. This process is critical for the maintenance of genetic stability. Failure of the check points to stop the cycle when it is appropriate to do so leads to genetic instability, which is a hallmark of cancer. [2]

Quiescent (G_0) cells enter G_1 after exposure to chemical mediators, some of which are associated with damage. For example, a wound can stimulate a quiescent skin cell to divide, thus repairing the lesion. The impetus for a cell to enter the cycle (i.e. to move from G_0 into G_1) may be *growth factors* acting on *growth factor receptors*, although the action of other types of ligands on G protein–coupled receptors (see **Ch. 3**) can also initiate this process.

Growth factors stimulate the synthesis of both positive regulators of the cell cycle that control the changes necessary for cell division and negative regulators that counterbalance the positive regulators. The maintenance of normal cell numbers in tissues and organs requires a balance between the positive and the negative regulatory signals. *Apoptosis* [3] also controls cell numbers.

Positive Regulators of the Cell Cycle

The cycle begins when a growth factor acts on a quiescent cell, provoking it to divide. Growth factors stimulate production of two families of proteins, namely *cyclins* and serine/threonine protein kinases called *cyclin-dependent kinases* (cdks), coded for by the *delayed response* genes. The cdks sequentially phosphorylate various enzymes – activating some and inhibiting others – to coordinate the progression of the cell through the cycle.

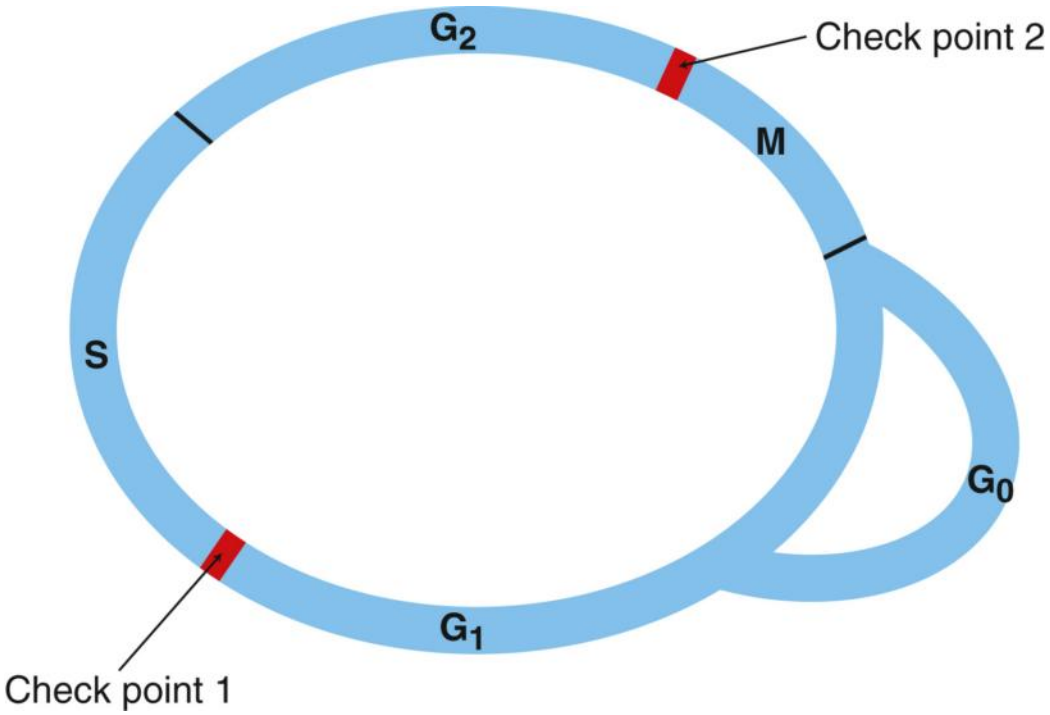

FIG. 6.1 The main phases of the cell cycle of dividing cells.

Each cdk is inactive and must bind to a cyclin partner before it can phosphorylate its target protein(s). After such a phosphorylation event the cyclin is degraded (**Fig. 6.2**) by the *ubiquitin/protease system*. Here, several enzymes sequentially add

small molecules of ubiquitin to the cyclin. The resulting ubiquitin polymer acts as an 'address label' that directs the cyclin to the *proteasome* where the polyubiquinated cyclin is readily degraded.

There are eight main groups of cyclins. According to the 'classical model' of the cell cycle (see **Satyanarayana and Kaldis, 2009**), those of principal importance in the control of the cycle are cyclins A, B, D and E. Each cyclin is associated with, and activates, a particular cdk. Cyclin A activates cdks 1 and 2; cyclin B, cdk 1; cyclin D, cdks 4 and 6; and cyclin E, cdk 2. Precise timing of each step is essential and many cycle proteins are degraded after they have carried out their functions. [4] The actions of the cyclin/cdk complexes throughout the cell cycle are depicted in **Fig. 6.3**.

The activity of these cyclin/cdk complexes is negatively modulated at one or other of the two check points, holding the cell before embarking onto its next stage. In quiescent G_0 cells, cyclin D is present in low concentration, and an important regulatory protein – the *Rb protein* [5] is hypophosphorylated (i.e. phosphorylated but not in a hyperphosphorylated state). This restrains the cell cycle at check point 1 by inhibiting the expression of several proteins critical for further cycle progression. The Rb protein accomplishes this by binding to transcription factors and preventing them from promoting expression of the genes that code for proteins (such as cyclins E and A, DNA polymerase, thymidine kinase and dihydrofolate reductase) needed for DNA replication during S phase. This configuration is maintained until a cell is instructed to divide thus:

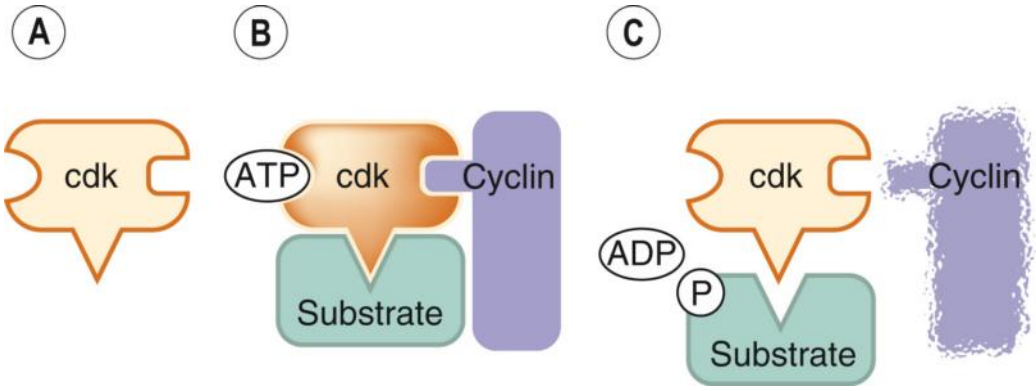

FIG. 6.2 Schematic representation of the activation of a cyclin-dependent kinase (cdk).(A) An inactive cdk. (B) The inactive cdk binds to a cyclin and is activated; it can now phosphorylate a specific protein substrate (e.g. an enzyme). (C) After the phosphorylating event, the cyclin is degraded.

- Growth factor action on a cell in G_0 propels it into G_1, which prepares the cell for S phase. The concentration of cyclin D increases and the cyclin D/cdk complex phosphorylates and activates the proteins required for DNA replication.
- In mid-G_1, the cyclin D/cdk complex phosphorylates the Rb protein, releasing a transcription factor that activates the genes for the components essential for the next phase – DNA synthesis. The action of the cyclin E/cdk complex is necessary for transition from G_1, past check point 1, into S phase.
- Once into S phase, the processes that have been set in motion cannot be reversed and the cell is committed to DNA replication and mitosis. Cyclin E/cdk and cyclin A/cdk

regulate progress through the S phase, phosphorylating and thus activating the proteins/enzymes involved in DNA synthesis.

- In G_2 phase, the cell, which now has double the number of chromosomes, produces the messenger RNAs and proteins needed to duplicate all other cellular components for allocation to the two daughter cells.
- Cyclin A/cdk and cyclin B/cdk complexes are active during G_2 phase and are necessary for entry into M phase, i.e. for passing check point 2. The presence of cyclin B/cdk complexes in the nucleus is required for mitosis to commence.

Mitosis occurs in four stages:

- *Prophase*. The duplicated chromosomes (which are at this point a tangled mass in the nucleus) condense, each now consisting of two *daughter chromatids* (the original chromosome and an identical copy). These are released into the cytoplasm as the nuclear membrane disintegrates.
- *Metaphase*. The chromosomes are aligned at the equator of the cell (see **Fig. 6.3**).
- *Anaphase*. A specialised cytoskeletal device, the mitotic apparatus, captures the chromosomes and draws them to opposite poles of the dividing cell (see **Fig. 6.3**).
- *Telophase*. A nuclear membrane forms round each set of chromosomes. Finally, the cytoplasm divides between the two forming daughter cells. The last step in mitosis is *cytokinesis*, where the plasma membrane between each

daughter cell is pinched- off and split. [6] Each daughter cell will be in G_0 phase and will remain there unless stimulated into G_1 phase once more, as described earlier.

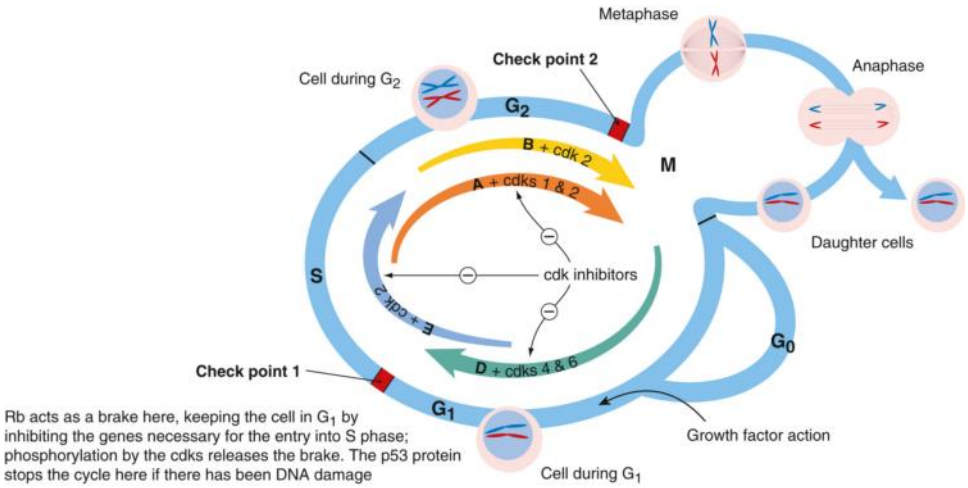

FIG. 6.3 Schematic diagram of the cell cycle, showing the role of the cyclin/cyclin-dependent kinase (cdk) complexes.The processes outlined in the cycle occur inside a cell such as the one shown in Fig. 6.4. A quiescent cell (in G_0 phase), when stimulated to divide by growth factors, is propelled into G_1 phase and prepares for DNA synthesis. Progress through the cycle is determined by sequential action of the cyclin/cdk complexes – depicted here by *coloured arrows*, the arrows being given the names of the relevant cyclins: D, E, A and B. The cdks are given next to the relevant cyclins. The thickness of each arrow represents the intensity of the cdk action at that point in the cycle. The activity of the cdks is regulated by cdk inhibitors. If there is DNA damage, the products of the tumour suppressor gene *p53* arrest the cycle at

check point 1, allowing for repair. If repair fails, apoptosis (see Fig. 6.5) is initiated. The state of the chromosomes is shown schematically in each G phase – as a single pair in G_1, and each duplicated and forming two daughter chromatids in G_2. Some changes that occur during mitosis (metaphase, anaphase) are shown in a subsidiary circle. After the mitotic division, the daughter cells may enter G_1 or G_0 phase. *Rb,* Retinoblastoma gene.

During metaphase, the cyclin A and B complexes phosphorylate cytoskeletal proteins, nuclear histones and possibly components of the *mitotic spindle* (the microtubules along which the chromatids are pulled during metaphase).

Negative Regulators of the Cell Cycle

One of the main negative regulators is the Rb protein, which restrains the cell cycle when it is hypophosphorylated.

Inhibitors of the cdks also serve as negative regulators, their main action being at check points. There are two known families of inhibitors: the *CIP family* (cdk inhibitory proteins, also termed KIP or kinase inhibitory proteins) – proteins p21, p27 and p57; and the *Ink family* (inhibitors of kinases) – proteins p16, p19 and p15.

Protein p21 is a good example of the role of a cyclin/cdk inhibitor. It is under the control of the *p53* gene – a particularly important

negative regulator which is relevant in carcinogenesis – that operates at check point 1.

Inhibition of the cycle at check point 1

The *p53* gene has been called the 'guardian of the genome'. It codes for the p53 protein, a transcription factor found in only low concentrations in normal healthy cells. However, following DNA damage, the protein accumulates and activates the transcription of several genes, one of which codes for p21. Protein p21 inactivates cyclin/cdk complexes, thus Rb phosphorylation is prevented, and it becomes hypophosphorylated. This causes arrest of the cycle at check point 1, allowing DNA repair to take place. If the repair is successful, the cycle proceeds past check point 1 into S phase. If the repair is unsuccessful, the *p53* gene triggers apoptosis or cell suicide. [7]

Inhibition of the cycle at check point 2

DNA damage can arrest the cycle at check point 2, but the mechanisms involved are poorly understood. Inhibition of the accumulation of cyclin B/cdk complex in the nucleus seems to be a factor. For more detail on the control of the cell cycle, see section on microRNAs later in this chapter and **Swanton (2004)**.

The cell cycle

- The term *cell cycle* refers to the sequence of events that take place within a cell as it prepares for division. The quiescent or resting state is called G_0.

- Growth factor action stimulates a cell in G_0 to enter the cycle.
- The phases of the cell cycle are:
  - G_1: preparation for DNA synthesis
  - S: DNA synthesis
  - G_2: preparation for division
  - M, mitosis: division into two daughter cells
- In G_0 phase, a hypophosphorylated protein, coded for by the *Rb* gene, arrests the cycle by inhibiting expression of critical factors necessary for DNA replication.
- Progress through the cycle is controlled by specific kinases (cdks) that are activated by binding to specific proteins termed cyclins.
- Four main cyclins D, E, A and B, together with their cdk complexes, drive the cycle; cyclin D/cdk also releases the Rb protein-mediated inhibition.

There are protein inhibitors of cdks in the cell. Protein p21 is particularly important; it is expressed when DNA damage triggers transcription of gene *p53* and arrests the cycle at check point 1.

Interactions Between Cells, Growth Factors and the Extracellular Matrix

Cell proliferation is regulated by the integrated interplay between growth factors, cells themselves, the ECM and the matrix metalloproteinases (MMPs). The ECM is secreted by the cells and provides a supportive framework. It also profoundly influences cell behaviour by signalling through the cell's integrins (proteins on a

cell's extracellular surface that sense the ECM and signal to the cell what environment it is in or which cell neighbours it has). Matrix expression by cells is regulated by growth factors and cytokines (see **Järveläinen et al., 2009**; **Verrecchia and Mauviel, 2007**). The activity of some growth factors is, in turn, determined by the matrix, because they are sequestered by matrix components and released by proteinases (e.g. MMPs) secreted by the cells.

The action of growth factors acting through receptor tyrosine kinases or receptor-coupled kinases (see **Ch. 3**) is a fundamental part of these processes. Important examples include *fibroblast growth factor* (FGF), *epidermal growth factor* (EGF), *platelet-dependent growth factor* (PDGF), *vascular endothelial growth factor* (VEGF) and *transforming growth factor* (TGF)-β.

The main components of the ECM are:

- Fibre-forming elements, e.g. *collagen species* (the main proteins of the matrix) and *elastin*.
- Non-fibre-forming elements, e.g. proteoglycans, glycoproteins and adhesive proteins such as *fibronectin*. Proteoglycans have a growth-regulating role, in part by functioning as a reservoir of sequestered growth factors. Other elements are associated with the cell surface, where they bind cells to the matrix. Adhesive proteins link the various elements of the matrix together and also form links between the cells and the matrix through cell surface integrins.

Other proteins in the ECM are *thrombospondin* and *osteopontin*, which are not structural elements but modulate cell–matrix

interactions and repair processes. The production of the ECM components is regulated by growth factors, particularly TGF-β.

The ECM is a target for drug action. Both beneficial and adverse effects have been reported. Thus, glucocorticoids decrease collagen synthesis in chronic inflammation and cyclo-oxygenase (COX)-2 inhibitors can modify fibrotic processes apparently through an action on TGF-β. Statins can decrease fibrosis by inhibiting angiotensin-induced connective tissue growth factor production (**Rupérez et al., 2007**) and reducing MMP expression. This may contribute to their effects in cardiovascular diseases (**Tousoulis et al., 2010**). The adverse actions of some drugs attributable to an effect on the ECM include the osteoporosis and skin thinning caused by glucocorticoids (discussed in **Järveläinen et al., 2009**). The ECM is also an important target in the search for new drugs that regulate tissue repair.

The Role of Integrins

Integrins are transmembrane kinase-linked receptors (see **Ch. 3**) comprising α and β subunits. Interaction with the ECM elements (e.g. fibronectin) triggers various cell responses, such as cytoskeletal rearrangement (not considered here) and co-regulation of growth factor function.

Intracellular signalling by both growth factor receptors and integrins is important for optimal cell proliferation (**Fig. 6.4**). Following integrin stimulation an adapter protein and an enzyme *(focal adhesion kinase [FAK])* activate the kinase cascade initiating growth factor signalling. There is extensive cross-talk between the integrin and growth factor pathways (**Streuli and Akhtar, 2009**).

Autophosphorylation of growth factor receptors (see **Ch. 3**) is enhanced by integrin activation, and integrin-mediated adhesion to the ECM (see **Fig. 6.4**) not only suppresses the concentrations of cdk inhibitors but also is required for the expression of cyclins A and D, and therefore for the progression of the cell cycle. Furthermore, integrin activation inhibits apoptosis (see later), further facilitating growth factor action (see reviews by **Barczyk et al., 2010** and **Gahmberg et al., 2009**).

Several therapeutic monoclonal antibodies, including **natalizumab** (used to treat multiple sclerosis) and **abciximab** (an antithrombotic; see **Ch. 23**), target integrins.

The Role of Matrix Metalloproteinases

Degradation of the ECM by MMPs is necessary for tissue growth, repair and remodelling. When growth factors stimulate a cell to enter the cell cycle, they also stimulate the secretion of MMPs (as inactive precursors), which then sculpt the matrix, producing the local changes necessary to accommodate the increased cell numbers. Metalloproteinases in turn release growth factors from the ECM and, in some cases (e.g. interleukin [IL]-1β), process them from precursor to their active form. The action of these enzymes is regulated by tissue inhibitors of metalloproteinases (TIMPs), which are also secreted by local cells.

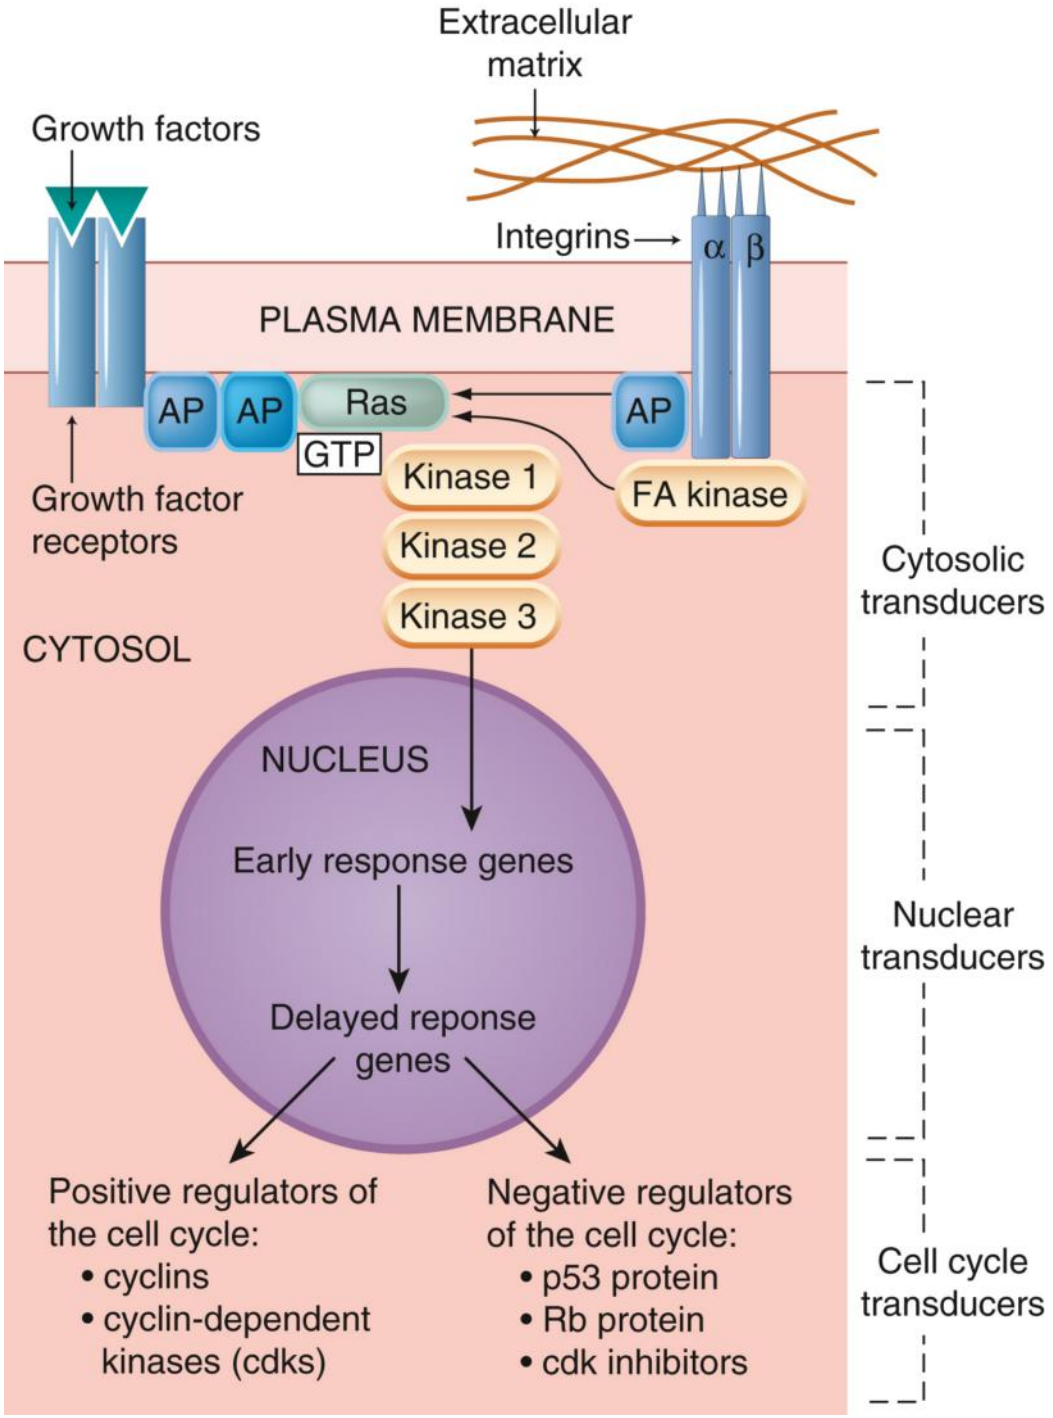

FIG. 6.4 Simplified diagram of the effect of growth factors on a cell in G_0.The overall effect of growth factor action is the generation of the cell cycle transducers. A cell such as the one

depicted will then embark on G_1 phase of the cell cycle. Most growth factor receptors have integral tyrosine kinase (see Fig. 3.17). These receptors dimerise, then cross-phosphorylate their tyrosine residues. The early cytosolic transducers include proteins that bind to the phosphorylated tyrosine residues. Optimum effect requires cooperation with integrin action. Integrins (which have α and β subunits) connect the extracellular matrix with intracellular signalling pathways and also with the cell cytoskeleton (not shown here). G protein–coupled receptors can also stimulate cell proliferation, because their intracellular pathways can connect with the Ras/kinase cascade (not shown). *AP,* Adapter protein; *cdk*, cyclin-dependent kinase; *FA kinase,* focal adhesion kinase; *Rb,* retinoblastoma protein.

In addition to their physiological function, metalloproteinases are involved in the tissue destruction that accompanies various diseases, such as rheumatoid arthritis, osteoarthritis, periodontitis, macular degeneration and myocardial restenosis. They also have a critical role in the growth, invasion and metastasis of tumours (**Clark et al., 2008**; **Jackson et al., 2017**; **Marastoni et al., 2008**). Because of this, much effort has gone into developing synthetic MMP inhibitors for treating cancers and inflammatory disorders, although clinical trials so far have shown limited efficacy and significant adverse effects (see **Gialeli et al., 2011**).

Doxycycline, an antibiotic, also inhibits MMPs, and is used experimentally for this purpose.

Interactions between cells, growth factors and the matrix

- Cells secrete the components of the ECM and become embedded in this tissue.
- The ECM influences the growth and behaviour of the cells. It also acts as a reservoir of growth factors.
- Integrins are transmembrane cellular receptors that can interact with elements of the ECM. They modulate growth factor signalling pathways and also mediate cytoskeletal adjustments within the cell.
- Growth factors cause cells to release metalloproteinases that degrade the local matrix so that it can accommodate the increase in cell numbers.
- In turn, metalloproteinases release growth factors from the ECM and can activate some that are present in precursor form.

Angiogenesis

Angiogenesis, which normally accompanies cell proliferation, entails the formation of new capillaries from existing small blood vessels. Without this, new tissues (including tumours) cannot feed and grow. Angiogenic stimuli include cytokines and various growth

factors, in particular *VEGF*. The sequence of events in angiogenesis is as follows:

1. The basement membrane is degraded locally by proteinases.
2. Endothelial cells migrate out, forming a 'sprout'.
3. Following these leading cells, other endothelial cells proliferate under the influence of VEGF.
4. Matrix material is laid down around the new capillary.

A monoclonal antibody, **bevacizumab**, which neutralises VEGF, is used as adjunct treatment for various cancers (see **Ch. 57**), and following injection into the eye, to treat age-related macular degeneration, a condition in which retinal blood vessels over-proliferate, causing blindness (see **Ch. 27**).

Apoptosis and Cell Removal

Apoptosis is cell 'suicide' in a controlled and orderly manner. It is regulated by a built-in genetically programmed self-destruct mechanism consisting of a specific sequence of biochemical events. It is thus unlike *necrosis*, which is a wholly disorganised disintegration of damaged cells that releases substances which trigger the inflammatory response. [8]

Apoptosis plays an essential role in embryogenesis, shaping organs during development by eliminating cells that have become redundant. It is the mechanism that each day unobtrusively removes some 10 billion cells from the human body. It is involved in numerous physiological events, including the shedding of the intestinal lining, the death of time-expired neutrophils and the turnover of tissues as the newborn infant grows to maturity. It is

the basis for the development of self-tolerance in the immune system (see **Ch. 7**) and acts as a first-line defence against carcinogenic mutations by purging cells that could become malignant.

Disorders of apoptosis are also implicated in the pathophysiology of many conditions, including:

- chronic neurodegenerative diseases such as Alzheimer's and Parkinson's disease and multiple sclerosis (see **Ch. 40**);
- conditions with acute tissue damage or cell loss, such as myocardial infarction (see **Ch. 22**), stroke and spinal cord injury (see **Ch. 40**);
- depletion of T cells in HIV infection (see **Ch. 53**);
- osteoarthritis (see **Ch. 36**);
- haematological diseases, such as aplastic anaemia (see **Ch. 24**);
- evasion of the immune response by cancer cells and resistance to cancer chemotherapy (see **Ch. 57**);
- autoimmune/inflammatory diseases such as myasthenia gravis (see **Ch. 14**), rheumatoid arthritis (see **Ch. 25**), and bronchial asthma (see **Ch. 28**);
- viral infections with ineffective eradication of virus-infected cells (see **Ch. 53**).

Apoptosis is particularly important in the regulation of the immune response and in the many conditions in which it is an underlying component. There is evidence that T cells have a negative regulatory pathway controlled by surface *PCD receptors* (e.g. the PD-1 receptor), and that there is normally a balance

between the stimulatory pathways triggered by antigens and this negative regulatory apoptosis-inducing pathway. The balance is important in the maintenance of peripheral tolerance. A disturbance of this balance is seen in autoimmune disease, in the 'exhaustion' of T cells in chronic viral diseases such as HIV, and possibly in tumour escape from immune destruction (**Zha et al., 2004**). Indeed PD-1 generally acts to inhibit T-cell receptor signalling, and PD-1 inhibitors (check point inhibitors) cause activation of T cells, allowing them to once more recognise and attack the tumour (see also **Ch. 57**).

Apoptosis is a *default response*; i.e. continuous active signalling by tissue-specific trophic factors, cytokines and hormones and cell-to-cell contact factors (adhesion molecules, integrins, etc.) are required for cell survival and viability. The self-destruct mechanism is automatically triggered unless it is actively and continuously inhibited by these anti-apoptotic factors. Different cell types require differing sets of *survival factors*, which function only locally. If a cell strays or is dislodged from the area protected by its paracrine survival signals, it will die.

Withdrawal of these survival factors – which has been termed *death by neglect* – is not the only pathway to apoptosis (**Fig. 6.5**). The death machinery can be activated by ligands that stimulate *death receptors* and by DNA damage. But it is generally accepted that cell proliferation processes and apoptosis are tightly integrated.

Morphological Changes in Apoptosis

As the cell dies it 'rounds up', the chromatin condenses into dense masses, nucleases chop up the genome into unusable different sized

fragments (seen on an electrophoretic gel as DNA 'laddering'), the cytoplasm shrinks and there is blebbing of the plasma membrane. Finally, mediated by a family of proteolytic enzymes known as caspases, the cell is transformed into a cluster of membrane-bound entities. This cellular 'corpse' displays 'eat me' signals, such as phosphatidylserine on its surface, which are recognised by macrophages, which then phagocytose the remains. It is important that these cellular fragments are enclosed by a membrane because otherwise the release of cell constituents could trigger an inflammatory reaction. An additional safeguard against this is that phagocytosing macrophages release anti-inflammatory mediators such as TGF-β, annexin-1 and IL-10.

The Major Players in Apoptosis

The repertoire of reactions in apoptosis is extremely complex and varies between species and cell types. Yet it could be that the pivotal reaction(s) that lead to either cell survival or cell death, reaching this tipping point can be controlled by either a single gene or a combination of key genes. Either way, these genes are desirable targets for drugs used to treat many proliferative diseases.

Only a simple outline of apoptosis can be given here. **Portt et al. (2011)** have reviewed the whole area in detail. The major players are a family of cysteine aspartate-directed proteinases (*caspases*) present in the cell in inactive form. These undertake delicate protein surgery, selectively cleaving specific sets of target proteins (enzymes, structural components, all of which contain a characteristic motif recognised by the caspases), inactivating some and activating others. A cascade of about nine different caspases is

required, some functioning as initiators that transmit the initial apoptotic signals, and others being responsible for the final phase of cell death (see **Fig. 6.5**).

The 'executioner' caspases (e.g. caspase 3) directly cleave and inactivate cell constituents such as the DNA repair enzymes, protein kinase C and cytoskeletal components. Activation of a DNAase cuts genomic DNA between the nucleosomes, generating DNA fragments of approximately 180 base pairs.

However, not all caspases are death-mediating enzymes; some have a role in the processing and activating of cytokines (e.g. caspase 8 is active in processing the inflammatory cytokines IL-1 and IL-18).

Besides the caspases, another pathway can be triggered by *apoptotic initiating factor* (AIF), a protein released from mitochondria that enters the nucleus and triggers cell suicide.

Pathways to Apoptosis

There are two main routes to cell death: stimulation of death receptors by external ligands (the *extrinsic pathway*) and an internal *mitochondrial pathway*. Both routes activate initiator caspases and converge on a final common effector caspase pathway.

The Extrinsic Pathway

Lurking in the plasma membrane of most cell types are members of the tumour necrosis factor receptor (TNFR) superfamily (also known as Fas receptors), which function as 'death receptors' (see **Fig. 6.5**). Important family members include TNFR-1 and CD95 (also known as Fas ligands or Apo-1), but there are many others

(e.g. PD-1, a death receptor that can be induced on activated T cells, as discussed previously).

Each receptor has a 'death domain' in its cytoplasmic tail. Stimulation of the receptors by a ligand such as tumour necrosis factor (TNF [9]) itself or TRAIL [10] causes them to trimerise and recruit an adapter protein that binds to their death domains. The resulting complex activates caspase 8 (and probably caspase 10), which in turn activates the downstream effector caspases (see **Fig. 6.5**).

The mitochondrial pathway

This pathway can be triggered by DNA damage, by withdrawal of cell survival factors or other causes. In some way, the cell can 'audit' such damage and decide whether to initiate the apoptotic pathway. It is possible that *promyelocytic leukaemia bodies*, large complexes of proteins in the nucleus, participate in this task (**Wyllie, 2010**), although how they do so is not clear.

Regulating the apoptotic event are the members of the Bcl-2 protein family, a group of proteins with homologous domains allowing interactions between individual members. If the cell selects the apoptotic route, the p53 protein activates p21 and proapoptotic members of the Bcl-2 family – Bid, Bax and Bak. In addition to these proapoptotic species, this family has antiapoptotic members (e.g. Bcl-2 itself [11]). These factors compete with each other at sites on the surface of the mitochondria and the outcome depends upon the relative competing concentrations of these molecular players. In the case of a proapoptotic signal, oligomers of

Bax and or Bak form pores in the mitochondrial membrane through which proteins such as cytochrome C can leak.

When released, cytochrome C complexes with a protein termed Apaf-1 (apoptotic protease-activating factor-1), the pair then combining with procaspase 9 to activate it. This latter enzyme orchestrates the effector caspase pathway. The triumvirate of cytochrome C, Apaf-1 and procaspase 9 is termed the *apoptosome* (see **Fig. 6.5** and see **Riedl and Salvesen, 2007**). Nitric oxide (see **Ch. 21**) is another mediator that can have proapoptotic or antiapoptotic actions.

In normal cells, survival factors (specified earlier) continuously activate antiapoptotic mechanisms. The withdrawal of survival factors can cause death in several different ways depending on the cell type. A common mechanism is tipping the balance between Bcl-2 family members leading to loss of the antiapoptotic protein action, with the resultant unopposed action of the proapoptotic members of the Bcl-2 family of proteins (see **Fig. 6.5**).

The two main cell death pathways are connected to each other, in that caspase 8 in the death receptor pathway can activate the proapoptotic Bcl-2 family proteins and thus activate the mitochondrial pathway.

FIG. 6.5 A simplified diagram of the two main signalling pathways in apoptosis.The 'death receptor' pathway is activated when death receptors such as members of the tumour necrosis factor (TNF) family are stimulated by specific death ligands. This recruits adapter proteins that activate initiator caspases (e.g. caspase 8), which in turn activate effector caspases such as caspase 3. The mitochondrial pathway is activated by diverse signals, one being DNA damage. In the presence of DNA damage that cannot be repaired, the p53 protein (see text and Figs 6.3 and 6.4) activates a subpathway that releases cytochrome C from the mitochondrion, with subsequent involvement of the *apoptosome* and activation of an initiator caspase, caspase 9. The apoptosome is a complex of procaspase 9, cytochrome C and apoptotic-activating protease factor-1 (Apaf-1). Both these pathways converge on the effector caspase (e.g. caspase 3), which brings about the demise of the cell. The survival factor sub-pathway normally restrains apoptosis by inhibiting the mitochondrial pathway through activation of the antiapoptotic factor Bcl-2. The receptor labelled *'R'* represents the respective receptors for trophic factors, growth factors, cell-to-cell contact factors (adhesion molecules, integrins), etc. Continuous stimulation of these

receptors is necessary for cell survival/proliferation. If this pathway is non-functional *(shown in grey)*, this antiapoptotic drive is withdrawn. *IAP,* Inhibitor of apoptosis.

MicroRNAs, the cell cycle and apoptosis

MicroRNAs (miRNAs), discovered only around the turn of the millennium, are a family of small 'non-protein coding' RNAs present within plants and animals. Coded by sections of the genome found outside the normal protein coding sequences of genes, miRNAs negatively regulate the ribosomal translation processes of many other genes. They are now known to inhibit the expression of genes coding for cell cycle regulation, apoptosis (see **Fig. 6.5**), cell differentiation and development (**Carleton et al., 2007**; **Lynam-Lennon et al., 2009**). About 3% of human genes encode for miRNA and some 30% of human genes coding for proteins are themselves regulated by miRNAs.

Altered miRNA expression is now believed to be linked to a variety of diseases, including diabetes, obesity, Alzheimer's disease, cardiovascular system diseases, inflammatory conditions and neurodegenerative diseases (**Barbato et al., 2009**), as well as carcinogenesis, metastasis and resistance to cancer therapies (**Garzon et al., 2009**; **Wurdinger and Costa, 2007**). miRNAs are also believed to function as oncogenes and/or tumour suppressor genes and to regulate T cells (**Zhou et al., 2009**). Not surprisingly, miRNAs are being heralded as targets for new drug development for a variety of disease states (**Christopher et al., 2016**; **Rupaimoole and Slack, 2017**).

Apoptosis

- Apoptosis is PCD. It is an essential biological process and critical, for example, for embryogenesis and tissue homeostasis.
- Apoptosis depends upon a cascade of proteinases called caspases. Two sets of initiator caspases converge on a set of effector caspases, bringing about the apoptotic event.
- Two main pathways activate the effector caspases: the death receptor pathway and the mitochondrial pathway.
  - Stimulation of the TNFR family initiates the death receptor pathway. The main initiator is caspase 8.
  - The mitochondrial pathway is activated by internal factors such as DNA damage, which results in transcription of gene *p53*. The p53 protein activates a sub-pathway that releases cytochrome C from the mitochondrion. This, in turn, complexes with protein Apaf-1 and together they activate initiator caspase 9.
- In undamaged cells, survival factors (cytokines, hormones, cell-to-cell contact factors) continuously activate antiapoptotic mechanisms. Withdrawal of survival factors causes cell death through the mitochondrial pathway.
- The effector caspases (e.g. caspase 3) initiate a cascade of proteases that cleave cell constituents, DNA, cytoskeletal components, enzymes, etc. This reduces the cell to a cluster of membrane-bound entities that are eventually phagocytosed by macrophages.

Pathophysiological Implications

As mentioned before, cell proliferation and apoptosis are involved in many physiological and pathological processes. These are:

- the growth of tissues and organs in the embryo and later during development;
- the replenishment of lost or 'time-expired' cells such as leukocytes, gut epithelium and uterine endometrium;
- immunological responses, including development of immunological tolerance to host proteins;
- repair and healing after injury or inflammation;
- the hyperplasia (increase in cell number and in connective tissue) associated with chronic inflammatory, hypersensitivity and autoimmune diseases (see **Ch. 7**);
- the growth, invasion and metastasis of tumours (see **Ch. 57**);
- regeneration of tissues.

The role of cell proliferation and apoptosis in the first two processes listed is self-evident and needs no further comment. Their involvement in immune tolerance is discussed briefly previously but the other processes require further discussion.

Repair and Healing

Repair occurs when tissues are damaged or lost. It is also implicated in the resolution of the local inflammatory reaction to a pathogen or chemical irritant. In some instances, damage or tissue loss can lead

to *regeneration*, which is different from repair and is considered later.

There is considerable overlap between the mechanisms activated in inflammation and repair. Both entail an ordered series of events including cell migration, angiogenesis, proliferation of connective tissue cells, synthesis of ECM and finally remodelling – all coordinated by the growth factors and cytokines that are appropriate for the particular tissue involved. TGF-β is a key regulator of several of these processes. [12]

Repair, healing and regeneration

- Repair and healing occur when tissues are damaged. It is a common sequel to inflammation. Connective tissue cells, white blood cells and blood vessels are commonly involved.
- Regeneration is the replacement of the tissue or organ that has been damaged or lost. It depends upon the presence of a pool of primitive stem cells that have the potential to develop into any cell in the body. Complete regeneration of a tissue or organ is rare in mammals. The more rapid repair processes – often accompanied by scarring – usually make good the damage. This may be an evolutionary trade-off in mammals for the lost power of regeneration.
- However, it might be possible eventually to activate regenerative pathways in mammals – at least to some extent and in some organs.

Hyperplasia

Hyperplasia (cell proliferation and matrix expansion) is a hallmark of chronic inflammatory and autoimmune diseases such as rheumatoid arthritis (see Chs **7** and **25**), psoriasis, chronic ulcers and chronic obstructive lung disease. It also underlies the bronchial hyper-reactivity of chronic asthma (see **Ch. 28**) and glomerular nephritis.

Cell proliferation and apoptotic events are also implicated in atherosclerosis, restenosis and myocardial repair after infarction (see **Ch. 22**).

The Growth, Invasion and Metastasis of Tumours

Growth factor signalling systems, antiapoptotic pathways and cell cycle controllers are of increasing interest as targets for novel approaches to the treatment of cancer (see **Ch. 57**).

Stem Cells and Regeneration

Regeneration of tissue replaces that lost following damage or disease and allows restoration of function. Many animals (e.g. amphibians) have impressive regenerative powers and can even regrow an entire organ such as a limb or a tail. The essential process is the activation of *stem cells* – a pool of undifferentiated cells that have the potential to develop into any of the more specialised cells in the body – 'totipotent' or 'pluripotent' cells (**Burgess, 2016**; **Slack, 2014**). Not only do amphibians have a plentiful supply of these primitive cells but many of their more specialised cells can de-differentiate, becoming stem cells again. These can then multiply and retrace the foetal developmental pathways that generated the

organ, by differentiating into the various cell types needed to replace the missing structure.

However, during evolution, mammals have lost this ability in all but a few tissues. Blood cells, intestinal epithelium and the outer layers of the skin are replaced continuously throughout life but there is a low turnover and replacement of cells in organs such as liver, kidney and bone. This 'physiological renewal' is affected by local tissue-specific stem cells.

Almost alone among mammalian organs, the liver has significant ability to replace itself. It can regenerate to its original size in a remarkably short time, provided that at least 25% has been left intact. [13] The mature parenchymal liver cells participate in this process as well as all the other cellular components of the liver.

It is necessary to distinguish *embryonic stem cells* (ES cells) from *adult stem cells* (AS cells) and *progenitor cells*. ES cells are the true pluripotent cells of the embryo that can differentiate into any other cell type. AS cells have a more restricted capability, whereas progenitor cells are able to differentiate only into a single cell type. ES cells are absent in the adult mammal, but AS cells are present, although they are few in number. In mammals, tissue or organ damage (with the exception of the liver, mentioned previously) normally leads to repair, rather than regeneration.

Until recently, it was assumed (with a few exceptions) that this was an unalterable situation, but recent work has suggested that it might be possible to activate the regenerative pathways in mammals – at least to some extent and in some organs. For this to happen, it is necessary to encourage some stem cells to proliferate, develop and differentiate at the relevant sites; or – and this is a rather more

remote prospect in humans – to persuade some local specialised cells to de-differentiate. This can occur in some mammals under special circumstances. However, it may be that repair is the Janus face of regeneration, being an evolutionary trade-off in mammals for the lost power of regeneration. [14]

Where are the relevant stem cells that could be coaxed into regenerative service? Various possibilities are being vigorously investigated and, in some cases, tested clinically. These include:

- ES cells (limited availability and serious ethical issues)
- bone marrow-derived mesenchymal stem cells (**Zhang et al., 2017**)
- muscle-derived stem cells (**Kelc et al., 2013**)
- human-induced pluripotent stem cells (**Nishikawa et al., 2008**)
- tissue-resident progenitor cells.

For a tissue such as the liver to regenerate, local tissue-specific stem cells must be stimulated by growth factors to enter the cell cycle and to proliferate. Other essential processes (already discussed) include angiogenesis, activation of MMPs and the interaction between the matrix and fibronectin to link all the new elements together. The concomitant replacement of components of the lost connective tissue (fibroblasts, macrophages, etc.) is also necessary.

Because most tissues do not regenerate spontaneously, mechanisms that could restore regenerative ability could be of immense therapeutic value. Stem cell therapy has become an attractive prospect for treating all manner of diseases, ranging from

erectile dysfunction and urinary incontinence to heart disease and neurodegeneration. Animal studies have confirmed that this is a potentially rewarding area although routine stem cell therapy in humans is still a distant prospect. The literature is daunting, but the following examples provide an insight into the obstacles and aspirations of the field: repair of damaged heart muscle (see **Ch. 21**; see **Lovell and Mathur, 2011**), repair of retinal degeneration (**Ong and da Cruz, 2012**), stroke (**Banerjee et al., 2011**) and replacement of insulin-secreting cells to treat type 1 diabetes mellitus (see **Ch. 32**; **Voltarelli et al., 2007**).

Therapeutic Prospects

Theoretically, all the processes described in this chapter could constitute useful targets for new drug development. In the following, we list those approaches that are proving or are likely to prove fruitful.

Apoptotic Mechanisms

Compounds that could modify apoptosis are being intensively investigated (**MacFarlane, 2009**; **Melnikova and Golden, 2004**). Here we can only outline some of the more important approaches.

Drugs that promote apoptosis by various mechanisms were heralded as a potential new approach to cancer treatment, and are actively being studied, although none has yet been approved for clinical use. Potential proapoptotic therapeutic approaches need to be targeted precisely to the diseased tissue to avoid the obvious risks of damaging other tissues. Examples include the following:

- An antisense compound against Bcl-2 (**oblimersen**) is being tested for chronic lymphocytic leukaemia.
- **Obatoclax** and **navitoclax** are small molecule inhibitors of Bcl-2 action, being tested for treating haematological malignancies. For details see **MacFarlane (2009)**.
- MicroRNA technology could also be used to promote apoptosis (see **Fig. 6.5**).
- Monoclonal agonist antibodies to the death receptor ligand TRAIL (e.g. **lexatumumab**) are undergoing clinical trials for treatment of solid tumours and lymphomas (**MacFarlane, 2009**).
- **Bortezomib**, which inhibits the proteasome, is available for the treatment of selected cancers. It causes the build-up of Bax, an apoptotic promoter protein of the Bcl-2 family that acts by inhibiting antiapoptotic Bcl-2. Bortezomib acts partly by inhibiting nuclear factor κB (NF-κB) action (see **Ch. 3**).
- One of the most cancer-specific genes codes for an endogenous caspase inhibitor, *survivin*. This occurs in high concentrations in certain tumours and a small molecule suppressor of survivin is in clinical trial (**Giaccone and Rajan, 2009**), the objective being to induce cancer cell suicide.

Inhibiting apoptosis might prevent or treat a wide range of common degenerative disorders. Unfortunately, success in developing such inhibitors for clinical use has so far proved elusive and a number have been found to lack efficacy in clinical trials. Current areas of interest include the following:

- Blocking the PD-1 death receptor with a targeted antibody (such as **nivolumab**) is a potentially fruitful new avenue to explore for the treatment of HIV, hepatitis B and hepatitis C infections, as well as other chronic infections and some cancers that express the ligand for PD-1 (**Trivedi et al., 2015**).
- Several caspase inhibitors are under investigation for treating myocardial infarction, stroke, liver disease, organ transplantation and sepsis. **Emricasan** is one such candidate undergoing trials in patients requiring liver transplants.

Angiogenesis and Metalloproteinases

The search for clinically useful anti-angiogenic drugs and MMP inhibitors is continuing but has not so far been successful. At present, only one new drug has been approved for use in cancer treatment: **bevacizumab**, a monoclonal antibody that neutralises VEGF, and which is also used to treat age-related macular degeneration, a disease also associated with excessive proliferation of retinal blood vessels.

Cell Cycle Regulation

The main endogenous positive regulators of the cell cycle are the cdks. Several small molecules that inhibit cdks by targeting the ATP-binding sites of these kinases have been developed; an example is **flavopiridol**, which inhibits all the cdks, causing arrest of the cell cycle, and is currently in clinical trials for the treatment of acute myeloid leukaemia; it also promotes apoptosis, has anti-angiogenic

properties and can induce differentiation (**Dickson and Schwartz, 2009**).

Some compounds affect upstream pathways for cdk activation and may find a use in cancer treatment. Examples are **perifosine** (although its future is uncertain at the moment) and **lovastatin** (a cholesterol-lowering drug, see **Ch. 22**, which may also have anticancer properties).

Bortezomib, a boronate compound, covalently binds the proteasome, inhibiting the degradation of proapoptotic proteins. It is used in treating multiple myeloma (see **Ch. 57**).

Of the various components of the growth factor signalling pathway, receptor tyrosine kinases, the Ras protein and cytoplasmic kinases have been the subjects of most interest. Kinase inhibitors recently introduced for cancer treatment include **imatinib**, **gefitinib lapatinib**, **sunitinib** and **erlotinib** (see **Ch. 57**).

QUESTIONS

QUESTION 6.1

Cell proliferation and the cell cycle are tightly controlled processes, regulated by a variety of different proteins.

Which one of the following changes would accelerate G1 to S phase progression?

OPTIONS:

A. Hyperphosphorylation of Rb protein

B. An increase in p53 protein

C. An increase in p21 protein

D. Increased expression of cyclin B

E. Increased expression of cyclin-dependent kinase (cdk) 4

QUESTION 6.2

Cell proliferation and tissue remodelling are tightly controlled processes, regulated by a variety of different proteins.

Which one of the following changes would reduce tissue remodelling?

OPTIONS:

A. Degradation of the extracellular matrix (ECM)

B. Activation of focal adhesion kinase (FAK)

C. Enhanced integrin signalling

D. Activation of tissue-inhibitors of metalloproteinases (TIMPs)

E. Secretion of vascular endothelial growth factor (VEGF)

QUESTION 6.3

Apoptosis is a key regulatory process designed to remove unwanted and damaged cells. It is controlled by the expression and activation of proteins in the intrinsic and extrinsic pathways.

Which of the following would not trigger apoptosis?

OPTIONS:

A. Decrease in secretion of trophic factors

B. Increased levels of bcl-2

C. Increased levels of TRAIL

D. Activation of programmed cell death protein-1 (PD-1) on T cells

E. Activation of caspase 8

QUESTION 6.4

When tissues are damaged or lost, organisms can activate mechanisms to repair or regenerate (replace) them.

Which of the following statements about tissue regeneration and repair is correct?

OPTIONS:

A. Regeneration is the main mechanism invoked following tissue damage in mammals.

B. In mature organisms, repair is mediated by the differentiation of embryonic stem cells.

C. Liver regeneration requires the dedifferentiation of parenchymal cells.

D. Progenitor cells can migrate to different locations and repair damaged tissue.

E. Adult stem cells have the potential to be differentiated in situ to promote tissue regeneration.

ANSWERS

ANSWER 6.1

RATIONALE:

A.

B. p53, when active, up-regulates cell cycle inhibitors such as p21 and apoptotic proteins and so would halt the cell cycle.

C. p21 is a cell cycle inhibitor that acts by inhibiting the actions of cdks and so would halt the cell cycle.

D. Cyclin B acts during the G2 phase of the cell cycle and so would not affect G1/S progression.

E. Cdk 4 activation is dependent upon levels of cyclin D; just increasing expression of cdk 4 would not increase cell cycle progression.

CORRECT ANSWER WITH EXPLANATION:

A. Hyperphosphorylation of Rb protein

In its phosphorylated state, Rb releases transcription factors required for the transcription of proteins needed to drive cells through the S phase of the cell cycle. So an increase in pRb phosphorylation would enhance G1/S progression.

ANSWER 6.2

RATIONALE:

A. Metalloproteinase degradation of the ECM releases growth factors and is necessary for tissue growth, repair and remodelling.

B. Following integrin stimulation an adapter protein and an enzyme (focal adhesion kinase; FAK) activate the kinase cascade initiating growth factor signalling.

C. Integrin signalling enhances autophosphorylation of growth factor receptors, and integrin-mediated adhesion to the ECM not only suppresses the concentrations of cdk inhibitors but also is required for the expression of cyclins A and D, and therefore for the progression of the cell cycle. Furthermore, integrin activation inhibits apoptosis.

D.

E. VEGF stimulates angiogenesis which provides oxygen and nutrients to new tissue.

CORRECT ANSWER WITH EXPLANATION:

D. Activation of tissue-inhibitors of metalloproteinases (TIMPs)

TIMPs are secreted by local cells and inhibit the actions of matrix metalloproteinases (MMPs), so restricting growth factor availability and tissue growth, repair and remodelling.

ANSWER 6.3

RATIONALE:

A. Trophic factors are necessary for growth and survival. They increase the expression of antiapoptotic factors such as Bcl-2 to promote cell survival.

B.

C. TRAIL activates the extrinsic apoptotic pathway by binding to membrane receptors of the tumour necrosis factor (TNF) family.

D. PD-1 is a death receptor that can be induced on activated T cells.

E. The extrinsic pathway recruits caspase 8 as a key initiator of the apoptotic caspase cascade.

CORRECT ANSWER WITH EXPLANATION:

B. Increased levels of bcl-2

Bcl-2 is an antiapoptotic protein that promotes cell survival by competing with the proapoptotic family members to maintain mitochondrial integrity.

ANSWER 6.4

RATIONALE:

A. Most mammalian tissues, through evolution, have lost the ability to regenerate and rely instead on physiological renewal.

B. In mature organisms, repair is mediated by adult stem cells.

C. Undifferentiated liver stem cells are stimulated to grow and differentiate to regenerate damaged liver tissue.

D. Progenitor cells are tissue specific and can only differentiate into a single cell type.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Adult stem cells have the potential to be differentiated in situ to promote tissue regeneration.

Provision of growth factors and activation of other essential processes such as angiogenesis can stimulate dormant tissue-specific adult stem cells to enter the cell cycle and proliferate.

[1] Not strictly identical in the case of stem cells, as one differentiates and the other remains stem.

[2] The main daily job of our immune system is to detect and destroy cells which have genetic instability, which may become cancerous if missed. This immuno-surveillance removes thousands of incorrectly divided or dangerously damaged cells each day. Occasionally, our immune system will encounter a foreign body such as a virus or bacteria and will then 'moonlight' on that job for a while too.

[3] The term is originally a Greek word that describes the falling of leaves or petals from plants. Termed in 1972 by Professor James Cormack of Aberdeen University's Greek Department, the second 'p' is silent – APE oh TOE sis.

[4] This sequencing ensures that cells cycle in one direction only, i.e. there is no point dividing before you made two identical copies of your chromosome set.

[5] So named because mutations of the *Rb* gene are associated with retinoblastoma tumours.

[6] The entire cell cycle process, in order, is summed up in the acronym IPMATC: interphase, prophase, metaphase, anaphase, telophase and cytokinesis.

[7] Thus p53 is 'the guardian of the genome', preventing any unrepairable errors or genomic instability that occur in a cell from passing on to daughter cells by killing the cell and another healthy cell will replace the p53-destroyed cell. It is better for an organism to kill off less than perfect cells than to have any error whatsoever kept for future generations – 'the needs of the many outweigh the needs of the few' as Spock would say.

[8] There are other several other forms of programmed cell death (PCD) including *autophagy* and (confusingly) *programmed necrosis* or *necroptosis* (see Galluzzi et al., 2018). Here we will focus on apoptosis, also known as 'Type I PCD'.

[9] TNF was first thought to be secreted by bacteria, since it was known that infected tumours would sometimes recede and be cured. This 'bacterial-secreted' *tumour killing factor* was discovered to be TNF, released instead from our macrophages responding to the bacterial infection. A side effect of the TNF was tumour death, hence its name. TNF is also known as *cachexin*, the agent responsible for muscle apoptosis and wastage in cancer patients.

[10] TRAIL is **t**umour necrosis factor-a–**r**elated **a**poptosis-**i**nducing **l**igand, of course; what else? See Janssen et al. (2005) for discussion of a role of TRAIL. PD-L1, a ligand for the PD-1 receptor, is found on all haemopoietic cells and many other tissues.

[11] Another brake on cell death is a family of caspase-inhibiting proteins called IAPs (inhibitors of apoptosis proteins).

[12] Next time you cut yourself, have a look at the scar exactly a week later. It may be that almost the scar has nearly vanished. This impressive biological process (bleeding, scabbing, scarring, wound healing) in a week is dependent upon growth factors from the scab stimulating epithelial and endothelial stem cells to remodel and match what was damaged – even down to replicating a fingerprint.

[13] There is an account of liver regeneration in Greek mythology. Prometheus stole the secret of fire from Zeus and gave it to mankind. To punish him, Zeus had him shackled to a crag in the Caucasus and every day an eagle tore at his flesh and devoured much of his liver. During the night, however, it regenerated and in the morning was whole again. The legend doesn't say whether the requisite 25% was left after the eagle had had its fill, and the regeneration described seems unrealistically fast – rat liver takes 2 weeks or more to get back to the original size after 66% hepatectomy.

[14] Bovine myosatellite stem cells have been used to grow beefburgers in the lab (so-called 'no-kill' alternatives). The fact that one burger can cost up to £250,000 to make may mean that only professional footballers can afford them for now.

7: Cellular mechanisms

host defence

OVERVIEW

Everyone has experienced an inflammatory episode at some time or other and will be familiar with the typical symptoms which include redness, swelling, heat, pain and loss of function at the site of injury or infection, sometimes accompanied by fever and malaise. Inflammatory mediators are considered separately in **Chapter 17**; here we focus on the cellular players involved in the host defence response and explain the bare bones of this sophisticated and crucial mechanism. An appreciation of these responses and their functions is key to understanding the actions of anti-inflammatory and immunosuppressant drugs – a major class of therapeutic agents with multiple clinical applications (see **Ch. 25**).

Introduction

All living creatures are born into a world that poses a constant challenge to their physical well-being and survival. Evolution, which has equipped us with homeostatic systems that maintain a stable internal environment in the face of changing external temperatures and fluctuating supplies of food and water, has also provided us

with mechanisms for combating the ever-present threat of infection and for promoting healing and restoration of normal function in the event of injury. In mammals, this function is subserved by the *innate* (or non-adaptive or non-specific) and *adaptive* (alternatively *acquired or specific*) immune systems. These work together through a variety of mediators and mechanisms to mount the *inflammatory response*. Whilst predominantly protective, dysregulation of the initiation, magnitude, duration, location or resolution of inflammation contributes to a wide spectrum of diseases where drug therapy may help restore order.

The main functions of this host inflammatory response then are *defence, repair* and the restoration of function – in other words, nothing less than the ongoing biosecurity and survival of the organism. Immunodeficiency due to genetic causes (e.g. *leukocyte adhesion deficiency*), untreated infection with organisms such as HIV, radiation overexposure or immunosuppressant drugs is consequently a life-threatening state.

Like airport security systems in the mundane world, the body has the cellular and molecular equivalents of guards, identity checks, alarm systems and a communication network with which to summon back-up when required. It also has access to an astonishing data bank that stores precise molecular details of previous unwanted intruders and prevents them from returning. This host response has two main arms, which work together hand-in-hand. These are:

- *The innate response*. This developed early in evolution and is present in virtually all organisms. In fact, some of the key mammalian gene families and other components were first

identified in plants and insects. This is the first line of defence.

- *The adaptive immune response*. This appeared much later in evolutionary terms and is found almost exclusively in vertebrates. It provides the physical basis for our immunological 'memory' and is the second, and supremely effective, line of defence.

While we consider these separately it must be appreciated that their functions and actions are closely intertwined.

The inflammatory response

- The inflammatory response occurs in tissues following injury or exposure to a pathogen or other noxious substance.
- It comprises two components: an *innate* non-adaptive response and an *adaptive* (acquired or specific) immunological response.
- These reactions are generally protective, but if inappropriately deployed they are deleterious.
- The normal outcome of the response is healing with or without scarring; alternatively, if the underlying cause persists or the response fails to resolve, chronic inflammation results.
- Many diseases that require drug treatment involve inflammation. Understanding the action and use of anti-inflammatory and immunosuppressive drugs therefore necessitates an understanding of the underlying biology.

The Innate Immune Response

Mucosal epithelial tissues, which are exposed to the external environment, constantly secrete antibacterial proteins such as *defensins* together with a type of 'all-purpose' immunoglobulin known as immunoglobulin A (IgA) as a sort of pre-emptive defensive strategy. Elsewhere the innate response is activated immediately following infection or injury. [1]

The innate immune response

- The innate response occurs immediately on injury or infection. It comprises vascular and cellular elements. Mediators generated by cells or from plasma modify and regulate the magnitude of the response.
- Utilising Toll and other recognition receptors, sentinel cells in body tissues, such as macrophages, mast and dendritic cells detect specific pathogen or damage-associated molecular patterns. This triggers the release of cytokines, particularly interleukin (IL)-1 and tumour necrosis factor (TNF)-α, as well as various chemokines.
- IL-1 and TNF-α act on local postcapillary venular endothelial cells, causing:
  - vasodilatation and fluid exudation
  - expression of adhesion molecules on the cell surfaces
- Exudate contains enzyme cascades that generate bradykinin (from kininogen), and C5a and C3a (from complement).

Complement activation lyses bacteria.

- C5a and C3a stimulate mast cells to release histamine, which dilates local arterioles.
- Tissue damage and cytokines release prostaglandins PGI_2 and PGE_2 (vasodilators) and leukotriene (LT) B_4 (a chemokine).
- Cytokines stimulate synthesis of vasodilator nitric oxide, which increases vascular permeability.
- Using adhesion molecules, leukocytes roll on, adhere to and finally migrate through activated vascular endothelium towards the pathogen (attracted by chemokines, IL-8, C5a and LTB_4), where phagocytosis and bacterial killing take place.

Pattern Recognition

One of the most important functions of any security system is the ability to establish identity. How does an organism decide whether a cell or stray molecule is a bona fide citizen or an unwanted and potentially dangerous intruder? In the case of the innate response this is achieved through a network of *pattern recognition receptors* (PRRs). They recognise *pathogen-associated molecular patterns* (PAMPs) – common products produced by bacteria, fungi, parasites and viruses, which they cannot readily change to evade detection.

PRRs consist of multiple families that may be classified by protein domain homology (see **Li and Wu, 2021**, for a recent review). These include membrane-bound receptors such as the G protein–coupled FPR (formyl peptide receptor) family which recognise *N*-formylated peptides characteristic of bacterial protein

synthesis (and liberated from damaged mitochondria too); *C-type lectin receptors* (CLRs) which predominantly detect fungal beta-glucan and mannose; and cytoplasmic receptors such as the *NOD-like receptors* (**n**ucleotide-binding **o**ligomerisation **d**omain-like receptors), a large family of intracellular proteins that can recognise fragments of bacterial proteoglycan – as well as several other families including *retinoic acid-inducible gene-1* (RIG-1) like receptors and *absent in melanoma-2-like receptors* (ALRs) which detect intracellular pathogen-originated RNA and DNA, respectively. It also includes what is probably the best-studied of these PRRs, the *Toll-like receptors* (TLRs; see **Fitzgerald and Kagan 2020**, for a recent review).

The Toll [2] gene was first identified in *Drosophila* in the mid-1990s but analogous genes were soon found in vertebrates. It was quickly established that the main function of this family of proteins was to detect highly conserved components in pathogens and to signal their presence to both arms of the immune system.

Humans have a repertoire of 10 TLRs but some other animals have more. Structurally, they are transmembrane glycoproteins belonging to the *receptor tyrosine kinase* family (see **Ch. 3**). Phylogenetically they are highly conserved. Unlike the antigen receptors on T and B cells that develop and change through life, endowing each lymphocyte clone with a structurally unique receptor (see later), TLRs are encoded for by discrete genes in the host DNA. **Table 7.1** lists these receptors and the chief pathogenic products they recognise, where these are known. There are two main types of TLR, located respectively on the cell surface and in endosomes. The latter type generally recognises pathogen

RNA/DNA (presumably because they appear in phagosomes), while the former recognises other pathogen components such as cell wall material, endotoxin, etc. Some TLRs also recognise *damage associated molecular patterns* (DAMPs), molecules or motifs released either actively or passively when host cells are damaged (e.g. heat shock proteins). This provides an additional way of detecting internal damage and 'raising the alarm' (indeed, DAMPs are often referred to as *alarmins*).

How a single family of receptors can recognise such a wide spectrum of different chemicals is a molecular mystery. Some solve this problem by acting in concert. TLR 1, 2 and 6 act in this way whereas others recruit additional 'accessory' proteins that modulate their binding properties to achieve the same goal (e.g. TLR 4 with MD-2 and CD14). When activated, Toll receptors dimerise and initiate complex signalling pathways that activate genes coding for proteins and factors crucial to the deployment or modulation of the inflammatory response, many of which we will discuss further. Interestingly, from the pharmacological viewpoint, TLR 7 also recognises some synthetic antiviral compounds such as *imidazoquinolones*. The ability of these drugs to provoke TLR activation probably underlies their clinical effectiveness (see **Ch. 53**). Conversely, given their role in the initiation of inflammation and the near ubiquity of this process in pathology, TLRs are themselves now the subject of therapeutic targeting in multiple disease states (see **Anwar et al., 2019**, for a recent review)

TLRs are strategically located on 'sentinel' cells – those likely to come into early contact with invaders. These include *macrophages* as well as *mast cells* and (crucially) the *dendritic cells*, which are

especially abundant in skin and other inside–outside interfaces and *intestinal epithelial cells,* which are exposed to pathogens in the food that we eat. Genetic defects in the TLR system have been discovered. These can lead to an inability to mount an effective host defence response or sometimes to a constitutively active inflammatory response.

Table 7.1

CpG DNA, Unmethylated CG dinucleotide; *dsRNA,* double-stranded RNA; *Gm neg/pos,* Gram-negative/positive (bacteria); *GPI,* glycosylphosphatidylinositol anchoring proteins; *ssRNA,* single-stranded RNA.

[a] Operates in conjunction with MD-2 (lymphocyte antigen 96, a lipopolysaccharide binding protein) and CD14.

Having outlined how 'non-self' pathogens are detected by the innate immune system, we can now describe the events that follow.

Responses to Pattern Recognition

Vascular events

The interaction of a PAMP with TLRs triggers the sentinel cells to produce a range of pro-inflammatory polypeptides called *cytokines*, including *tumour necrosis factor* (*TNF*)-*α* and *interleukin* (*IL*)-*1*. The intracellular maturation and processing of IL-1 (and some other cytokines) is managed by *inflammasomes*, multiprotein complexes that vary according to the type of inflammatory stimulus. The inflammasome thus initiates a precisely tailored inflammatory

response appropriate to the situation (see **Zheng et al., 2020**, for a recent overview).

Also released, either as a direct consequence of tissue damage or following cytokine stimulation, are lower-molecular-weight inflammatory mediators including the prostaglandins (PGs), such as PGE_2 and PGI_2 (prostacyclin), and histamine (both being further discussed in **Ch. 17**). These act on the vascular endothelial cells of the postcapillary venules along with cytokines, to trigger the expression of *adhesion molecules* on the intimal surface and an increase in vascular permeability (allowing immune cells to pass from the blood to the affected tissue). Simultaneously they modulate perfusion, dilatating small arterioles to increase blood flow whilst there is a slowing (and sometimes a cessation) of blood flow in the postcapillary venules promoting exudation of fluid (seen as swelling or oedema).

Leukocytes adhere to the endothelial cells through interactions between their cell surface *integrins* and adhesion molecules on endothelial cells, halting their flow through the microcirculation. They are then able to migrate out of the vessels, attracted by *chemokines* (a subtype of cytokine) generated by the microorganisms themselves or as a result of their interaction with the tissues. Polypeptide chemokines released during TLR activation play an important part in this. (Cytokines and chemokines are considered separately in **Ch. 17**.)

The resulting fluid exudate contains the components for four proteolytic enzyme cascades: the *complement system*, the *coagulation system*, the *fibrinolytic system* and the *kinin system* (**Fig. 7.1**). The components of these cascades are inactive proteases

that are activated by cleavage, each activated component then activating the next in sequence.

The *complement system* comprises nine major protein components, designated C1 to C9. Activation of the cascade may be initiated by substances derived from microorganisms, such as yeast cell walls or endotoxins. This pathway of activation is termed the alternative pathway, as opposed to the classic pathway, which is dealt with later. One of the main events is the enzymatic splitting of C3, giving rise to various peptides, one of which, C3a (termed an anaphylatoxin), stimulates mast cells to secrete further chemical mediators and can also directly stimulate smooth muscle, while C3b (termed an opsonin) attaches to the surface of a microorganism, facilitating ingestion by phagocytes. C5a, generated enzymatically from C5, also releases mediators from mast cells and is a powerful chemotactic attractant and activator of leukocytes.

The final components in the sequence, complement-derived mediators C5 to C9, coalesce to form a membrane attack complex that can attach to, and lyse, some bacterial membranes. Complement can therefore mediate the destruction of invading bacteria and damage multicellular parasites; however, it may sometimes cause injury to the host. The principal enzymes of the coagulation and fibrinolytic cascades, thrombin and plasmin, can also activate the cascade by hydrolysing C3, as can enzymes released from leukocytes.

The coagulation system and the fibrinolytic system are described in **Chapter 23**. Factor XII is activated to XIIa (e.g. by collagen), and the end product, fibrin, laid down during a host–pathogen interaction, may also serve to limit the extent of the infection.

Thrombin is additionally involved in the activation of the kinin and, indirectly, the fibrinolytic systems (see **Ch. 23**). The kinin system is another enzyme cascade activated in inflammation. It yields several pro-inflammatory and pain-producing mediators, in particular bradykinin.

Eventually, the inflammatory exudate drains through the lymphatics to local lymph nodes or lymphoid tissue. Here, specialised leukocytes recognise the products of the invading microorganism and trigger the adaptive phase of the response.

Cellular events

Of the cells involved in inflammation, some (e.g. vascular endothelial cells, mast cells, dendritic cells and tissue macrophages) are normally present in tissues, while other actively motile cells (e.g. neutrophils) gain access from the circulating blood.

Polymorphonuclear leukocytes

Neutrophil polymorphs – the 'shock troops' of inflammation – are the first blood leukocytes to enter an infected or damaged tissue (**Fig. 7.2**). The whole process is cleverly choreographed: under direct observation, the neutrophils may be seen first to *roll* along the activated endothelium, then to *adhere* and finally to *migrate* out of the blood vessel and into the extravascular space. This process is regulated by the successive activation of different families of *adhesion molecules* on the inflamed endothelium (*selectins*, *intercellular adhesion molecule* [ICAM] and *integrins*) which engage corresponding *counter-ligands* on the neutrophil, capturing it as it rolls along the surface, stabilising its interaction with the

endothelial cells with the aid of PECAM (*platelet endothelial cell adhesion molecule*), and enabling it to migrate out of the vessel

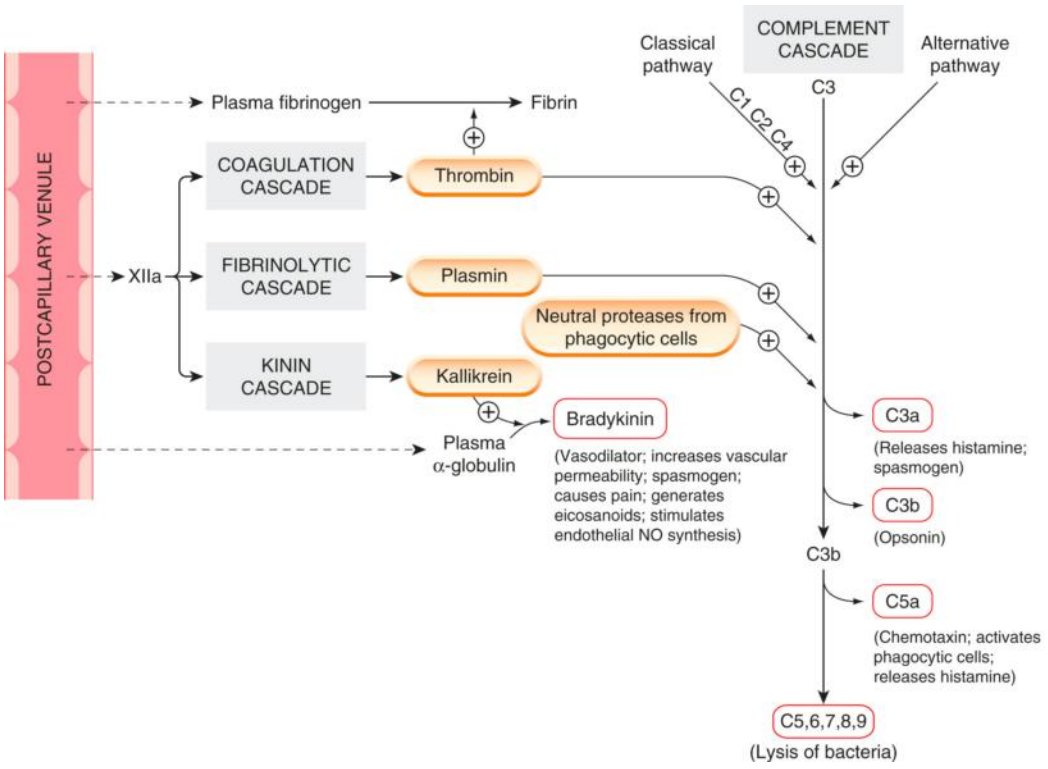

FIG. 7.1 Four enzyme cascades are activated when plasma leaks out into the tissues as a result of the increased vascular permeability of inflammation.Factors causing cellular migration are depicted in Fig. 7.2. Mediators generated are shown in *red-bordered boxes*. Complement components are indicated by *C1*, *C2*, etc. When plasmin is formed, it tends to increase kinin formation and decrease the coagulation cascade. XIIa, Factor XIIa, see text. Adapted from Dale, M.M., Foreman, J.C., Fan, T-P. (Eds) 1994. Textbook of Immunopharmacology, third ed. Blackwell Scientific, Oxford.

Neutrophils are attracted to invading pathogens by chemicals, a process known as *chemotaxis*. Some of these (such as the tripeptide

formyl-Met-Leu-Phe) are released by the microorganism, whereas others, such as C5a, are produced locally or in some cases released from nearby cells such as macrophages (e.g. chemokines such as IL-8).

Neutrophils can engulf, kill and digest microorganisms. Together with eosinophils, they have surface receptors for C3b, which acts as an opsonin that forms a link between neutrophil and invading bacterium (an even more effective link may be made by antibodies). Neutrophils kill microorganisms by internalising them into vacuoles. An NADPH oxidase enzyme on the leukocyte surface raises the pH of the normally acidic vacuole to ensure optimal enzymatic digestion of the organism by neutral proteases. Toxic oxygen radicals are also produced by this enzyme, but it is now believed that these are less important in microbial killing (see **Segal, 2016**). If a neutrophil is inappropriately activated, these biochemical weapons may be turned inadvertently on the host, causing tissue damage (an example being in the acute respiratory distress syndrome,[ARDS]). When neutrophils have exhausted their potential, they undergo apoptosis and are cleared by phagocytic macrophages, a process known as *efferocytosis*. It is this mass of live and apoptotic neutrophils that constitutes 'pus'.

Mast cells

Another important type of 'sentinel' cells is mast cells. These express TLRs, but also have surface receptors both for IgE and for the complement-derived anaphylatoxins C3a and C5a. Ligands acting at these receptors trigger mediator release, as does direct cellular damage. One of the main substances released is histamine;

others include *heparin, leukotrienes, PGD* $_2$*, platelet-activating factor (PAF), nerve growth factor* and some interleukins and proteases. Unusually, mast cells have preformed packets of cytokines that they can release instantaneously (by Ca^{2+}-mediated exocytosis; see **Ch. 4**) when stimulated. This makes them extremely effective triggers of the inflammatory response.

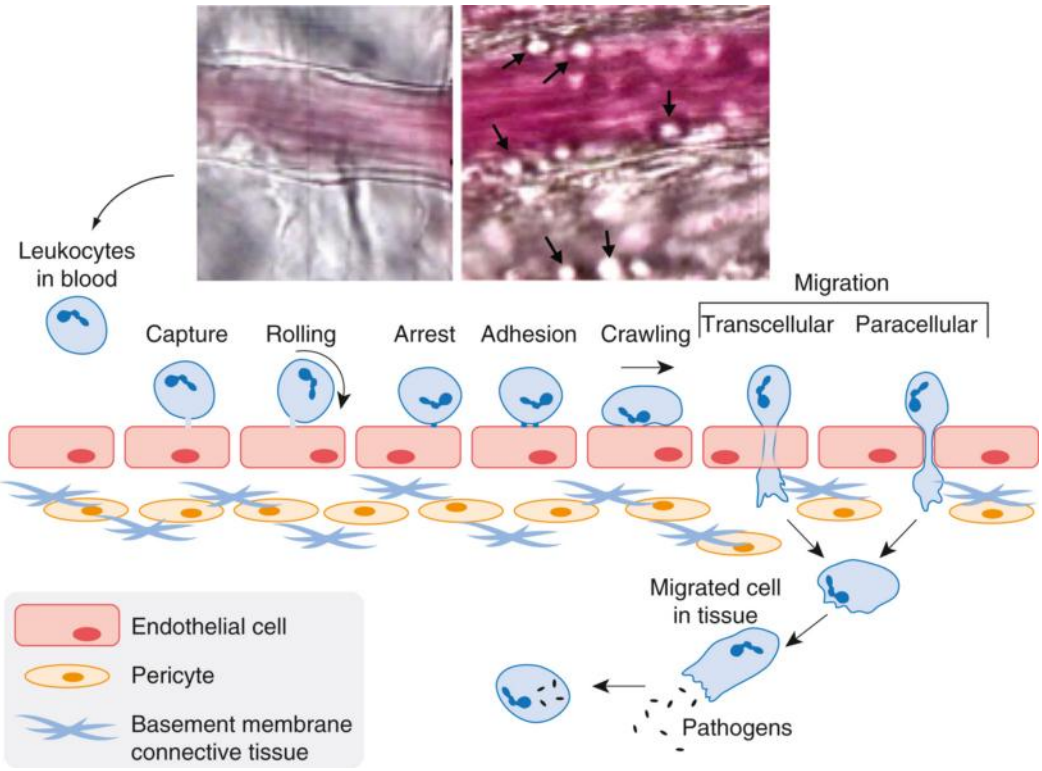

FIG. 7.2 Simplified diagram of the events leading up to polymorphonuclear leukocyte (PMN) migration in a local acute inflammatory reaction.In response to activation of pattern recognition receptors, tissue macrophages release the pro-inflammatory cytokines IL-1 and TNF-α. These act on the endothelial cells of postcapillary venules, causing exudation of fluid and expression of adhesion factors that recognise counter-ligands on blood-borne neutrophils. Free-flowing neutrophils in the blood are first 'captured' by *selectins* on activated endothelial cells. These cells then roll along the endothelium before their progress is arrested by the action of *integrins* and they adhere to the vessel wall. The

activated cells then ‘crawl’ along the endothelium until they find a suitable site for transmigration. In a minority of cases, neutrophils can actually move through endothelial cells (*transcellular transmigration*) but they mainly migrate through the junction between endothelial cells (*paracellular transmigration*). Further adhesion molecules then guide the cell through the gaps. The migrating cells must also migrate through gaps in the layer of pericytes (contractile cells) that surround the venules as well as the basement membrane (comprised of connective tissue). Chemotactic gradients formed by the release of substances released by or from the pathogen guide the cell to its target where it can kill and/or phagocytose the invader. Neutrophils characteristically die after this event, in which case they enter apoptosis and are phagocytosed by macrophages, resolving the inflammatory event. *Photo inset:* Photomicrograph of a normal, un-inflamed microcirculation in the mesenteric bed of mouse *(left-hand panel)* and following a period of inflammation *(right-hand panel)*. The arrows indicate neutrophils adhering to the endothelium as well as some that have already transmigrated. Diagram modified from Nourshargh, S., Hordijk, P.L., Sixt, M., 2010.

Monocytes/macrophages

Monocytes (a fascinating and multi-functional cell if ever there was one, see **Guilliams et al., 2018**, if interested) follow polymorphs into inflammatory lesions after a delay (sometimes several hours). Migration also depends upon adhesion molecule binding similar to that seen with neutrophils, although monocyte chemotaxis utilises additional chemokines, such as *MCP-1* [3] (which, reasonably enough, stands for *monocyte chemoattractant protein-1*) and *RANTES* (which very *unreasonably* stands for *regulated on activation normal T cell expressed and secreted*; immunological nomenclature has excelled itself here!).

Once in tissues, blood monocytes differentiate into *macrophages*, supplementing the tissue-resident macrophage population. [4] The newly differentiated cell may acquire different phenotypes including *M1*, *M2* or – more controversially – *regulatory (Mreg)*, depending upon its activation and function. The M1 phenotype is generally regarded as a pro-inflammatory cell, whereas M2 is probably more involved in tissue repair and healing (although the validity of these simplistic distinctions remains debatable: see **Martinez and Gordon, 2014**, and **Orecchioni et al., 2019**). Macrophages therefore have a remarkable range of abilities, being not only a jack-of-all-trades but also a master of many.

Activation of monocyte/macrophage TLRs stimulates the generation and release of chemokines and other cytokines that act on vascular endothelial cells, attract other leukocytes to the area and give rise to systemic manifestations of the inflammatory response such as fever (many of these inflammatory mediators have pyrogenic properties).

Macrophages also engulf tissue debris and dead cells, as well as phagocytosing and killing most (but unfortunately not all) microorganisms. They also play an important part in *antigen presentation*. When stimulated by glucocorticoids, macrophages can additionally secrete *annexin 1* (a potent anti-inflammatory polypeptide; see **Ch. 33**), which controls the development of the local inflammatory reaction helping to limit any collateral damage.

Dendritic cells

These, along with monocytes and macrophages, represent members of the 'mononuclear phagocyte system' (see **Guilliams et al., 2014**). They are present in many tissues, especially those that subserve a barrier function (e.g. the skin, where they are sometimes referred to as *Langerhans cells* after their discoverer). As a key 'sentinel cell' they can detect the presence of pathogens and when thus activated they can migrate into lymphoid tissue, where they play a crucial part in antigen presentation.

Eosinophils

These cells have similar capacities to neutrophils but, like mast cells, are also 'armed' with a battery of substances stored in their granules, which, when released, kill multicellular parasites (e.g. helminths). These include *eosinophil cationic protein*, a *peroxidase*

enzyme, the *eosinophil major basic protein* and a *neurotoxin*. The eosinophil is considered by many to be of primary importance in the pathogenesis of the late phase of asthma where, it is suggested, secreted granule proteins cause damage to bronchiolar epithelium (see **Ch. 28**). Indeed, the recent success of drugs targeting IL-5 (a key inducer of eosinophil differentiation and activation) and its receptor in severe asthma testifies to its pathological role in this complex disease (see **Pelaia et al., 2020**).

Basophils

Basophils are very similar in many respects to mast cells. Except in certain inflammatory diseases, such as viral infections and myeloproliferative disorders, the basophil content of the tissues is generally tiny and in health they form only <0.1% of circulating white blood cells. Their role is primarily in the control of parasitic infection.

Vascular endothelial cells

Originally considered to be 'passive' lining cells, vascular endothelial cells (see also Chs **22** and **23**) are now known to play an active part in inflammation. Small arteriole endothelial cells secrete nitric oxide (NO), causing relaxation of the underlying smooth muscle (see **Chs 19 and 21**), vasodilatation and increased delivery of plasma and blood cells to the inflamed area. The endothelial cells of the postcapillary venules regulate plasma exudation and thus the delivery of plasma-derived mediators. Vascular endothelial cells express several adhesion molecules (the ICAM and selectin families), as well as a variety of receptors, including those for histamine, acetylcholine and IL-1. In addition to NO, the cells can

synthesise and release other vasodilator agents such as PGI_2 and PGE_2, the vasoconstrictor agent endothelin, plasminogen activator, PAF and several cytokines. Endothelial cells also participate in the angiogenesis that occurs during inflammatory resolution, chronic inflammation and cancer (see **Chs 6** and **57**).

Platelets

Platelets are involved primarily in coagulation and thrombotic phenomena (see **Ch. 23**) but also play a part in inflammation. They have low-affinity receptors for IgE and may contribute to the first phase of allergic asthma (see **Ch. 28**). In addition to generating thromboxane $(TX)A_2$ and PAF, they can generate free radicals and pro-inflammatory cationic proteins. *Platelet-derived growth factor* contributes to the repair processes that follow inflammatory responses or damage to blood vessels.

Natural killer cells

Natural killer (NK) cells are a specialised type of lymphocyte. In an unusual twist to the receptor concept, NK cells kill targets (e.g. virus-infected or tumour cells) that *lack* ligands for inhibitory receptors on the NK cells themselves. These ligands are known as *major histocompatibility complex* (MHC) molecules, and any cells lacking these become a target for NK-cell attack, a strategy sometimes dubbed the 'mother turkey strategy'. [5] MHC proteins (also called *HLA* in leukocytes) are expressed on the surface of most host cells.

There are three major classes of MHC molecules. From our viewpoint, the most significant are the Class I MHC proteins which are involved in the host response to intracellular pathogens such as

viruses, and the Class II group which are more concerned with defence against extracellular threats such as those posed by bacteria or parasites. MHC molecules are specific for a particular individual, enabling the NK cells to avoid damaging their host's cells. NK cells also have other functions: they are equipped with Fc receptors and, in the presence of antibodies directed against a target cell, they can kill the cell by antibody-dependent cellular cytotoxicity.

The Adaptive Immune Response

The adaptive response provides the cellular basis of an 'immunological memory'. It provides a more powerful defence than the innate response, as well as being highly specific for the invading pathogen. Here we will provide only a simplified outline, stressing those aspects relevant for an understanding of drug action; for more detailed coverage, see textbooks in the *References and Further Reading* section at the end of this chapter.

The key cellular players in the adaptive response are the *lymphocytes*. [6] These are long-lived cells derived from precursor stem cells within the bone marrow. Following release into the blood and maturation, they dwell in the lymphoid tissues such as the lymph nodes and spleen. Here, they are poised to detect, intercept and identify the foreign proteins presented to them by antigen-presenting cells (APCs) such macrophages or dendritic cells. The three main groups of lymphocytes are:

- *B cells*, which mature in the bone marrow. They are responsible for antibody production, i.e. the *humoral* immune response.

- *T cells*, which mature in the thymus. They are important in the induction phase of the immune response and in *cell-mediated* immune reactions.
- *NK cells*. These are really part of the innate system. They are activated by *interferons* and release cytotoxic granules that destroy target cells identified as 'foreign' or abnormal.

T and B lymphocytes express antigen-specific receptors that recognise and react with virtually all the foreign proteins and polysaccharides we are likely to encounter during our lifetime. This receptor repertoire is generated randomly and so could recognise 'self' proteins as well as foreign antigens, with devastating results. However, *tolerance* to self-antigens is acquired during fetal life by apoptotic deletion of T-cell clones in the thymus that recognise the host's own tissues. Dendritic cells and macrophages involved in the innate response also have a role in preventing harmful immune reactions against the host's own cells.

The adaptive immune response occurs in two phases, termed the *induction phase* and the *effector phase*.

The adaptive immune response

- The adaptive (specific, acquired) immunological response boosts the effectiveness of the innate responses. It has two phases, the induction phase and the effector phase, the latter consisting of (i) antibody-mediated and (ii) cell-mediated components.

- During the *induction phase*, naive T cells bearing either the CD4 or the CD8 co-receptors are presented with antigen, triggering proliferation:
  - CD8-bearing T cells develop into cytotoxic T cells that can kill virally infected cells.
  - CD4-bearing T-helper (Th) cells are stimulated by different cytokines to develop into Th1, Th2, Th9, Th17, Th22 or Treg cells.
    - *Th1* cells develop into cells that release cytokines that activate macrophages; these cells, along with cytotoxic T cells, control cell-mediated responses.
    - *Th2* cells control antibody-mediated responses by stimulating B cells to proliferate, giving rise to antibody-secreting plasma cells and memory cells.
    - *Th9* cells augment *Treg* function and are protective against parasitic infection.
    - *Th17* cells are similar to Th1 cells and are important in some human diseases such as rheumatoid arthritis.
    - *Th22* cells are involved in epithelial barrier immunity.
    - *Treg* cells restrain the development of the immune response.
- The effector phase utilises both antibody- and cell-mediated responses.
- Antibodies provide:
  - more selective complement activation
  - more effective pathogen phagocytosis
  - more effective attachment to multicellular parasites, facilitating their destruction

  - direct neutralisation of some viruses and of some bacterial toxins.
- Cell-mediated reactions provide:
  - $CD8^+$ cytotoxic T cells that kill virus-infected cells
  - cytokine-releasing $CD4^+$ T cells that enable macrophages to kill intracellular pathogens such as the tubercle bacillus
  - memory cells primed to react rapidly to a known antigen
  - help for B-cell activation.
- Inappropriately deployed immune reactions are termed *hypersensitivity reactions*.
- Anti-inflammatory and immunosuppressive drugs are used when the normally protective inflammatory and/or immune responses escape control.

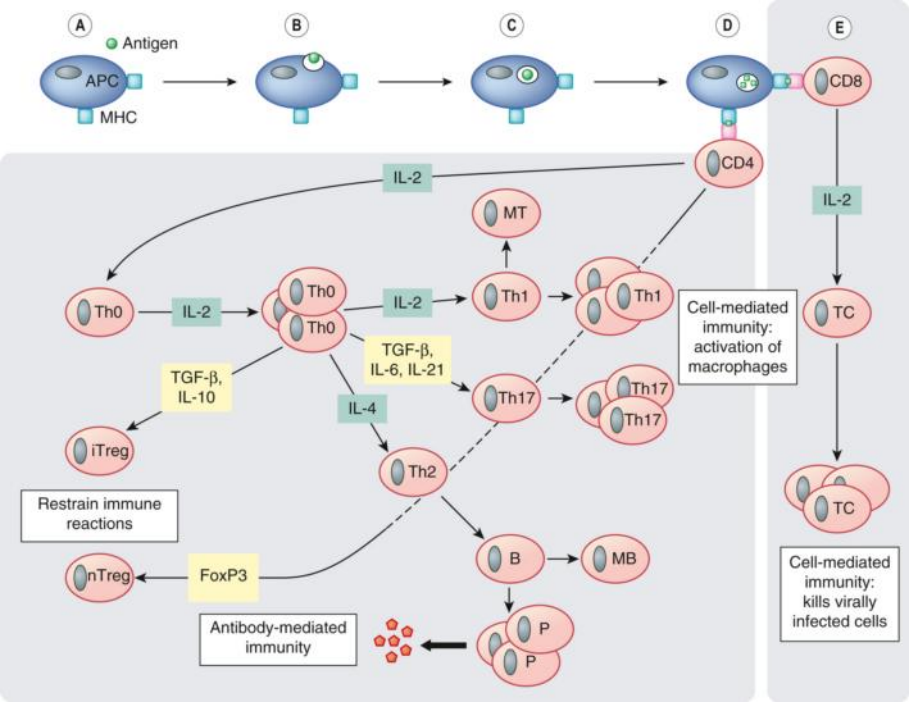

FIG. 7.3 Simplified diagram of the induction and effector phases of lymphocyte activation.APCs ingest and process antigen (A–D) before presenting fragments to naive, uncommitted CD4 (*c*luster of *d*ifferentiation 4) T cells in conjunction with MHC class II molecules, or to naive CD8 T cells in conjunction with MHC class I molecules, thus 'arming' them. Armed CD4+ T cells synthesise and express IL-2 receptors and also release this cytokine. This stimulates the cells by autocrine action, causing generation and proliferation of T-helper zero (Th0) cells. Autocrine cytokines (e.g. IL-4) cause differentiation of some Th0 cells to give Th2 cells, which are responsible for the development of antibody-mediated

immune responses. These Th2 (and sometimes Th1) cells cooperate with and activate B cells to proliferate and give rise eventually to memory B cells (MB) and plasma cells (P), which secrete antibodies. The T cells that aid B cells in this way are referred to as T_{FH} (follicular homing) cells. Further stimulation by other autocrine cytokines (e.g. IL-2, 6) causes proliferation of Th0 cells to give Th1, Th17, Th9, Th22 or iTreg cells. Th1 and Th17 cells secrete cytokines that activate macrophages (responsible for some cell-mediated immune reactions). Th22 cells promote repair of damaged epithelium and augment mucosal immunity. iTreg (inducible T regulatory cell derived from Th0 precursors) and nTreg (naturally occurring T regulatory cell matured in the thymus) cells restrain and inhibit the development of the immune response, thus preventing autoimmunity and excessive immune activation. Th9 cells promote the survival and function of Treg cells. The armed CD8+ T cells (E) also synthesise and express IL-2 receptors and release IL-2, which further stimulates the cells by autocrine action to proliferate and give rise to cytotoxic T cells (TC). These can kill virally infected cells. IL-2 secreted by CD4+ cells also stimulates CD8+

cells to proliferate. Note that the 'effector phase' described in the text relates to the 'protective' action of the immune response. When the response is inappropriately deployed – as in chronic inflammatory conditions such as rheumatoid arthritis – the Th1/Th17 component of the immune response is dominant and the activated macrophages release IL-1 and TNF-α, which in turn trigger the release of the chemokines and inflammatory cytokines that play a major role in the pathology of the disease. Please see **Raphael et al. (2015)** and **Saravia et al. (2019)** for an overview of T-cell subsets in health and disease. *APC*, Antigen-presenting cell; *IL*, interleukin; *MT,* memory T cell; *MB,* memory B cell; *MHC*, major histocompatibility complex; *TC,* cytotoxic T cell; *TGF*, transforming growth factor; *P,* plasma cell; *Treg,* regulatory T cell. Th 9 and Th22 cells not detailed for clarity.

The Induction Phase

During the induction phase, antigen is 'presented' to T cells in the lymph nodes by macrophages or large dendritic cells (**Fig. 7.3**). This antigen may constitute part of an invading pathogen (e.g. the coat of a bacterium) or be released by such an organism (e.g. a

bacterial toxin), or it may be a vaccine, an environmental agent such as pollen, an insect bite, a foodstuff or a substance introduced experimentally to study the immune response (e.g. the injection of egg albumin into the guinea pig).

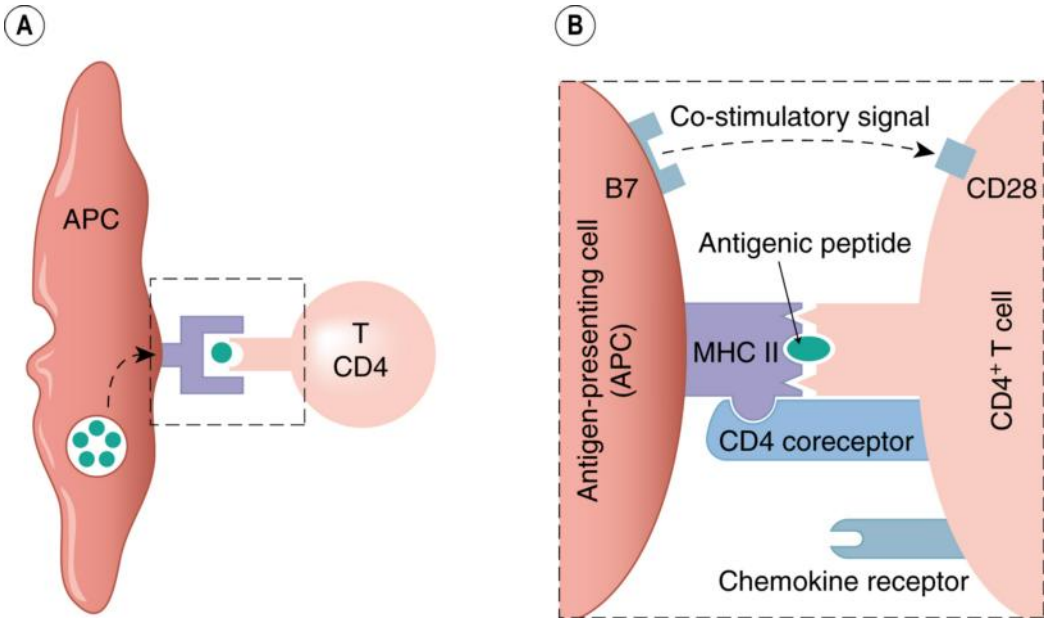

FIG. 7.4 The activation of a T cell by an antigen-presenting cell *(APC)*.(A) The APC encounters a foreign protein, and this is proteolytically processed into peptide fragments. The activation process then involves three stages: (i) interaction between the complex of pathogen-derived antigen peptide fragments with major histocompatibility complex *(MHC)* class II and the antigen-specific receptor on the T cell; (B) (ii) interaction between the CD4 co-receptor on the T cell and an MHC molecule on the APC; and (iii) the B7 protein on the APC cell surface binds to CD28 on the T cell providing a co-stimulatory signal. The CD4 co-receptor, together with a T-cell chemokine receptor, constitute the main binding sites for the HIV virus (see **Ch. 53**).

APCs ingest and proteolytically 'process' the antigen and once they reach local lymph nodes, they 'present' the fragments on their surface to lymphocytes in combination with various MHC molecules. This is followed by complex interactions of those T cells with B cells and other T cells (**Fig. 7.4**). Two types of lymphocytes 'attend' APCs. They are generally distinguished by the presence, on their surface, of CD4 or CD8 receptors. These are *co-receptors* that cooperate with the main antigen-specific receptors in antigen recognition. Macrophages also carry surface CD4 proteins.

The two types of lymphocyte involved in the adaptive response are:

- Uncommitted (naive) $CD4^+$ Th lymphocytes, or Th precursor (Thp) cells, in association with class II MHC molecules.
- Naive $CD8^+$ T lymphocytes in association with class I MHC molecules. [7]

Activation of a T cell by an APC requires that several 'identification' and 'authentication' signals pass between the two cells at this 'immune synapse' (see **Medzhitov and Janeway, 2000**). As detailed in **Fig. 7.3**, following activation, the T cells both generate IL-2 and acquire IL-2 receptors. IL-2 has an autocrine [8] action, stimulating proliferation and giving rise to a clone of Tho cells, which, depending on the prevailing cytokine milieu, differentiate into four major types of 'helper cells' (as well as others and further subtypes, which is beyond our remit here), each of which possesses a unique surface marker profile, generates a characteristic cytokine profile and has a different biological role. These characteristics are summarised in **Table 7.2**. Some potent

anti-inflammatory drugs act by blocking the IL-2 receptor, thus preventing lymphocyte proliferation (see **Ch. 25**).

Knowledge of the relationship between T-cell subsets, their respective cytokine profiles and pathological conditions can be used to manipulate the immune responses for disease prevention and treatment. There are already many experimental models in which modulation of the Th1/Th2 balance with recombinant cytokines or cytokine antagonists alters the outcome of the disease.

The Effector Phase

During the effector phase, the activated B lymphocytes differentiate either into *plasma cells* or into *memory cells*. The B plasma cells produce specific antibodies, which are effective in the extracellular fluid, but which cannot neutralise pathogens within cells. T-cell-mediated immune mechanisms overcome this problem by activating macrophages or directly killing virus-infected host cells. Antigen-sensitive memory cells are formed when the clone of lymphocytes that are programmed to respond to an antigen is greatly expanded after the first contact with the organism. They allow a greatly accelerated and more effective response to subsequent antigen exposure. In some cases, the response is so rapid and efficient that a single exposure is often sufficient to ensure that the pathogen can never gain a foothold again. Vaccination and immunisation procedures make use of this invaluable phenomenon.

Table 7.2

Th9 and Th22 cells are not included here for reasons of space but appropriate references are highlighted in **Fig. 7.3** should readers wish todiscover more about these 'new' additions.

FOX P3, 'Forkhead box 3', a transcriptional regulator which has a key role in regulation of the immune system; *IFN,* interferon; *IL,* interleukin; *TGF,* transforming growth factor; *TNF,* tumour necrosis factor.

[a] Two populations are commonly encountered: inducible (iTreg) and naturally occurring Treg cells (nTreg).

The Antibody-Mediated (Humoral) Response

There are five main classes of antibody – IgG, IgM, IgE, IgA and IgD – which differ from each other in certain structural respects. All are γ-globulins (immunoglobulins), which both recognise and interact specifically with antigens (i.e. proteins or polysaccharides foreign to the host), as well as activating one or more further components of the host's defence systems.

An antibody is a Y-shaped protein molecule (see **Ch. 5**) in which the arms of the Y (the **f**ragment **a**ntigen **b**inding – Fab portion) include a variable recognition site for specific antigens, and the invariable stem of the Y (the '**c**onstant' Fc portion) activates host defences. The B cells that are responsible for antibody production recognise foreign molecules by means of surface receptors similar the immunoglobulins. Mammals harbour B-cell clones with recognition sites for an immense number of different antigens. Once they encounter a ligand that they recognise, synthesis of that

particular species is greatly expanded and subsequently shed into the circulating blood forming a reservoir of circulating antibody specific for that particular antigen.

The induction of antibody-mediated responses varies with the type of antigen. With most antigens, a cooperative process between Th2 cells and B cells is generally necessary to produce a response. B cells can also present antigen to T cells which then release cytokines that act further on the B cell. The anti-inflammatory glucocorticoids (see Chs **25** and **33**) and the immunosuppressive drug **ciclosporin** affect the molecular events crucial to induction. The cytotoxic immunosuppressive drugs inhibit the proliferation of both B and T cells. Eicosanoids may play a part in controlling these processes as PGs of the E series can inhibit lymphocyte proliferation, probably by inhibiting the release of IL-2.

As you might guess, the ability to make antibodies has huge survival value; children born without this ability, such as those suffering from Bruton's agammaglobulinemia [9] suffer repeated infections such as pneumonia, skin infections and tonsillitis. Before the days of antibiotics, they died in early childhood, and even today they require regular replacement therapy with immunoglobulin. Apart from their ability to neutralise pathogens, antibodies can boost the effectiveness and specificity of the host's defence reaction in several ways.

Antibodies and complement

Formation of the antigen–antibody complex exposes a binding site for complement on the Fc domain. This activates the complement sequence and sets in train its attendant biological effects (see **Fig.**

7.1). This route to C3 activation (the 'classic pathway') provides an especially selective way of activating complement in response to a particular pathogen, because the antigen–antibody reaction that initiates it is not only a highly specific recognition event but also occurs in close association with the pathogen. The lytic property of complement can be used therapeutically: monoclonal antibodies (mAbs) and complement together can be used to rid bone marrow of cancer cells as an adjunct to chemotherapy or radiotherapy (see **Ch. 57**).

Antibodies and the phagocytosis of bacteria

When antibodies are attached to their antigens on microorganisms by their Fab portions, the Fc domain is exposed. Phagocytic cells (neutrophils and macrophages) express surface receptors for these projecting Fc portions, which serve as a very specific link between microorganism and phagocyte.

Antibodies and cellular toxicity

In some cases, for example, with parasitic worms, the invader may be too large to be ingested by phagocytes. Antibody molecules can form a link between parasite and the host's white cells (in this case, eosinophils), which are then able to damage or kill the parasite. NK cells in conjunction with Fc receptors can also kill antibody-coated target cells (an example of *antibody-dependent cell-mediated cytotoxicity*).

Antibodies and mast cells or basophils

Mast cells and basophils have receptors for IgE, a particular form of antibody that can attach ('fix') to their cell membranes. When this

cell-fixed antibody reacts with an antigen, an entire panoply of pharmacologically active mediators is secreted. This very complex reaction is found widely throughout the animal kingdom and presumably confers clear survival value to the host. Having said that, its precise biological significance is not always entirely clear, although it may be of importance in association with eosinophil activity as a defence against parasitic worms. When inappropriately triggered by substances not inherently damaging or dangerous to the host, it is implicated in certain types of allergic reaction and seemingly contributes more to illness than to survival in the modern world.

The Cell-Mediated Immune Response

Cytotoxic T cells (derived from $CD8^+$ cells) and inflammatory (cytokine-releasing) Th1 cells are attracted to inflammatory sites in a similar manner to neutrophils and macrophages and are involved in cell-mediated responses (see **Fig. 7.3**).

Cytotoxic T cells

Armed cytotoxic T cells kill intracellular microorganisms such as viruses. When a virus infects a mammalian cell, there are two aspects to the resulting defensive response. The first step is the expression on the cell surface of peptides derived from the pathogen in association with MHC molecules. The second step is the recognition of the peptide–MHC complex by specific receptors on cytotoxic ($CD8^+$) T cells (**Fig. 7.4** shows a similar process for a $CD4^+$ T cell). The cytotoxic T cells then destroy virus-infected cells by programming them to undergo apoptosis. Cooperation with macrophages may be required for killing to occur.

Macrophage activating $CD4^+$ Th1 cells

Some pathogens (e.g. Mycobacteria, Listeria) survive and actually multiply within macrophages after ingestion. Armed $CD4^+$ Th1 cells release cytokines that activate macrophages to kill these intracellular pathogens. Th1 cells also recruit macrophages by releasing cytokines that act on vascular endothelial cells (e.g. TNF-α) and chemokines (e.g. MCP-1) that attract the macrophages to the sites of infection.

A complex of microorganism-derived peptides plus MHC molecules is expressed on the macrophage surface and is recognised by cytokine-releasing Th1 cells, which then generate cytokines that enable the macrophage to deploy its killing mechanisms. Activated macrophages (with or without intracellular pathogens) are veritable factories for the production of chemical mediators: they can generate and secrete not only many cytokines but also toxic oxygen metabolites and neutral proteases that kill extracellular organisms (e.g. *Pneumocystis jiroveci* and helminths), complement components, eicosanoids, NO, a fibroblast-stimulating factor, pyrogens and the 'tissue factor' that initiates the extrinsic pathway of the coagulation cascade (see **Ch. 23**), as well as various other coagulation factors. This is the cell-mediated reaction that is primarily responsible for allograft rejection. Macrophages are also important in coordinating the repair processes that must occur for inflammation to resolve.

The specific cell-mediated or humoral immunological response is superimposed on the innate non-specific vascular and cellular reactions described previously, making them not only markedly

more effective but also much more selective for particular pathogens.

The general events of the inflammatory and hypersensitivity reactions specified earlier vary in some tissues. In the airway inflammation of asthma for example, eosinophils and neuropeptides play a particularly significant role (see **Ch. 28**). In central nervous system (CNS) inflammation, there is less neutrophil infiltration and monocyte influx is delayed, possibly because of lack of adhesion molecule expression on CNS vascular endothelium and deficient generation of chemokines. It has long been known that some tissues – the CNS parenchyma, the anterior chamber of the eye and the testis – are *immunologically privileged* sites, in that a foreign antigen introduced directly does not provoke an immune reaction (which could be very disadvantageous to the host). [10] However, introduction elsewhere of an antigen already in the CNS parenchyma will trigger the development of immune/inflammatory responses in the CNS.

Systemic Responses in Inflammation

In addition to the local changes in an inflammatory site, there are commonly more general systemic manifestations of inflammatory disease. Typically, these could include fever, an increase in blood leukocytes and the release from the liver of acute-phase proteins. The latter includes *C-reactive protein, α_2-macroglobulin, fibrinogen, α_1-antitrypsin, serum amyloid A* and some complement fragments. While the function of many of these components is still a matter of conjecture, many seem to have some antimicrobial actions. C-reactive protein, for example, binds to some

microorganisms, and the resulting complex activates complement. Other proteins scavenge iron (an essential nutrient for invading organisms) or block proteases, perhaps protecting the host against the worst excesses of the inflammatory response.

The Role of the Nervous System in Inflammation

It has become clear in recent years that the central, autonomic and peripheral nervous systems all play an important part in the regulation of the inflammatory response. This occurs at various levels:

- *The neuroendocrine system*. Adrenocorticotrophic hormone (ACTH), released from the anterior pituitary gland in response to endogenous circadian rhythm or to stress (and thus episodes of illness), releases cortisol from the adrenal glands. This hormone plays a crucial role in regulating immune function at all levels, hence the use of glucocorticoid drugs in the treatment of inflammatory disease. This topic is explored fully in **Chapters 25** and **33**.
- *The CNS*. Surprisingly, cytokines such as IL-1 can signal the development of an inflammatory response directly to the brain through receptors on the vagus nerve. This may elicit an 'inflammatory reflex' and trigger activation of a cholinergic anti-inflammatory pathway. See **Sternberg (2006)** and **Chavan et al. (2017)** for interesting discussions of this topic.
- *The autonomic nervous system*. Both the sympathetic and parasympathetic systems can modulate the development of the inflammatory response. Generally speaking, their

influence is anti-inflammatory. Receptors for noradrenaline and acetylcholine (such as alpha 7 nicotinic acetylcholine receptor) are found on macrophages and many other cells involved in the immune response although the origins of these ligands are unclear. Opioid receptors are also found on inflammatory cells and they also have multiple effects on many aspects of the inflammatory response (**Liang et al., 2016**).

- *Peripheral sensory neurons*. Some sensory neurons release inflammatory neuropeptides when appropriately stimulated. These neurons are fine afferents (capsaicin-sensitive C and Aδ fibres; see **Ch. 43**) with specific receptors at their peripheral terminals. Kinins, 5-hydroxytryptamine (5-HT) and other chemical mediators generated during inflammation act on these receptors, stimulating the release of neuropeptides such as the tachykinins (neurokinin A, substance P) and calcitonin gene-related peptide (CGRP), which have pro-inflammatory or algesic actions. The neuropeptides are considered further in **Chapter 17**.

Unwanted Inflammatory and Immune Responses and their Unintended Consequences

The immune response has to strike a delicate balance. According to one school of thought, an infection-proof immune system would be a possibility but would come at a serious cost to the host. With many millions of potential antigenic sites in the host, such a 'super-immune' system would be some 1000 times more likely to attack the host itself, triggering *autoimmune disease*. It is not uncommon

to encounter patients in whom exposure to ordinarily innocuous substances such as pollen or peanuts inadvertently activates the immune system. When this happens, the ensuing inflammation itself inflicts self-harm – either acutely as in (for example) anaphylaxis or chronically in (for example) asthma or rheumatoid arthritis. In either case, appropriate anti-inflammatory or immunosuppressive therapy may be required.

A proportionate response is also required in the case of acute infection with bacterial or viral pathogens. Whilst elimination of the invading organism is clearly the desired outcome, without adequate regulation there is the risk that a sustained or exaggerated host response will pose a greater threat than the pathogen itself. Such dysregulation of the immune response is responsible for syndromes including *sepsis*, ARDS and COVID-19-associated pneumonitis (see **Nedeva et al., 2019**).

Unwanted immune responses, termed allergic or hypersensitivity reactions, are generally classified into four types.

Type I hypersensitivity

Also called immediate or anaphylactic hypersensitivity (often known simply as 'allergy'), type I hypersensitivity occurs in individuals who predominantly exhibit a Th2 rather than a Th1 response to antigen. In these individuals, substances that are not inherently noxious (such as grass pollen, house dust mites, certain foodstuffs or drugs, animal fur and so on) provoke the production of antibodies of the IgE type. [11] These fix onto mast cells and eosinophils. Subsequent contact with the problematic substance causes the release of histamine, PAF, eicosanoids and cytokines.

The effects may be localised to the nose (hay fever), the bronchial tree (the initial phase of asthma), the skin (urticaria) or the gastrointestinal tract. In some cases, the reaction is more generalised and produces anaphylactic shock, which can be severe and life-threatening. Some important unwanted effects of drugs include anaphylactic hypersensitivity responses (see **Ch. 58**).

Type II hypersensitivity

Also called antibody-dependent cytotoxic hypersensitivity, type II hypersensitivity occurs when the mechanisms outlined previously are directed against cells within the host that are (or appear to be) foreign. For example, host cells or proteins altered by drugs are sometimes mistaken by the immune system for foreign organisms and evoke antibody formation. The antigen–antibody reaction triggers complement activation (and its sequelae) and may promote attack by NK cells. Examples include alteration by drugs of neutrophils, leading to agranulocytosis (see **Ch. 57**), or of platelets, leading to thrombocytopenic purpura (see **Ch. 23**). These type II reactions are also implicated in some types of autoimmune thyroiditis (e.g. Hashimoto's disease; see **Ch. 34**).

Type III hypersensitivity

Also called complex-mediated hypersensitivity, type III hypersensitivity occurs when antibodies react with soluble antigens. The antigen–antibody complexes can activate complement or attach to mast cells and stimulate the release of inflammatory mediators.

An experimental example of this is the Arthus reaction that occurs if a foreign protein is injected subcutaneously into a rabbit or guinea pig bearing pre-existing high circulating concentrations of

antibody. Within 3–8 h the area becomes red and swollen because the antigen–antibody complexes precipitate in small blood vessels and activate complement. Neutrophils are attracted and activated (by C5a) to generate toxic oxygen species and to secrete enzymes.

Mast cells are also stimulated by C3a to release mediators. Damage caused by this process is involved in serum sickness, which occurs when antigen persists in the blood after sensitisation, causing a severe reaction, as in the response to mouldy hay (known as Farmer's lung), and in certain types of autoimmune kidney and arterial disease. Type III hypersensitivity is also implicated in lupus erythematosus (a chronic, autoimmune inflammatory disease).

Type IV hypersensitivity

The prototype of type IV hypersensitivity (also known as cell-mediated or delayed hypersensitivity) is the tuberculin reaction, a local inflammatory response seen when proteins derived from cultures of the tubercle bacillus are injected into the skin of a person who has been sensitised by a previous infection or immunisation. An 'inappropriate' cell-mediated immune response is stimulated, accompanied by infiltration of mononuclear cells and the release of various cytokines. Cell-mediated hypersensitivity is also the basis of the reaction seen in some other infections (e.g. mumps and measles), as well as with mosquito and tick bites. It is also important in the skin reactions to drugs or industrial chemicals (see **Ch. 58**), where the chemical (termed a hapten) combines with proteins in the skin to form the 'foreign' substance that evokes the cell-mediated immune response (see **Fig. 7.3**).

In essence, inappropriately deployed T-cell activity underlies all types of hypersensitivity, initiating types I, II and III, and being involved in both the initiation and the effector phase in type IV. These reactions are the basis of the clinically important group of autoimmune diseases. Immunosuppressive drugs (see **Ch. 25**) and/or glucocorticoids (see **Ch. 33**) are routinely employed to treat such disorders.

The Outcome of the Inflammatory Response

It is important not to lose sight of the fact that the inflammatory response is a defence mechanism and not a disease per se. Its role is to restore normal structure and function to the infected or damaged tissue, and in the vast majority of cases, this is what occurs.

The healing and resolution phase of the inflammatory response is, however, an active process and does not simply 'happen' in the absence of further inflammation. Resolution utilises its own unique palette of mediators and cytokines (including various growth factors, annexin A1, lipoxins, omega-3 polyunsaturated acid-derived mediators and IL-10; see **Ch. 17**) to terminate residual inflammation and to promote remodelling and repair of damaged tissue.

In some cases, healing will be complete, but if there has been marked damage, repair is usually necessary, and this may result in scarring. If the pathogen persists, it is enclosed by the host in a fibrous capsule 'prison' to prevent any further damage. Alternatively, the acute inflammatory response may transform into a chronic inflammatory response. This is a slow, smouldering reaction that can continue indefinitely, destroying tissue and

promoting local proliferation of cells and connective tissue. The principal cell types found in areas of chronic inflammation are mononuclear cells and abnormal macrophage-derived cells. During healing or chronic inflammation, growth factors trigger angiogenesis and cause fibroblasts to lay down fibrous tissue. Infection by some microorganisms, such as syphilis, tuberculosis and leprosy, bear the characteristic hallmarks of chronic inflammation from the start and result in the formation of macrophage aggregates called *granulomas*. The cellular and mediator components of this type of inflammation are also seen in many, if not most, chronic autoimmune and hypersensitivity diseases and are important targets for drug action.

QUESTIONS

QUESTION 7.1

Acute inflammation is an important part of host defence and healing.

Which of the following would not directly enhance the acute inflammatory response?

OPTIONS:

A. C5a

B. Chemokines

C. Adhesion molecules

D. Interleukin-4

E. Monocytes

QUESTION 7.2

Different subtypes of T lymphocytes, activated by a range of cellular interactions, coordinate a range of cell-mediated responses through differential cytokine release.

Which of the following statements about T lymphocyte subtype activation and effector function is incorrect?

OPTIONS:

A. CD4 TFH (follicular homing) cells cooperate with and activate B cells.

B. CD4 Th1 cells are activated in conjunction with major histocompatibility complex (MHC) class I molecules and enhance macrophage function.

C. CD4 Th2 cells are activated in conjunction with MHC class II molecules and enhance antibody production.

D. CD8 T cells are activated in in conjunction with MHC class I molecules to mediate cytotoxic effects.

E. CD4 inducible Treg restrains and inhibits the development of the immune response.

QUESTION 7.3

Inappropriate activation of the immune system against non-pathogenic or self-antigens can manifest as hypersensitivity reactions.

Which of the following hypersensitivity conditions is NOT antibody mediated?

OPTIONS:

A. Complex-mediated hypersensitivity implicated in lupus erythematosus

B. Anaphylactic hypersensitivity

C. Arthus reaction

D. Type II reactions implicated in some types of autoimmune thyroiditis

E. Delayed hypersensitivity involving autoimmune responses such as diabetes mellitus

ANSWERS

ANSWER 7.1

RATIONALE:

A. C5a is an active fragment of the complement cascade and is involved in the chemotactic recruitment of neutrophils to the site of infection.

B. Chemokines (chemotactic cytokines) are involved in attracting leucocytes to the site of infection.

C. Enhanced adhesion molecule expression on the surface of endothelial cells increases leucocyte tethering to the endothelium and transmigration into the tissue.

D.

E. Monocytes attracted by chemokines and enhanced adhesion molecule expression pass from the blood into the tissue to mature into tissue macrophages to engulf pathogens.

CORRECT ANSWER WITH EXPLANATION:

D. Interleukin-4

Interleukin-4 is an anti-inflammatory cytokine released by Th2 cells which mediates the humoral/antibody response through activation of B cells.

ANSWER 7.2

RATIONALE:

A. CD4 TFH cells are Th2 cells which enhance B cell antibody production.

B.

C. CD4 Th0 cells differentiate into Th2 cells on exposure to interleukin (IL)-4 and stimulate B cells.

D. CD8, cytotoxic cells recognise viral or tumour antigens presented on class I MHC.

E. Inducible Tregs develop from CD4 TH0 precursors but suppress the immune response through secretion of anti-inflammatory cytokines.

CORRECT ANSWER WITH EXPLANATION:

B. CD4 Th1 cells are activated in conjunction with MHC class I molecules and enhance macrophage function.

CD4 Th1 cells recognise antigen presented by class II MHC on antigen presenting cells.

ANSWER 7.3

RATIONALE:

A. Type III complex-mediated hypersensitivity involves antibody generation against soluble self-antigens and deposition of antigen–antibody complexes.

B. Anaphylactic hypersensitivity involves the production of IgE and degranulation of mast cells.

C. An Arthus reaction occurs if a foreign protein is injected subcutaneously into a rabbit or guinea pig bearing pre-existing high circulating concentrations of antibody. Antigen–antibody complexes precipitate in small blood vessels and activate complement.

D. Type II reactions involve the generation of self-reactive autoantibodies against host cellular surface proteins.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Delayed hypersensitivity involving autoimmune responses such as diabetes mellitus

Delayed hypersensitivity is a cell-mediated response driven by the infiltration and activation of mononuclear cells particularly cytotoxic cells.

[1] One immunologist described the innate immune response as the organism's 'knee jerk' response to infection; it is an excellent description.

[2] The name, which loosely translates from German as ‘Great!’ or ‘Eureka!’, has remained firmly attached to the family. Discovered in fruit fly experiments, Christiane Nüsslein-Volhard exclaimed ‘Das ist ja *toll*!’ The name has stuck since then.

[3] Human immunodeficiency virus-1 binds to the surface CD4 glycoprotein on monocytes/macrophages but is able to penetrate the cell only after binding also to MCP-1 and RANTES receptors. This is a case where the innate immune system inadvertently aids the enemy.

[4] Literally ‘big eaters’, compared with neutrophils, originally called *microphages* or ‘little eaters’.

[5] Citing the zoologist Schliedt in his book *River Out of Eden*, Richard Dawkins explains that the ‘rule of thumb a mother turkey uses to recognise nest robbers is a dismayingly brusque one; in the vicinity of the nest, attack anything that moves unless it makes a noise like a baby turkey’.

[6] White blood cells (WBCs) or leukocytes in blood are mostly neutrophils (50%–60%) or lymphocytes (20%–40%), with the rest being monocytes (3%–7%), eosinophils (1%–5%) and less than 1% basophils. The WBC count in a healthy adult is in the range 3.5–11 million per mL of blood – higher values may indicate chronic bacterial or viral infection; lower levels occur in anaemia or in immunosuppressed individuals (e.g. when undergoing treatment with chemotherapeutic drugs [see Ch. 57]).

[7] The main reason that it is difficult to transplant organs such as kidneys from one person to another is that their respective MHC molecules are different. Lymphocytes in the recipient will react to

non-self (*allogenic*) MHC molecules in the donor tissue, which is then likely to be rejected by a rapid and powerful immunological reaction.

[8] In 'autocrine' signalling the mediator acts on the cell that released it. In 'paracrine' signalling, the mediator acts on neighbouring cells, whilst in 'juxtacrine' signalling, it acts on cells in direct contact.

[9] Mainly boys: Col. Bruton was chief of paediatrics at the Walter Reid army hospital. 'Bruton's agammaglobulinemia' is caused by a defect in a tyrosine kinase (BTK) coded on the X chromosome. BTKs promote leukocyte survival and proliferation and BTK inhibitors are proving useful in treating certain leukaemias (see Ch. 57).

[10] Cold sore sufferers can blame this phenomenon for their misery – herpes simplex virus resides in the facial nervous tissue and becomes activated following stress or environmental stimuli, for example, exposure to the sun. The virus can reside in the CNS tissue for a whole lifetime from infancy, stubbornly resistant to the attempts of our immune cells to remove it. It can be transmitted to the baby from a carrier via a kiss, before the infant's immune system can eliminate the virus (usually by 6 months old). Bonnie babies are destined to suffer forever more.

[11] Such individuals are said to be 'atopic', from a Greek word meaning 'out of place'.

8: Method and measurement in pharmacology

OVERVIEW

We emphasised in **Chapters 2** to **5** that drugs, being molecules, produce their effects by interacting with other molecules. This interaction can lead to effects at all levels of biological organisation, from molecules to human populations. [1]

Gaddum, a pioneering pharmacologist, commented in 1942: 'A branch of science comes of age when it becomes quantitative.' In this chapter, we cover the principles of metrication at the various organisational levels, ranging from laboratory methods to clinical trials. Assessment of drug action at the population level is the concern of pharmacoepidemiology and pharmacoeconomics (see **Ch. 1**), disciplines that are beyond the scope of this book.

We consider first the general principles of bioassay and its extension to studies in human beings; we describe the development of animal models to bridge the predictive gap between animal physiology and human disease; we next discuss aspects of clinical trials used to evaluate therapeutic efficacy in a clinical setting; finally, we consider summarising multiple datasets in a meta-analysis and the principles of balancing overall benefit and risk. Experimental design and

statistical analysis are central to the interpretation of all types of pharmacological data.

BIOASSAY

Bioassay, originally defined as the estimation of the concentration or potency of a substance by measurement of the biological response that it produces, has played a key role in the development of pharmacology. Quantitation of drug effects by bioassay is necessary to compare the properties of different substances, or the same substance under different circumstances. It is used:

- to measure the pharmacological activity of new or chemically undefined substances;
- to investigate the function of endogenous mediators;
- to measure drug toxicity and unwanted effects.

Bioassay plays a key role in the development of new drugs, discussed in **Chapter 60**.

The use of bioassay to measure the *concentration* of drugs and other active substances in the blood or other body fluids – once an important technology – has now been largely replaced by analytical chemistry techniques.

Many hormones and chemical mediators were discovered by the biological effects that they produce. For example, the ability of extracts of the posterior lobe of the pituitary to produce a rise in blood pressure and a contraction of the uterus was observed at the beginning of the 20th century. Quantitative assay procedures based on these actions enabled a standard preparation of the extract to be

established by international agreement in 1935. By use of these assays, it was shown that two distinct peptides – vasopressin and oxytocin – were responsible, and they were eventually identified and synthesised in 1953. Biological assay had already revealed much about the synthesis, storage and release of the hormones, and was essential for their purification and identification. The recent growth of *biopharmaceuticals* (see **Ch. 5**) as therapeutic agents has relied on bioassay techniques and the establishment of standard preparations. Biopharmaceuticals, whether derived from natural sources (e.g. monoclonal antibodies, vaccines) or by recombinant DNA technology (e.g. erythropoietin), tend to vary from batch to batch, and need to be standardised with respect to their biological activity. Varying glycosylation patterns, for example, which are not detected by immunoassay techniques, may affect biological activity.

BIOLOGICAL TEST SYSTEMS

Nowadays, an important use of bioassay is to provide information that will predict the effect of the drug in the clinical situation (where the aim is to improve function in patients suffering from the effects of disease). The choice of laboratory test systems (in vitro and in vivo 'models') that provide this predictive link is an important aspect of quantitative pharmacology.

By the 1960s, pharmacologists had become adept at using isolated organs and laboratory animals (usually under anaesthesia) for quantitative experiments, and had developed the principles of bioassay to allow reliable measurements to be made with these sometimes difficult and unpredictable test systems.

These ‘traditional’ assay systems address drug action at the physiological level – roughly, the mid-range of the organisational hierarchy shown in **Fig. 8.1**. Extension of the range in both directions, towards the molecular and atomistic as well as in the opposite direction towards the clinical, has taken place since.

The introduction of radioligand binding assays (see **Ch. 3**) and subsequently the use of engineered cell lines expressing normal and mutated receptors and signalling molecules changed dramatically the ways in which bioassay could be used to study the molecular and cellular consequences of receptor activation. Indeed, the range of techniques for analysing drug effects at the cellular level is now very impressive and expanding rapidly. An example (**Fig. 8.2**) is the use of fluorescence-activated cell sorting (FACS) to measure the effect of a corticosteroid on the expression of a cell surface marker protein by human blood monocytes. Quantitative cellular assays of this kind are now widely used in pharmacology. More recently, techniques based on X-ray crystallography, cryo electron microscopy, nuclear magnetic resonance spectroscopy and fluorescence signals have thrown much new light on drug action at the atomic and molecular levels (see reviews by **Lohse et al., 2012**; **Nygaard et al., 2013**; **Safdari et al., 2018**), and allow, for the first time, measurement as well as detection of the initial molecular events. These approaches have also played an important role in reducing the need to use living animals or animal tissues although it is important to be aware that many cell culture systems still rely on animal-based products and most cells still require animal sera to grow successfully in culture.

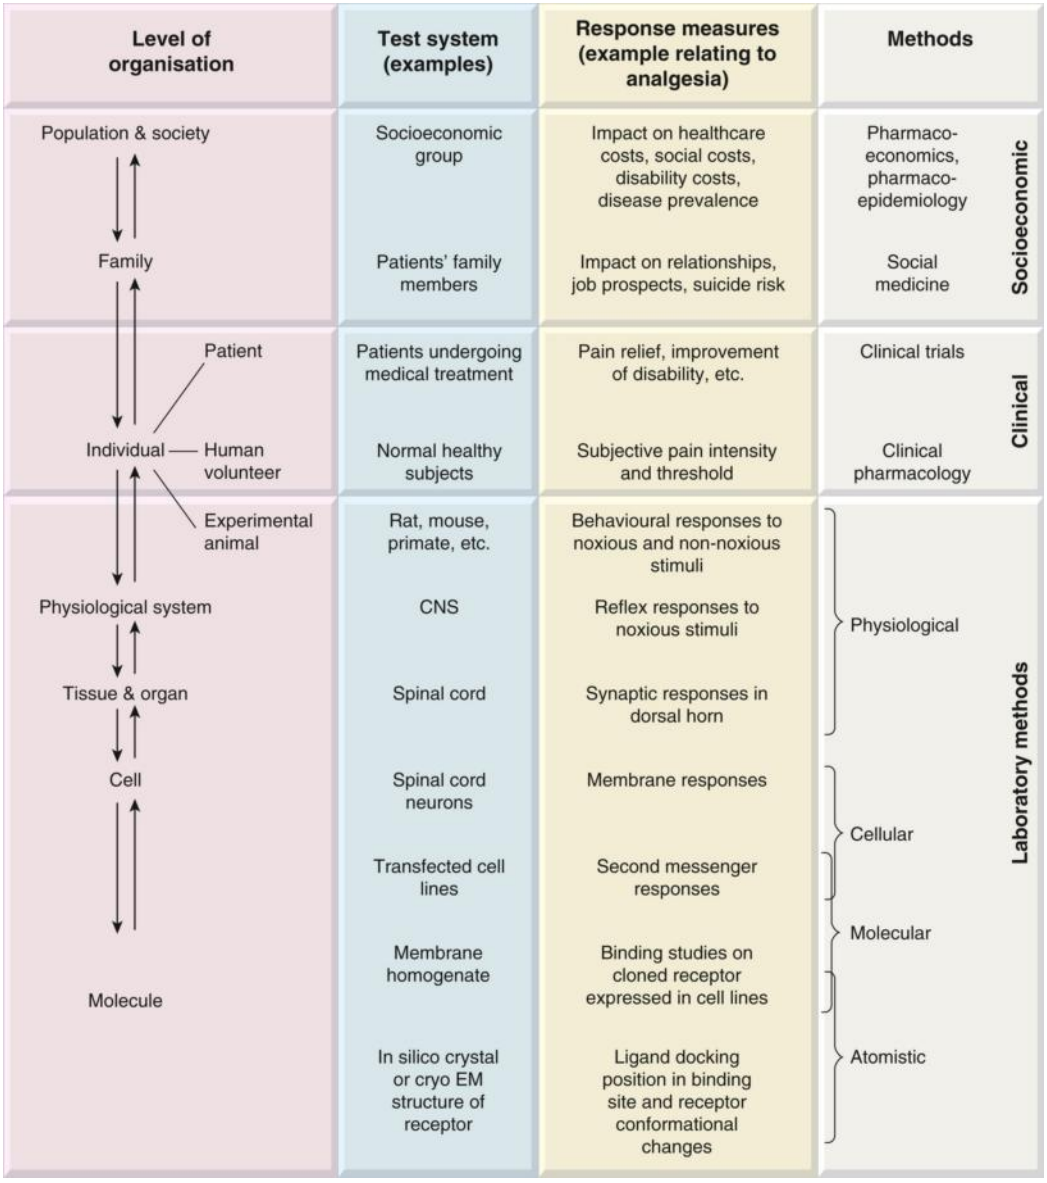

FIG. 8.1 Levels of organisation and types of pharmacological measurement. *CNS,* Central nervous system; *EM*, electron microscopy.

These approaches have important implications for basic understanding of drug action, and for drug design, but the need remains for measurement of drug effects at the physiological and clinical levels. Bridging the gap between events at the molecular level and at the physiological and therapeutic levels presents

difficulties, because human illness cannot, in many cases, be accurately reproduced in experimental animals. The use of genetically altered animals (GAAs) to model human disease is discussed in more detail later.

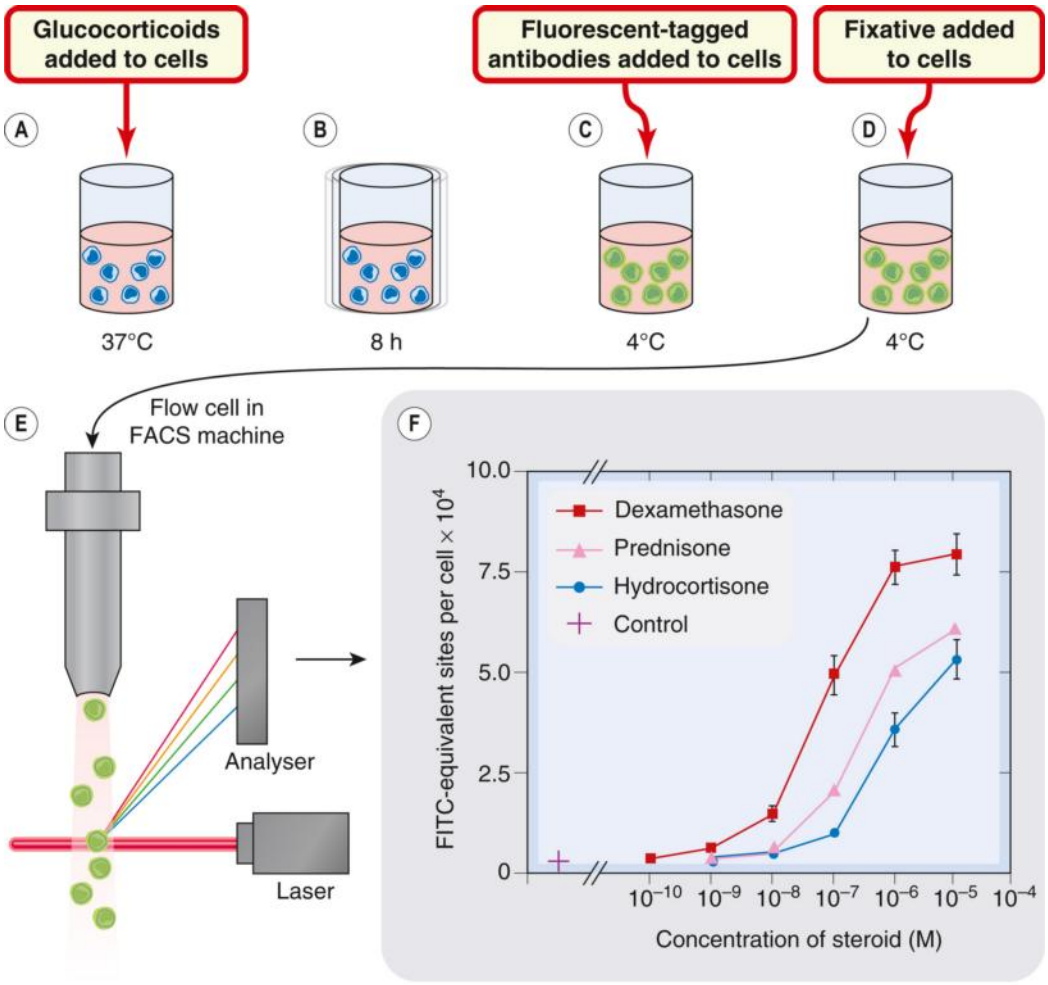

FIG. 8.2 Measuring the effect of glucocorticoid drugs on cell surface receptor expression using FACS (fluorescence-activated cell sorting).FACS technology enables the detection and measurement of fluorescent-tagged antibodies attached to structures on individual cells. In this experiment the effect of three glucocorticoids is tested on the expression of a cell surface haemoglobin scavenger receptor (CD 163). (A) Human monocytes were isolated from human venous blood and (B) incubated for 8 h alone or with various concentrations of the

glucocorticoids dexamethasone, prednisone or hydrocortisone (see Chs **27** and **34**). (C) The cells were then placed on ice and incubated with fluorescent-tagged antibodies to the receptor. (D) The cells were then fixed, washed and (E) subjected to FACS analysis. In this technique, cells flow through a small tube and are individually scanned by a laser. The reflected light is analysed using a series of filters (so that different coloured fluorescent tags can be used) and the data collected as *fluorescence intensity units*, compared with a standard (FITC) and expressed as 'FITC equivalents' to produce the final results (F), which can be plotted as a conventional log-concentration curve. Data courtesy N. Goulding.

GENERAL PRINCIPLES OF BIOASSAY

THE USE OF STANDARDS

Biological assays were originally designed to measure the *relative potency* of two preparations, usually a standard and an unknown. Maintaining stable preparations of various hormones, antisera and other biological materials as reference standards is the task of the UK National Board for Biological Standards Control. Nowadays bioassays are more commonly used to compare a new drug to a standard drug, the latter sometimes referred to as a 'prototypical' drug.

THE DESIGN OF BIOASSAYS

Given the aim of comparing the activity of two preparations, a standard (S) and an unknown (U), on a particular preparation, a bioassay must provide an estimate of the dose or concentration of U that will produce the same biological effect as that of a known dose or concentration of S. As **Fig. 8.3** shows, provided that the log dose–effect curves for S and U are parallel, the ratio, *M*, of equiactive doses will not depend on the magnitude of response chosen. Thus *M* provides an estimate of the potency ratio of the two preparations. A comparison of the magnitude of the effects produced by equal doses of S and U (A_1 in **Fig. 8.3**) does not provide an estimate of *M* (see **Fig. 8.3**).

The main problem with all types of bioassay is that of biological variation, and the design of bioassays is aimed at:

- minimising variation
- avoiding systematic errors resulting from variation
- estimation of the limits of error of the assay result.

Historically, bioassays were performed on native tissues but it is now more common to use cell lines genetically engineered to express a specific receptor type. This has several advantages:

- expression of only a single type of receptor
- human receptors can be expressed and studied
- multiple signalling pathways can be monitored (see **Ch. 3**)
- signalling bias can be analysed (see **Ch. 2**)
- replacement of living animals

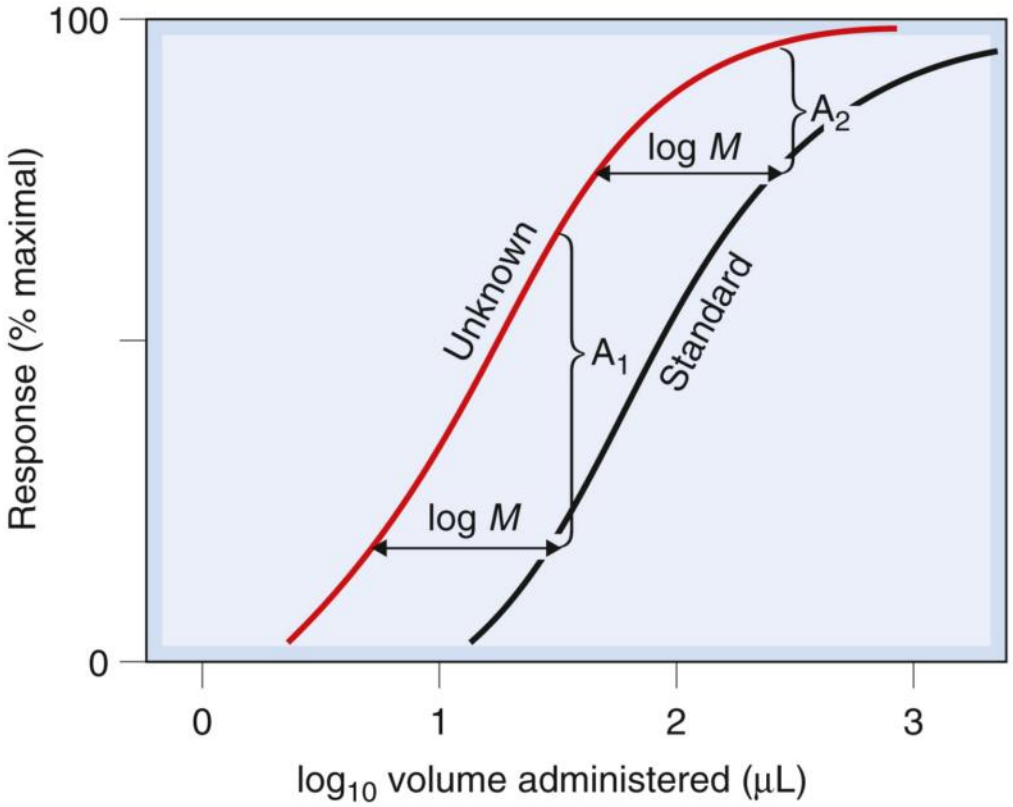

FIG. 8.3 Comparison of the potency of unknown and standard by bioassay.Note that comparing the magnitude of responses produced by the same dose (i.e. volume) of standard and unknown gives no quantitative estimate of their relative potency. (The differences, A_1 and A_2, depend on the dose chosen.) Comparison of equieffective doses of standard and unknown gives a valid measure of their relative potencies. Because the lines are parallel, the magnitude of the effect chosen for the comparison is immaterial; i.e. *log M* is the same at all points on the curves.

However, care must be taken to account for the level of recombinant receptor expression in engineered cell lines. Overexpression of receptors can result in weak partial agonist drugs appearing as 'full' agonists when the receptor reserve is larger than it would be for endogenously expressed receptors in native tissues (see **Ch. 2**).

Commonly, comparisons are based on analysis of *dose–response curves*, from which the matching doses of S and U are calculated. The use of a logarithmic dose scale means that the curves for S and U will normally be parallel, and the potency ratio (*M*) is estimated from the horizontal distance between the two curves (see **Fig. 8.3**). Assays of this type are known as *parallel line* assays, the minimal design being the 2 + 2 assay, in which two doses of standard (S_1 and S_2) and two of unknown (U_1 and U_2) are used. The doses are chosen to give responses lying on the linear part of the log dose–response curve, and are given repeatedly in randomised order, providing an inherent measure of the variability of the test system, which can be used, by means of straightforward statistical analysis, to estimate the confidence limits of the final result.

A simple example of an experiment to compare two analgesic drugs, **morphine** and **codeine** (see **Ch. 43**) in humans, based on a modified 2 + 2 design is shown in **Fig. 8.4**. Each of the four doses was given on different occasions to each of the four subjects, the order being randomised and both subject and observer being unaware of the dose given. Subjective pain relief was assessed by a trained observer, and the results showed morphine to be 13 times as potent as codeine. This, of course, does not prove its superiority, but merely shows that a smaller dose is needed to produce the same

effect. Such a measurement is, however, an essential preliminary to assessing the relative therapeutic merits of the two drugs, for any comparison of other factors, such as side effects, duration of action, tolerance or dependence, needs to be done on the basis of doses that are equiactive as analgesics.

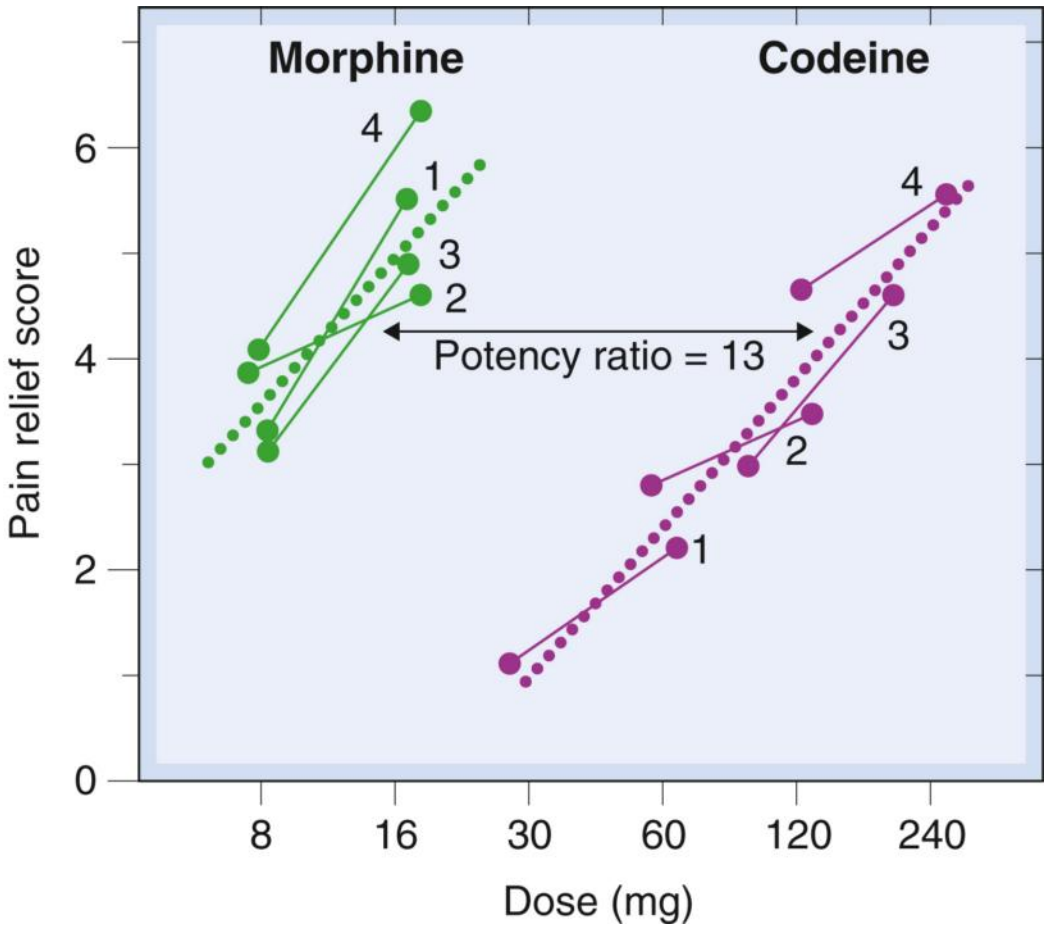

FIG. 8.4 Assay of morphine and codeine as analgesics in humans.Each of four patients (numbered *1–4*) was given, on successive occasions in random order, four different treatments (high and low morphine, and high and low codeine) by intramuscular injection, and the subjective pain relief score calculated for each. The calculated regression lines gave a potency ratio estimate of 13 for the two drugs. After Houde, R.W., et al., 1965. In: Analgetics. Academic Press, New York.

Problems arise if the two log dose–response curves are not parallel, or if the maximal responses differ, which can happen if the mechanism of action of the two drugs differs, or if one is a partial agonist (see **Ch. 2**). In this case it is not possible to define the relative potencies of S and U unambiguously in terms of a simple ratio and the experimenter must then face up to the fact that the comparison requires measurement of more than a single dimension of potency.

Bioassay

- Bioassay is the measurement of potency of a drug or unknown mediator from the magnitude of the biological effect that it produces.
- Bioassay normally involves comparison of the unknown preparation or novel drug with a standard. Estimates that are not based on comparison with standards are liable to vary from laboratory to laboratory.
- Comparisons are best made on the basis of dose–response curves, which allow estimates of the equiactive concentrations of unknown and standard to be used as a basis for the potency comparison. Parallel line assays follow this principle.
- The biological response may be *quantal* (the proportion of tests in which a given all-or-nothing effect is produced) or *graded*. Different statistical procedures are appropriate in each case.

- Different approaches to metrication apply according to the level of biological organisation at which the drug effect needs to be measured. Approaches range through molecular and chemical techniques, in vitro and in vivo animal studies and clinical studies on volunteers and patients, to measurement of effects at the socioeconomic level.

ANIMAL MODELS OF DISEASE

The aim of a disease model is to recapitulate in an animal the same pathological processes which underlie the human disorder. How well this can be achieved of course depends on the extent to which these pathological processes are known. There are many examples where simple intuitive models predict with fair accuracy therapeutic efficacy in humans. Ferrets vomit when placed in swaying cages, and drugs that prevent this are also found to relieve motion sickness and other types of nausea in humans. Irritant chemicals injected into rats' paws cause them to become swollen and tender, and this model predicts very well the efficacy of drugs used for symptomatic relief in inflammatory conditions such as rheumatoid arthritis in humans. As discussed elsewhere in this book, models for many important disorders, such as epilepsy, diabetes, hypertension and gastric ulceration, based on knowledge of the physiology of the condition, are available, and have been used successfully to produce new drugs, even though their success in predicting therapeutic efficacy is far from perfect. [2]

Not all animal models can be based on a known disease pathway as for many conditions, these are not known or are not fully

recapitulated in a non-human species and this can lead to limitations in how well the findings in animals translate to clinical benefits. For example, even in diseases with well-established genetic origins, such as Huntington's disease or cystic fibrosis, manipulating the same genes in animals does not necessarily generate the same pathophysiological outcomes. Another challenge is how to quantify the arising consequences of the model induction and the effects of pharmacological treatments. These depend very much on the specific disorder and as much as possible aim to measure in the animal a similar readout to those which can be quantified in humans. This is where well-defined physiological changes, e.g. changes in blood pressure, or blood biomarkers, e.g. proinflammatory cytokines, are particularly helpful as well as imaging or postmortem assessment of the arising pathological changes, e.g. tumour size. Not all disorders have well-defined biomarkers particularly those involving the central nervous system, and for these models, behavioural readouts are commonly used.

Ideally, an animal model should resemble the human disease in the following ways:

- similar pathophysiological phenotype (*face validity*)
- similar causation (*construct validity*)
- similar response to treatment (*predictive validity*)

Alongside these external validity criteria, internal validity, including experiment design, reproducibility, controls and methods to avoid bias, is also critical for the reliability of data obtained using animal models.

In practice, there are many difficulties, and the shortcomings of animal models are one of the main roadblocks on the route from basic medical science to improvements in therapy. The difficulties include the following.

- Many diseases, particularly in psychiatry, are defined by phenomena in humans that are difficult or impossible to observe in animals, which rules out face validity. As far as we know, mania or delusions have no counterpart in rats, nor does anything resembling a migraine attack or autism. Pathophysiological similarity is also inapplicable to conditions such as depression or anxiety disorders, where no clear brain pathology has been defined.
- The 'cause' of many human diseases is complex or unknown. To achieve construct validity for many degenerative diseases (e.g. Alzheimer's disease, osteoarthritis, Parkinson's disease), we need to model the upstream (causative) factors rather than the downstream (symptomatic) features of the disease, although the latter are the basis of most of the simple physiological models used hitherto. The inflammatory pain model mentioned earlier lacks construct validity for rheumatoid arthritis, which is an autoimmune disease.
- Relying on response to treatment as a test of predictive validity carries the risk that drugs acting by novel mechanisms could be missed, because the model will have been selected on the basis of its responsiveness to known drugs. With schizophrenia (**Ch. 47**), for example, it is clear that dopamine antagonists are effective, and many of the

models used are designed to assess dopamine antagonism in the brain, rather than other potential mechanisms that need to be targeted if drug discovery is to move on to address new targets.

PHARMACOLOGICAL MODELS

A common approach where a known pathology has not been established, particularly in behavioural pharmacology, has been the use of pharmacological treatments to induce a specific, quantifiable outcome in a living animal and then test if a drug treatment modifies this, e.g. *N*-methyl-D-aspartate (NMDA) receptor antagonist-induced hyperlocomotion as a model to test potential antipsychotics (see **Ch. 47**). Initial validation of these methods is commonly based on the ability of a known efficacious treatment to modulate the induced behaviour. These approaches can be helpful in finding drugs which act through similar mechanisms or have indirect effects on the system being altered by the pharmacologically induced readout. Most second-generation antipsychotics (see **Ch. 47**) and antidepressants (see **Ch. 48**) have been developed using this approach, however, as they do not necessarily involve relevant underlying pathology. There has also been a tendency, probably inappropriately, to use similar behavioural readouts in mechanistic studies or for evaluating drugs acting through novel mechanisms and this may be contributing to the subsequent poor translation to the clinic. Whilst pharmacological models are valuable in certain contexts, care in the interpretation of the arising data and recognition of these limitations is important.

GENETICALLY ALTERED ANIMAL MODELS

Nowadays, genetic approaches are increasingly used as an adjunct to conventional physiological and pharmacological approaches to disease modelling. Developments in the clustered regularly interspersed short palindromic repeats (CRISPR) Cas9 gene-editing technique (**Wang et al., 2013**) has further accelerated the use of GAAs in research and meant that the ability to alter genes in a range of species has become much more achievable.

Animal models

- Animal models of disease are important for investigating pathogenesis and for the discovery of new therapeutic agents. Animal models generally reproduce imperfectly only certain aspects of human disease states. Models of psychiatric illness are particularly problematic.
- GAAs are produced by introducing mutations into the germ cells of animals (usually mice or zebrafish), which allow new genes to be introduced ('knockins') or existing genes to be inactivated ('knockouts') or mutated in a stable strain of animals.
- GAAs are widely used to develop disease models for drug testing. Many such models are now available. Knockout models are particularly helpful for demonstrating the role of a specific receptor in the effects of a novel drug.
- The induced mutation operates throughout the development and lifetime of the animal, and may be lethal. Techniques of conditional mutagenesis allow the abnormal gene to be

switched on or off at a chosen time or within specific cell populations.

Progress in the technology for the generation of GAAs has now enabled the induction of genetic mutations in specific cell types and with specific promoters providing more control of where the modified gene is expressed.

By selective breeding, it is possible to obtain animal strains with characteristics resembling certain human diseases. Genetic models of this kind include spontaneously hypertensive rats, genetically obese mice, epilepsy-prone dogs and mice, rats with deficient vasopressin secretion and many other examples.

Genetic manipulation of the germline to generate *GAAs* (see **Offermanns and Hein, 2004**; **Rudolph and Moehler, 1999**) is important as a means of generating animal models that replicate human disease and are expected to be more predictive of therapeutic drug effects in humans. There has been a huge growth in GAA technologies in the last decade and these approaches now dominate animal models used in fundamental biology research and drug discovery. This versatile technology can be used in many different ways, for example:

- to inactivate individual genes, or mutate them to pathological forms
- to introduce new (e.g. human) genes
- to overexpress genes by inserting additional copies
- to allow gene expression to be localised to specific cell types and controlled by the experimenter

Progress from the early days of whole animal gene knockout or knockins has now largely been replaced with more sophisticated methods. It is now possible to mutate specific genes in animals to replicate known genetic mutations linked to disease. Animals can be generated to express human genes to enable more specific drug interaction studies. To avoid developmental effects, the mutated gene can be coupled to a specific promoter which is only activated by administration of an exogenous chemical activator such as doxycycline or tamoxifen. This also provides researchers with temporal control of when the mutated gene is expressed. It is also now possible to restrict the expression of the mutated gene to specific cell types, and genome editing technologies such as CRISPR Cas9 have enabled more sophisticated genetic manipulations to be achievable. Whilst mice are still the most widely used species for studying mammalian biology, other vertebrates (e.g. zebrafish) and invertebrates (*Drosophila*, *Caenorhabditis elegans*) are increasingly being used for drug screening purposes. CRISPR Cas9 has made genetic modifications more easily applicable to other species including rats.

Examples of such models include mice that overexpress mutated forms of the *amyloid precursor protein* or *presenilins*, which has been linked to the pathogenesis of Alzheimer's disease (see **Ch. 40**). When they are a few months old, these mice develop pathological lesions and cognitive changes resembling Alzheimer's disease although it should also be noted that recent trials of drugs which inhibit amyloid pathology have been disappointing in the clinic. Another neurodegenerative condition, Parkinson's disease (see **Ch. 40**), has been modelled in mice that overexpress

synuclein, a protein found in the brain inclusions that are characteristic of the disease. Mice with mutations in tumour suppressor genes and oncogenes (see **Ch. 6**) are widely used as models for human cancers. Mice in which the gene for a particular adenosine receptor subtype has been inactivated show distinct behavioural and cardiovascular abnormalities, such as increased aggression, reduced response to noxious stimuli and raised blood pressure. GAAs can, however, be misleading in relation to human disease. For example, the gene defect responsible for causing cystic fibrosis (a disease affecting mainly the lungs in humans), when reproduced in mice, causes a disorder that mainly affects the intestine.

REDUCING USE OF ANIMALS IN RESEARCH

Animal models remain an important approach for fundamental research, drug discovery and the development of new treatments including in toxicology. However, developments in nonanimal alternatives or replacement of mammalian models with less sentient species are important for the principles of the 3Rs (reduce, refine and replace). Today, much more of the early screening of novel molecules is undertaken in silico and using high-throughput cell-based assays (see **Ch. 60**). It is also possible to screen for potential toxicity using in vitro assays and identify potential problems before progressing to in vivo models. Future studies may also make more use of ‘organs on a chip’ which provide a better model of the complexity of multicell types found in tissues than cell cultures but without needing to obtain these from an animal. These are relatively new technologies but offer the exciting prospect of

creating model systems of human organs derived from human cells and hence the potential to improve the translation of findings to the clinic. It remains unlikely that any of these methods will replace the need for animal models in the near future, but they can reduce the numbers of animals being used by providing early indications of compounds which are unlikely to be successful due to adverse effects and refine the choice of compounds to take into animal tests. Current progress in new approach methodologies is described by **Fischer et al. (2020)**.

PHARMACOLOGICAL STUDIES IN HUMANS

Studies involving human subjects range from experimental pharmacodynamic or pharmacokinetic investigations to formal clinical trials. Non-invasive recording methods, such as *functional magnetic resonance imaging* (FMRI) to measure regional blood flow in the brain (a surrogate for neuronal activity) and *ultrasonography* to measure cardiac performance, have greatly extended the range of what is possible. The scientific principles underlying experimental work in humans designed (for example) to check whether mechanisms that operate in other species also apply to humans, or to take advantage of the much broader response capabilities of a person compared with a rat, are the same as for animals, but the ethical and safety issues are paramount. Ethics committees associated with all medical research centres tightly control the type of experiment that can be done, weighing up not only safety and ethical issues, but also the scientific importance of the proposed study. At the other end of the spectrum of

experimentation on humans are formal *clinical trials*, often involving thousands of patients, aimed at answering specific questions regarding the efficacy and safety of new drugs.

CLINICAL TRIALS

Clinical trials are an important and highly specialised form of biological assay, designed specifically to measure therapeutic efficacy and adverse effects in human participants. The need to use patients for experimental purposes raises serious ethical considerations, and imposes many restrictions. Here, we discuss some of the basic principles involved in clinical trials; the role of such trials in the course of drug development is described in **Chapter 60**. Appropriate statistical techniques are fundamental to the conduct of medical research studies, and we refer readers to **Bland (2015)** for a more detailed account.

A clinical trial is a method for comparing objectively, through a prospective interventional study, the results of two or more therapeutic options. For new drugs, this is carried out during phases II and III of clinical development (see **Ch. 60**). It is important to realise that, until about 60 years ago, methods of treatment were chosen on the basis of clinical impression, personal experience and expert opinion rather than objective testing. [3] Although many drugs, with undoubted effectiveness, remain in use without ever having been subjected to a controlled clinical trial, any new drug is now required to have been tested in this way before being licensed for clinical use. [4]

An introduction to the principles and organisation of clinical trials is given by **Hackshaw (2009)**. A clinical trial aims to compare the

response of a test group of patients receiving a new treatment (A) with that of a control group receiving an existing 'standard' treatment (B). Treatment A might be a new drug or a new combination of existing drugs, or any other kind of therapeutic intervention, such as a surgical operation, a diet, physiotherapy and so on. The standard against which it is judged (treatment B) might be a drug or non-drug treatment that is in current clinical practice or (if there is no currently available effective treatment) a placebo or no treatment at all.

The use of controls is crucial in clinical trials. Claims of therapeutic efficacy based on reports that, for example, 16 out of 20 patients receiving drug X got better within 2 weeks are of no value (particularly so when considering self-resolving minor illnesses). Here, we need knowledge of how 20 control patients receiving a different treatment, or none at all, would have fared. In a *parallel-group design*, the controls are provided by a separate group of patients from those receiving the test treatment, but sometimes a *crossover design* is possible in which the same patients are switched from test to control treatment and vice versa, and the results compared. Randomisation is essential to avoid bias in assigning individual patients to test or control groups. Hence, the *randomised controlled clinical trial* is now regarded as *the* essential tool for assessing clinical efficacy of new drugs.

Concern inevitably arises over the ethics of assigning patients at random to particular treatment groups (or to no treatment). However, the reason for setting up a trial is that doubt exists whether the test treatment offers greater or lesser benefit than the control treatment, and there is genuine clinical equipoise in

treatment selection. All would agree on the principle of informed consent, [5] whereby each patient must be told the nature and risks of the trial, and agree to participate on the basis that they will be randomly and unknowingly assigned to either the test or the control group. The regularly updated ‘Declaration of Helsinki’ sets out the widely accepted ground rules governing research on human subjects.

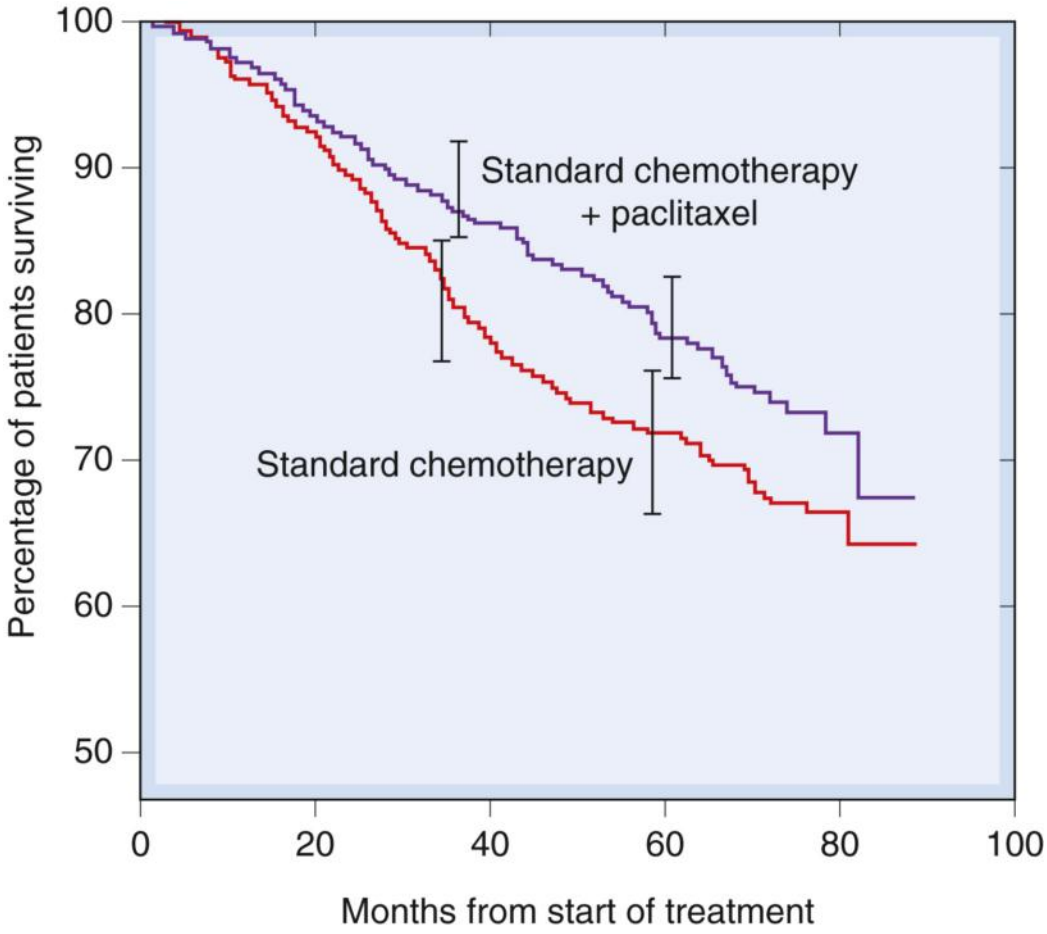

FIG. 8.5 Disease-free survival curves followed for 8 years in matched groups of breast cancer patients treated with a standard chemotherapy regime alone (629 patients), or with addition of paclitaxel (613 patients), showing a highly significant (p = 0.006) improvement with paclitaxel. Error bars represent 95% confidence intervals. Redrawn from Martín M, Rodríguez-Lescure A, Ruiz A, et al., Randomized phase 3 trial of fluorouracil, epirubicin, and cyclophosphamide alone or followed by

paclitaxel for early breast cancer. 2008. J. Natl. Cancer Inst. 100, 805–814.

Unlike the kind of bioassay discussed earlier, the large-scale clinical trial does not normally give any information about potency or the form of the dose–response curve, but merely compares the response produced by two or more stipulated therapeutic regimens. Survival curves provide one commonly used measure. **Fig. 8.5** shows rates of disease-free survival in two groups of breast cancer patients treated with conventional chemotherapy with and without the addition of paclitaxel (see **Ch. 57**). The divergence of the curves shows that paclitaxel significantly improved the clinical response. Additional questions may be posed, such as the incidence and severity of side effects, or whether the treatment is better or worse in particular subgroups of patients, but only at the expense of added complexity, risk of bias and sample size. The investigator must decide in advance, using a protocolised approach, what dose to use and how often to give it, and the trial will reveal only whether the chosen regimen performed better or worse than the control treatment. Unless different doses are compared, it will not say whether increasing or decreasing the dose would have improved the response.

A considerable amount of preliminary or fundamental design work (including a pilot or feasibility assessment) has to be completed prior to embarking on a clinical trial that measures patient outcomes with a new drug. The basic question or (null) hypothesis posed by a clinical trial is thus simpler than that addressed by most conventional bioassays. However, the recruitment and follow-up of clinical trial participants, with strict

safeguards against bias, are immeasurably more complicated, time-consuming and expensive than that of any laboratory-based assay. Observational studies may therefore be more practical or appropriate for assessing rare adverse effects where large sample sizes and long-term follow-up are needed.

RISK OF BIAS IN RANDOMISED CONTROLLED TRIALS

There are four main areas where rigorous procedures can be implemented to guard against the threat of bias:

1. random allocation of participants to ensure that treatment groups are equally balanced
2. adherence to the specified interventions
3. blinded assessment of outcomes
4. rigorous follow-up aimed at collecting the full dataset with minimal missing data

If two treatments, A and B, are being compared on a series of selected patients, the simplest form of randomisation is to allocate each patient to A or B by reference to a series of random numbers, toss of a coin or even drawing lots. In a properly randomised trial, neither the patient nor the investigator should have any influence on which treatment the patient will end up receiving, thus making the patient distribution fairly balanced at baseline. One difficulty, particularly if the groups are small, is that the two groups may turn out to be ill-matched with respect to characteristics such as age, sex or disease severity. *Stratified randomisation* avoids the difficulty by dividing the subjects into age, sex, severity, or other categories,

random allocation to A or B being used within each category. It is possible to treat two or more characteristics of the trial population in this way, but the number of strata can quickly become large, and the process is self-defeating when the number of subjects in each becomes too small. As well as avoiding error resulting from imbalance of groups assigned to A and B, stratification can also allow more sophisticated conclusions to be reached. B might, for example, prove to be better than A in a particular group of patients even if it is not significantly better overall.

Strict adherence to the treatment protocol can be difficult if the drug has to be taken on a daily basis over months and years. Participants may not be able to follow the treatment schedule, or they may move on to try different therapies if they feel that the trial intervention has failed to help. Here, researchers can monitor delivery of the treatment and adherence to specified schedules, and implement various statistical methods such as ‘intention to treat’ and ‘per protocol’ analysis to address deviations from the plan.

The double-blind technique, whereby neither subject nor investigator is aware at the time of the assessment which treatment is being used, is intended to minimise subjective bias. It has been repeatedly shown that, with the best will in the world, subjects and investigators both contribute to bias if they know which treatment is which. Awareness of the specific trial intervention may lead to changes in clinical management, or to biased reporting and measurement of outcomes. Although the use of a double-blind technique is an important safeguard, this is not always possible. A dietary regimen, for example, can seldom be disguised; with drugs, pharmacological effects may reveal to patients what they are taking

and predispose them to report accordingly. [6] In general, however, the double-blind procedure, with precautions if necessary to disguise such clues as the taste or appearance of the two drugs, is used whenever possible. [7] If full blinding of participants and investigators is not possible, one option is to measure outcomes using assessors who are unaware of the treatments being used (an example would be an open-label trial with blinded endpoint assessment by an external independent committee).

High-quality clinical trials have pre-specified follow-up time points where outcomes are measured in a defined manner. Study results may be incomplete and potentially biased if patients drop out of the study or fail to attend follow-up because the intervention did not improve their symptoms. Inadequate follow-up or missing data means that important outcomes (such as serious adverse events) may not have been detected.

THE SIZE OF THE SAMPLE

Feasibility, ethical and financial considerations mean that the trial should involve the minimum number of subjects required to adequately answer the clinical question. Much statistical thought has gone into the problem of deciding in advance how many subjects will be required to produce a clinically useful – and statistically meaningful – result (a *power* calculation).

Judgements on the appropriate sample size should be based on whether the aim is to demonstrate that two treatments are equivalent (e.g. new treatment is non-inferior to the one that is currently in use), or whether the aim is to demonstrate a significant difference between interventions. Two types of erroneous

conclusion are possible, referred to as *type I* and *type II errors*. A type I error occurs if the results show a difference between A and B when none actually exists (false-positive). A type II error occurs if no difference is found although A and B do actually differ (false-negative). A major factor that determines the size of sample needed is the degree of certainty the investigator seeks in avoiding either type of error. The probability of incurring a type I error is expressed as the *significance* of the result. To say that A and B are different at the $p < 0.05$ level of significance means that the probability of obtaining a false-positive result (i.e. incurring a type I error) is less than 1 in 20. For most purposes, this level of significance is considered acceptable as a basis for drawing conclusions.

The probability of detecting a genuine difference that exists between interventions and avoiding a type II error is termed the *power* of the trial. We tend to regard type II errors more leniently than type I errors, and it is often acceptable to design trials with a power of 0.8–0.9, which means that there is an 80%–90% chance of detecting a real effect. A larger sample size will confer greater power or ability to detect any difference that exists, with correspondingly more precise estimates of treatment effect.

The second factor that determines the sample size required is the magnitude of difference between A and B that is regarded as clinically important. For example, to detect that a given treatment reduces the mortality in a certain condition by at least 10 percentage points, say from 50% (in the control group) to 40% (in the treated group), would require 850 subjects, assuming that we wanted to achieve a $p < 0.05$ level of significance and a power of 0.9. If we were content only to power the trial to detect a larger treatment

benefit of a 20-percentage point reduction in mortality (and potentially fail to pick up a smaller 10-point benefit), only 210 subjects would be needed. In this example, missing a real 10-point reduction in mortality could result in abandonment of a treatment that would save 100 lives for every 1000 patients treated – an extremely serious mistake from society's point of view. This simple example emphasises the need to assess clinical benefit (which is often difficult to quantify) in parallel with statistical considerations (which are fairly straightforward) in planning trials.

CLINICAL OUTCOME MEASURES

The measurement of clinical outcome can be a complicated business, and both ethics committees and funders of clinical trials are placing much greater emphasis on outcomes that are important to patients and health services, rather than pharmacological or physiological endpoints. With rising disease burden in ageing populations, commissioners of health services are more preoccupied with assessing the cost-effectiveness of therapeutic procedures in terms of improved length and quality of life, and societal and (health) economic benefit. Various scales for assessing 'health-related quality of life' have been devised and tested (see **Walley and Haycocks, 1997**); these may be combined with measures of life expectancy to arrive at the measure 'quality-adjusted life years' (QALYs) as an overall measure of therapeutic efficacy, which attempts to combine both survival time and relief from suffering in assessing overall benefit. [8] The cost per QALY gained with a new treatment is a critical consideration in allocation of healthcare funds.

However, measuring long-term patient benefit may take years, so objective clinical effects, such as lowering of blood pressure, improved airway conductance or change in white cell count, continue to be used as outcome measures. These *surrogate markers* reflect pathophysiological changes of which the patient is most likely unaware, but can readily be measured in smaller, short-term trials. In many cases such changes correlate well with clinical outcome as it affects the patient; not always, though. Regulatory authorities are therefore rightly cautious about accepting surrogate end points as a measure of actual patient benefit, unless there is clear evidence that changes in the surrogate marker have a direct robust relationship with important outcomes.

PLACEBOS

A placebo is a dummy medicine containing no active ingredient (or alternatively, a dummy surgical procedure, diet or other kind of therapeutic intervention), which the patient believes is (or could be, in the context of a controlled trial) the real thing. The 'placebo response' (see review by **Enck et al., 2013**) is widely believed to be a powerful therapeutic effect, [9] producing a significant beneficial effect in about one-third of patients. While many clinical trials include a placebo group that shows improvement, few have compared this group directly with untreated controls, particularly where the natural history of the disease is symptom resolution without any intervention. The role of placebo is a topic of major debate, with some arguing that placebo has limited effect, except perhaps in trials involving pain or nausea (**Hróbjartsson and Gøtzsche, 2010**), while others have reported clinically meaningful

effects with placebo (**Howick et al., 2013**). There are also growing numbers of pragmatic trials where the new treatment is compared against 'standard or usual' care, rather than the artificial construct of a placebo dummy pill that has no relationship to typical clinical practice.

The risks of placebo therapies should not be underestimated. The use of active medicines may be delayed. The necessary element of deception [10] risks undermining the confidence of patients in the integrity of doctors. A state of 'therapy dependence' may be produced in people who are not ill, because there is no way of assessing whether a patient still 'needs' the placebo.

META-ANALYSIS

It is possible, using statistical techniques, to combine the data obtained in several individual trials in order to gain greater power and to compare consistency of findings between studies. This procedure, known as *meta-analysis*, can be very useful in arriving at a conclusion on the basis of several trials, of which some claimed superiority of the intervention over the control while others did not. The meta-analysis is usually based on a systematic review using defined search strategies, study selection and quality assessment criteria. This approach to summarising the overall body of evidence is certainly preferable to the 'take your pick' approach adopted by most human beings when confronted with diverse data sets. Statistical models involving multiple treatment comparisons in network meta-analysis can help determine which particular medicine, of several available drug options, has the greater chance of success.

The main drawback in any meta-analysis is susceptibility to selective reporting of results, hidden data and 'publication bias'. Negative studies (or unfavourable findings) are less likely to be reported than positive studies, partly because they are considered less interesting or, more seriously, because publication would harm the interests of the organisation that performed the trial. [11]

The published clinical trials literature contains reports of many trials that are poorly designed and unreliable. The Cochrane Collaboration (**www.cochrane.org**) sifts carefully through the literature and produces *systematic reviews* that collate and combine data only from trials (of drugs and other therapeutic interventions) that meet strict quality criteria. About 8600 such 'gold-standard' summaries are available, and provide the most reliable evaluation of trials data on a wide range of interventions.

Clinical trials

- A clinical trial is a special type of bioassay done to compare the clinical efficacy of a new drug or intervention with that of a standard treatment (or a placebo).
- At its simplest, the aim is a straight comparison of unknown (A) with standard (B) at a single-dose level. The result may be: 'B better than A', 'B worse than A', or 'No difference detected'. Efficacy, not potency, is compared.
- To avoid bias, clinical trials should ideally be:
  - *controlled* (comparison of A with B, rather than study of A alone);

  - *randomised* (assignment of subjects to A or B on a random basis);
  - *double-blind* (neither the subject nor the assessor knows whether A or B is being used).
- Type I errors (concluding that A is better than B when the difference is actually due to chance) and type II errors (concluding that A is not different from B because a real difference has escaped detection) can occur; the likelihood of either kind of error decreases as the methodological quality, sample size and number of end-point events are increased.
- Interim analysis of data, carried out by an independent group, may be used as a basis for determining if a trial should continue. Premature termination of the trial may occur if the interim data are already strongly conclusive (of major benefit or serious harm), or if a clear result is unlikely to be reached (futility).
- All experiments on human subjects require approval by an independent ethics committee.
- Clinical trials require very careful planning and execution, and are inevitably expensive.
- Clinical outcome measures may comprise:
  - physiological measures (e.g. blood pressure, liver function tests, airways function);
  - subjective assessments (e.g. pain relief, mood);
  - long-term outcome (e.g. survival or freedom from recurrent disease);
  - overall '*quality of life*' measures;
  - *'QALYs'*, which combine survival with quality of life.

- Meta-analysis is a statistical technique used to pool the data from several independent trials.

CLINICAL CONSIDERATION OF BENEFIT AND RISK

There are many different ways of quantifying and presenting the benefits and risks of drugs in clinical use. One useful approach is to *compare* from clinical trial data the proportion of test and control patients who will experience (A) a defined level of clinical benefit (e.g. survival beyond 2 years, pain relief to a certain predetermined level, slowing of cognitive decline by a given amount) and (B) adverse effects of defined degree. These estimates of proportions of patients showing beneficial or harmful reactions can be expressed as *number needed to treat* (NNT; i.e. the number of patients who need to be treated in order for one to show the given effect, whether beneficial or adverse). For example, in a recent study of pain relief by antidepressant drugs compared with placebo, the findings were as follows: for benefit (a defined level of pain relief), NNT = 3; for minor unwanted effects, NNT = 3; for major adverse effects, NNT = 22. Thus of 100 patients treated with the drug, on average 33 will experience pain relief, 33 will experience minor unwanted effects, and 4 or 5 will experience major adverse effects. *This format of presenting benefit and harm* information is helpful in guiding therapeutic choices. One advantage of this type of analysis is that it can take into account the underlying disease severity in quantifying benefit. Thus if drug A halves the mortality of an often fatal disease (reducing it from 50% to 25%, say), the NNT to save one life is 4; if

drug B halves the mortality of a rarely fatal disease (reducing it from 5% to 2.5%, say), the NNT to save one life is 40. Notwithstanding other considerations, drug A is judged to be more valuable than drug B, even though both reduce mortality by one-half. Furthermore, the clinician must realise that to save one life with drug B, 40 patients must be exposed to a risk of adverse effects, whereas only four are exposed for each life saved with drug A.

QUESTIONS

QUESTION 8.1

The bioassay, originally defined as the estimation of the concentration or potency of a substance by measurement of the biological response that it produces, has played a key role in the development of pharmacology.

Which of the following statements about bioassays is incorrect?

OPTIONS:

A. A bioassay is used for standardising preparations for therapeutic use, e.g. hormones.

B. Bioassays are used to compare a new drug to a standard drug.

C. Bioassays are usually performed on native tissues.

D. Two-by-two bioassays are only appropriate for drugs with the same mechanism of action.

E. The main error in bioassays is due to biological variation.

QUESTION 8.2

Clinical trials are an important and highly specialised form of biological assay, designed specifically to measure therapeutic response and adverse effects in human participants.

Which of the following statements related to the set up and analysis of clinical trials is correct?

OPTIONS:

A. A clinical trial is used to compare the potency of two therapeutic regimes.

B. A type I error occurs if the results show no difference between A and B when A and B do actually differ.

C. The error rate inversely correlates with the power of the trial.

D. A number needed to treat (NNT) = 22 for adverse events means that 22 out of 100 patients would experience the adverse event.

E. The nocebo effect describes the lack of response seen with a control or test drug.

ANSWERS

ANSWER 8.1

RATIONALE:

A. Quantitative bioassays enable a standard preparation of the hormones to be established. These assays provided information on the synthesis, storage and release of the hormones, and were essential for their purification and identification.

B. Biological assays were originally designed to measure the relative potency of two preparations, usually a standard and an unknown but now are more commonly used to compare a new drug to a standard drug, the latter sometimes referred to as a 'prototypical' drug.

C.

D. If the mechanism of action of the two drugs differs, the two log dose–response curves may not be parallel in which case it is not possible to define the relative potencies in terms of a simple ratio.

E. The main problem with all types of bioassay is that of biological variation, and the design of bioassays is aimed at minimising variation, avoiding systematic errors resulting from variation and including an estimation of the limits of error of the assay.

CORRECT ANSWER WITH EXPLANATION:

C. Bioassays are usually performed on native tissues.

Historically, bioassays were performed on native tissues but it is now more common to use cell lines genetically engineered to express a specific receptor type.

ANSWER 8.2

RATIONALE:

A. A large-scale clinical trial does not normally give any information about potency or the form of the dose–response curve, but merely compares the response (efficacy) produced by two or more stipulated therapeutic regimens.

B. A type I error occurs if the results show a difference between A and B when none actually exists (false-positive). A type II error

occurs if no difference is found although A and B do actually differ (false-negative).

C.

D. NNT is the number of patients who need to be treated in order for one to show the given effect, whether beneficial or adverse. For example, if NNT = 22, of 100 patients treated with the drug, on average 4 or 5 (100/22) will experience major adverse effects.

E. The nocebo effect describes the adverse effects reported with dummy (placebo) medicines.

CORRECT ANSWER WITH EXPLANATION:

C. The error rate inversely correlates with the power of the trial.

The probability of detecting a genuine difference that exists between interventions, and avoiding a type II error is termed the *power* of the trial. The likelihood of type I or II errors decreases as the methodological quality, sample size and number of end-point events is increased.

[1] Consider the effect of cocaine on organised crime, of organophosphate 'nerve gases' on the stability of dictatorships or of anaesthetics on the feasibility of surgical procedures for examples of molecular interactions that affect the behaviour of populations and societies.

[2] There have been many examples of drugs that were highly effective in experimental animals (e.g. in reducing brain damage following cerebral ischaemia) but ineffective in humans (stroke victims). Similarly, substance P antagonists (Ch. 19) are effective in animal tests for analgesia, but they proved inactive when tested in

humans. How many errors in the opposite direction may have occurred, we shall never know, because such drugs will never have been tested in humans.

[3] Not exclusively. James Lind conducted a controlled trial in 1753 on 12 mariners, which showed that oranges and lemons offered protection against scurvy. However, 40 years passed before the British Navy acted on his advice, and a further century before the US Navy did.

[4] It is fashionable in some quarters to argue that to require evidence of efficacy of therapeutic procedures in the form of a controlled trial runs counter to the doctrines of 'holistic' medicine. This is a fundamentally antiscientific view, for science advances only by generating predictions from hypotheses and by subjecting the predictions to experimental test. 'Alternative' medical procedures, such as homeopathy or 'detox', have rarely been rigorously tested, and where they have, they generally lack efficacy. Standing up for the scientific approach is the *evidence-based medicine* movement (see Sackett et al., 1996), which sets out strict criteria for assessing therapeutic efficacy, based on randomised controlled clinical trials, and urges scepticism about therapeutic doctrines whose efficacy has not been so demonstrated.

[5] Even this can be contentious, because patients who are unconscious, patients with dementia or patients with intellectual disability are unable to give such consent, yet no one would want to preclude trials that might offer improved therapies to these needy patients. Clinical trials in children are particularly problematic but are necessary if the treatment of childhood diseases is to be placed

on the same evidence base as is judged appropriate for adults. There are many examples where experience has shown that children respond differently from adults, and there is now an expectation that pharmaceutical companies should perform trials in children and vulnerable or older patients if the disease condition is relevant to these groups. If a trial uses very strict inclusion and exclusion criteria for participants, the resulting dataset may fail to be informative or generalisable to wider clinical practice.

6 The distinction between a true pharmacological response and a beneficial clinical effect produced by the knowledge (based on the pharmacological effects that the drug produces) that an active drug is being administered is not easy to draw, and we should not expect a mere clinical trial to resolve such a tricky semantic issue.

7 Maintaining the blind can be problematic. In a crossover trial of sildenafil (known to the lay public as the little blue pill Viagra) for limb ischaemia, all the patients were able to correctly guess the time that they were on sildenafil rather than placebo. Unsurprisingly, almost 90% asked to continue with the trial medication after the research study had finished.

8 As may be imagined, trading off duration and quality of life raises issues about which many of us feel decidedly squeamish. Not so economists, however. They approach the problem by asking such questions as: ‘How many years of life would you be prepared to sacrifice in order to live the rest of your life free of the disability you are currently experiencing?’ Or, even more disturbingly: ‘If, given your present condition, you could gamble on surviving free of disability for your normal lifespan, or (if you lose the gamble) dying

immediately, what odds would you accept?' Imagine being asked this by your doctor. 'But I only wanted something for my sore throat', you protest weakly.

[9] Its opposite, the *nocebo effect*, describes the adverse effects reported with dummy medicines.

[10] Surprisingly, deception may not even be necessary. Kaptchuk et al. (2010) found that symptoms of irritable bowel syndrome were improved slightly more in patients given inert sugar pills, described as such by the physician, than in patients given no pills. The effect was, however, small, and the patients were encouraged to think that the pills might engage 'mind-body healing processes'.

[11] To reduce this bias, measures are now in place to ensure that most clinical trials are registered and the results publicly disclosed.

9: Absorption and distribution of drugs

OVERVIEW

The physical processes of diffusion, penetration of membranes, binding to plasma protein and partition into fat and other tissues underlie the absorption and distribution of drugs. These processes are described, followed by more specific coverage of the process of drug absorption and related practical issue of routes of drug administration, and of the distribution of drugs into different bodily compartments. Drug interactions caused by one drug altering the absorption or distribution of another are described. There is a short final section on special drug delivery systems designed to deliver drugs efficiently and selectively to their sites of action.

Introduction

Drug disposition is divided into four stages designated by the acronym 'ADME':

- **A**bsorption from the site of administration
- **D**istribution within the body
- **M**etabolism
- **E**xcretion from the body

General aspects of drug absorption and distribution are considered here, together with routes of administration. Absorption and distribution of inhaled general anaesthetics (a special case) are described in **Chapter 41**. Metabolism and excretion are covered in **Chapter 10**. We begin with a description of the physical processes that underlie drug disposition.

Physical Processes Underlying Drug Disposition

Drug molecules move around the body in two ways:

- bulk flow (i.e. in the bloodstream, lymphatics or cerebrospinal fluid, or during passage through the gastrointestinal tract)
- diffusion (i.e. molecule by molecule, over short distances).

The chemical nature of a drug makes no difference to its transfer by bulk flow. The cardiovascular system provides a rapid long-distance distribution system. In contrast, diffusional characteristics differ markedly between different drugs. In particular, ability to cross hydrophobic diffusion barriers is strongly influenced by lipid solubility. Aqueous diffusion is part of the overall mechanism of drug transport, because it is this process that delivers drug molecules to and from the non-aqueous barriers. The rate of diffusion of a substance depends mainly on its molecular size, the *diffusion coefficient* being inversely proportional to the square root of molecular weight. Consequently, while large molecules diffuse more slowly than small ones, the variation with molecular weight is modest. Classical ‘small molecule’ drugs mainly fall within the

molecular weight range 200–1000 Da, and variations in aqueous diffusion rate have only a small effect on their overall pharmacokinetic behaviour, whereas biopharmaceuticals are typically much larger molecules (see **Ch. 5**). Thus, the molecular weight of a monoclonal antibody drug is approximately 150 kDa and of a small interfering RNA drug approximately 16 kDa, so diffusion can be an important limitation to the rate of onset of action of biopharmaceutical drugs.

For small molecule drugs, we can treat the body as a series of interconnected, well-stirred compartments, within each of which the drug concentration is uniform. It is movement *between* compartments, generally involving penetration of non-aqueous diffusion barriers, which determines where, and for how long, a drug will be present in the body after it has been administered. The analysis of drug movements with the help of a simple compartmental model is discussed in **Chapter 11**.

The Movement of Drug Molecules Across Cell Barriers

Cell membranes form the barriers between aqueous compartments in the body. A single layer of membrane separates the intracellular from the extracellular compartments. An epithelial barrier, such as the gastrointestinal mucosa or renal tubule, consists of a layer of cells tightly connected to each other so that molecules must traverse at least two cell membranes (inner and outer) to pass from one side to the other. The anatomical disposition and permeability of vascular endothelium (the cell layer that separates intravascular from extravascular compartments) varies from one tissue to

another. Gaps between endothelial cells are packed with a loose matrix of proteins that act as filters, retaining large molecules and letting smaller ones through. The cut-off of molecular size is not exact: water permeates rapidly whereas molecules of 80,000–100,000 Da permeate very slowly. In some regions, especially the *blood–brain barrier* (see later) and the placenta, there are tight junctions between the cells, and the endothelium is encased in an impermeable layer of periendothelial cells (*pericytes*). These features prevent potentially harmful molecules from penetrating to brain or fetus and have major consequences for drug distribution and activity.

In other organs (e.g. the liver and spleen), endothelium is discontinuous, allowing free passage between cells. In the liver, hepatocytes form the barrier between intra- and extravascular compartments and take on several endothelial cell functions. Fenestrated ('windowed') endothelium occurs in endocrine glands, facilitating transfer to the bloodstream of hormones or other molecules through pores in the endothelium. Formation of fenestrated endothelium is controlled by a specific endocrine gland-derived vascular endothelial growth factor (dubbed EG-VEGF). Endothelial cells lining postcapillary venules have specialised functions relating to leukocyte migration and inflammation, and the sophistication of the intercellular junction can be appreciated from the observation that leukocyte migration can occur without any detectable leak of water or small ions (see **Ch. 7**).

There are three main ways by which small molecules cross cell membranes (**Fig. 9.1**):

- by diffusing directly through the lipid;

- by combination with a *solute carrier* (SLC) or other membrane transporter;
- by diffusing through aqueous pores formed by special membrane glycoproteins (*aquaporins*) that traverse the lipid;
- further, small quantities of macromolecules may cross cell barriers by *pinocytosis* – 'cell drinking' (see later).

Of these routes, diffusion through lipid and carrier-mediated transport are particularly important in relation to pharmacokinetic mechanisms.

Diffusion through aquaporins is probably important in the transfer of gases such as carbon dioxide, but the pores are too small in diameter (about 0.4 nm) to allow most drug molecules (which usually exceed 1 nm in diameter) to pass through. Consequently, drug distribution is not notably abnormal in patients with genetic diseases affecting aquaporins. Pinocytosis involves invagination of part of the cell membrane and the trapping within the cell of a tiny vesicle containing extracellular constituents. The vesicle contents can then be released within the cell or extruded from its other side. This mechanism may be important for the transport of some macromolecules, but not for small molecules.

Diffusion Through LIPID

Non-polar molecules (in which electrons are uniformly distributed) dissolve freely in membrane lipids, and consequently diffuse readily across cell membranes, in contrast to polar molecules in which electrons are distributed non-uniformly. Weak acids and weak bases may exist in either ionised (highly polar) or non-ionised state

depending on pH (see later). The number of molecules crossing the membrane per unit area in unit time is determined by the *permeability coefficient*, *P*, and the concentration difference across the membrane. Permeant molecules must be present within the membrane in sufficient numbers and must be mobile within the membrane if rapid permeation is to occur. Thus, two physicochemical factors contribute to *P*, namely *solubility* in the membrane (which can be expressed as a partition coefficient for the substance distributed between the membrane phase and the aqueous environment) and *diffusivity*, which is a measure of the mobility of molecules within the lipid and is expressed as a diffusion coefficient. The diffusion coefficient varies only modestly between conventional drugs, as noted earlier, so the most important determinant of membrane permeability for conventional low-molecular-weight drugs is the partition coefficient (**Fig. 9.2**). Many pharmacokinetic characteristics of a drug – such as rate of absorption from the gut, penetration into different tissues and the extent of renal elimination – can be predicted from knowledge of its lipid solubility.

Low lipid solubility

FIG. 9.2 The importance of lipid solubility in membrane permeation.(A) and (B) show the concentration profile in a lipid membrane separating two aqueous compartments. A lipid-soluble drug (A) is subject to a much larger transmembrane concentration gradient (ΔC_m) than a lipid-insoluble drug (B). It therefore diffuses more rapidly, even though the aqueous concentration gradient ($C_1 - C_2$) is the same in both cases.

ION Trapping

Ionisation and membrane permeability affect not only the rate at which drugs permeate membranes but also the steady-state distribution of drug molecules between aqueous compartments. Lipid-soluble molecules diffuse into cells where they can be metabolised (e.g. by esterases); this may liberate a functionally important charged (and hence impermeant) metabolite, which is consequently trapped within the cell. This has been extensively exploited, notably in probing the function of intracellular mediators such as Ca^{2+} using fluorescent indicators such as fura-2, which is loaded into cells as an uncharged ester and trapped intracellularly as the charged form (see, for example, **Fig. 4.2**). The same approach has been used recently by pharmaceutical chemists seeking to target drugs (several of which are in development) to intracellular sites of action within monocytes and macrophages using esterase-sensitive chemical motifs conjugated to a drug such as a histone deacetylase inhibitor. This forms a prodrug (see later) that delivers the drug to

cells of the monocyte macrophage lineage which selectively express human carboxylesterase-1, the charged active drug product being trapped in the monocyte cytoplasm, which is its site of action (**Needham et al., 2011**).

pH and ionisation

One important complicating factor in relation to membrane permeation is that many drugs are weak acids or bases, and therefore exist in both un-ionised and ionised form, the ratio of the two forms varying with pH. For a weak base, B, the ionisation reaction is:

$$BH^+ \overset{K_a}{\rightleftharpoons} B + H^+$$

and the dissociation constant pK_a is given by the Henderson–Hasselbalch equation

$$pK_a = pH + \log_{10}\frac{[BH^+]}{[B]}$$

For a weak acid, AH:

$$AH \overset{K_a}{\rightleftharpoons} A^- + H^+$$
$$pK_a = pH + \log_{10}\frac{[AH]}{[A^-]}$$

In either case, the ionised species, BH^+ or A^-, has very low lipid solubility and is virtually unable to permeate membranes except where a specific transport mechanism exists. The lipid solubility of the uncharged species, B or AH, depends on the chemical nature of the drug; for many drugs, the uncharged species is sufficiently lipid-soluble to permit rapid membrane permeation, although there are exceptions (e.g. aminoglycoside antibiotics; see **Ch. 52**) where even the uncharged molecule is insufficiently lipid-soluble to cross membranes appreciably. This is usually because of hydrogen-bonding groups (such as hydroxyl in sugar moieties in aminoglycosides) that render the uncharged molecule hydrophilic.

pH partition and ion trapping

If a pH difference exists between body compartments, this can alter the steady-state distribution of drugs that are weak acids or weak bases via its influence on their ionisation. **Fig. 9.3** shows how a weak acid (e.g. **aspirin**, pK_a 3.5) and a weak base (e.g. **pethidine**, pK_a 8.6) would be distributed at equilibrium between three body compartments, namely plasma (pH 7.4), alkaline urine (pH 8) and gastric juice (pH 3). Within each compartment, the ratio of ionised to un-ionised drug is governed by the pK_a of the drug and the pH of that compartment. It is assumed that the un-ionised species can cross the membrane, and therefore reaches an equal concentration in each compartment. The ionised species is assumed not to cross at all. The result is that, at equilibrium, the total (ionised + un-ionised) concentration of the drug will be different in each compartment, with an acidic drug being concentrated in the compartment with high pH ('ion trapping'), and vice versa. The

concentration gradients produced by ion trapping can theoretically be very large if there is a large pH difference between compartments. Thus, aspirin would be concentrated more than 4-fold with respect to plasma in an alkaline renal tubule, and about 6000-fold in plasma with respect to the acidic gastric contents. Such large gradients are not achieved in reality for two main reasons. First, assuming total impermeability of the charged species is not realistic, and even a small permeability will attenuate considerably the concentration difference that can be reached. Second, body compartments rarely approach equilibrium. Neither the gastric contents nor the renal tubular fluid stands still, and the resulting bulk flow of drug molecules reduces the concentration gradients well below the theoretical equilibrium conditions. The pH partition mechanism nonetheless correctly explains some of the qualitative effects of pH changes in different body compartments on the pharmacokinetics of weakly acidic or basic drugs, particularly in relation to renal excretion and to penetration of the blood–brain barrier.

pH partition is not the main determinant of the site of absorption of drugs from the gastrointestinal tract. This is because the enormous absorptive surface area of the villi and microvilli in the ileum compared with the much smaller absorptive surface area in the stomach is of overriding importance. Thus absorption of an acidic drug such as aspirin is promoted by drugs that accelerate gastric emptying (e.g. **metoclopramide**) and slowed by drugs that slow gastric emptying (e.g. **propantheline**), even though the acidic pH of the stomach contents favours absorption of weak acids. Values of pK_a for some common drugs are shown in **Fig. 9.4**.

There are several important consequences of pH partition:

- Free-base trapping of some antimalarial drugs (e.g. **chloroquine**, see **Ch. 55**) in the acidic environment in the food vacuole of the malaria parasite contributes to the disruption of the haemoglobin digestion pathway that underlies their toxic effect on the parasite.
- Urinary acidification accelerates excretion of weak bases and retards that of weak acids (see **Ch. 10**).
- Urinary alkalinisation has the opposite effects: it reduces excretion of weak bases and increases excretion of weak acids.
- Increasing plasma pH (e.g. by administration of sodium bicarbonate) causes weakly acidic drugs to be extracted from the central nervous system (CNS) into the plasma. Conversely, reducing plasma pH (e.g. by administration of a carbonic anhydrase inhibitor such as **acetazolamide**, see **Ch. 29**) causes weakly acidic drugs to become concentrated in the CNS, potentially increasing their neurotoxicity. This has practical consequences in choosing a means to alkalinise urine in treating aspirin overdose: bicarbonate and acetazolamide each increase urine pH and hence increase salicylate elimination, but bicarbonate reduces whereas acetazolamide increases distribution of salicylate to the CNS.

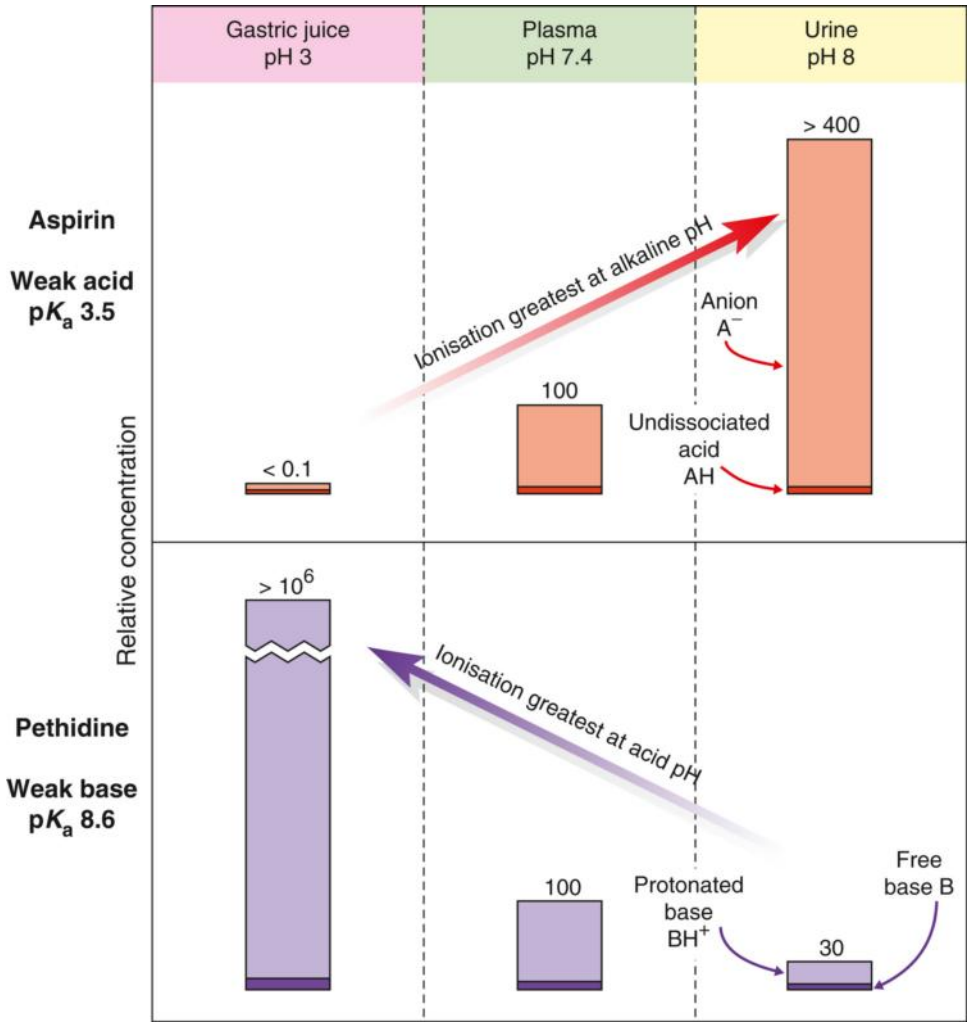

FIG. 9.3 Theoretical partition of a weak acid (aspirin) and a weak base (pethidine) between aqueous compartments (urine, plasma and gastric juice) according to the pH difference between them. Numbers represent relative concentrations (total plasma concentration = 100). It is assumed that the uncharged species in each case can permeate the cellular barrier separating the compartments, and therefore reaches the same concentration in all three. Variations

in the fractional ionisation as a function of pH give rise to the large total concentration differences with respect to plasma.

Carrier-Mediated Transport

Many cell membranes possess specialised transport mechanisms that regulate entry and exit of physiologically important molecules, such as sugars, amino acids, neurotransmitters and metal ions. They are broadly divided into *SLC transporters* and *ATP-binding cassette (ABC) transporters*. The former facilitate passive movement of solutes down their electrochemical gradient, while the latter are active pumps fuelled by ATP. Over 300 human genes are believed to code these transporters, most of which act mainly on endogenous substrates, but some also transport foreign chemicals ('xenobiotics') including drugs. The role of such transporters in neurotransmitter function is discussed in **Chapters 14**, **15** and **37**.

Organic cation transporters and organic anion transporters

Two structurally related SLCs of importance in drug distribution are the organic cation transporters (OCTs – see e.g. **Ciarimboli, 2008 and 2021**) and organic anion transporters (OATs – see e.g. **Nosaki and Izumi, 2020**). The carrier molecule consists of a transmembrane protein that binds one or more molecules or ions, changes conformation and releases its cargo on the other side of the membrane. Such systems may operate purely passively, without any energy source; in this case, they merely facilitate the process of transmembrane equilibration of a single transported species in the

direction of its electrochemical gradient. The OCTs translocate dopamine, choline and various drugs including **vecuronium**, **quinine** and **procainamide**. They are 'uniporters' (i.e. each protein transporter molecule binds one solute molecule at a time and transports it down its gradient). OCT2 (present in proximal renal tubules) concentrates drugs such as **cisplatin** (an important anticancer drug; see **Ch. 57**) in these cells, resulting in its selective nephrotoxicity; related drugs (e.g. **carboplatin**, **oxaliplatin**) are not transported by OCT2 and are less nephrotoxic; competition with **cimetidine** for OCT2 offers possible protection against cisplatin nephrotoxicity (**Fig. 9.5**). Other SLCs are coupled to the electrochemical gradient of Na^+ or other ions across the membrane, generated by ATP-dependent ion pumps (see **Ch. 4**); in this case, transport can occur against an electrochemical gradient. It may involve exchange of one molecule for another ('antiport') or transport of two molecules together in the same direction ('symport'). The OATs are responsible for the renal secretion of urate, prostaglandins, several vitamins and *p*-amino hippurate, and for drugs such as **probenecid**, many antibiotics, antiviral, non-steroidal anti-inflammatory and antineoplastic drugs. Uptake is driven by exchange with intracellular dicarboxylic acids (mainly α-ketoglutarate, partly derived from cellular metabolism and partly by co-transport with Na^+ entering cells down its concentration gradient). Metabolic energy is provided by ATP for Na^+/K^+ exchange. Carrier-mediated transport, because it involves a binding step, shows the characteristic of saturation.

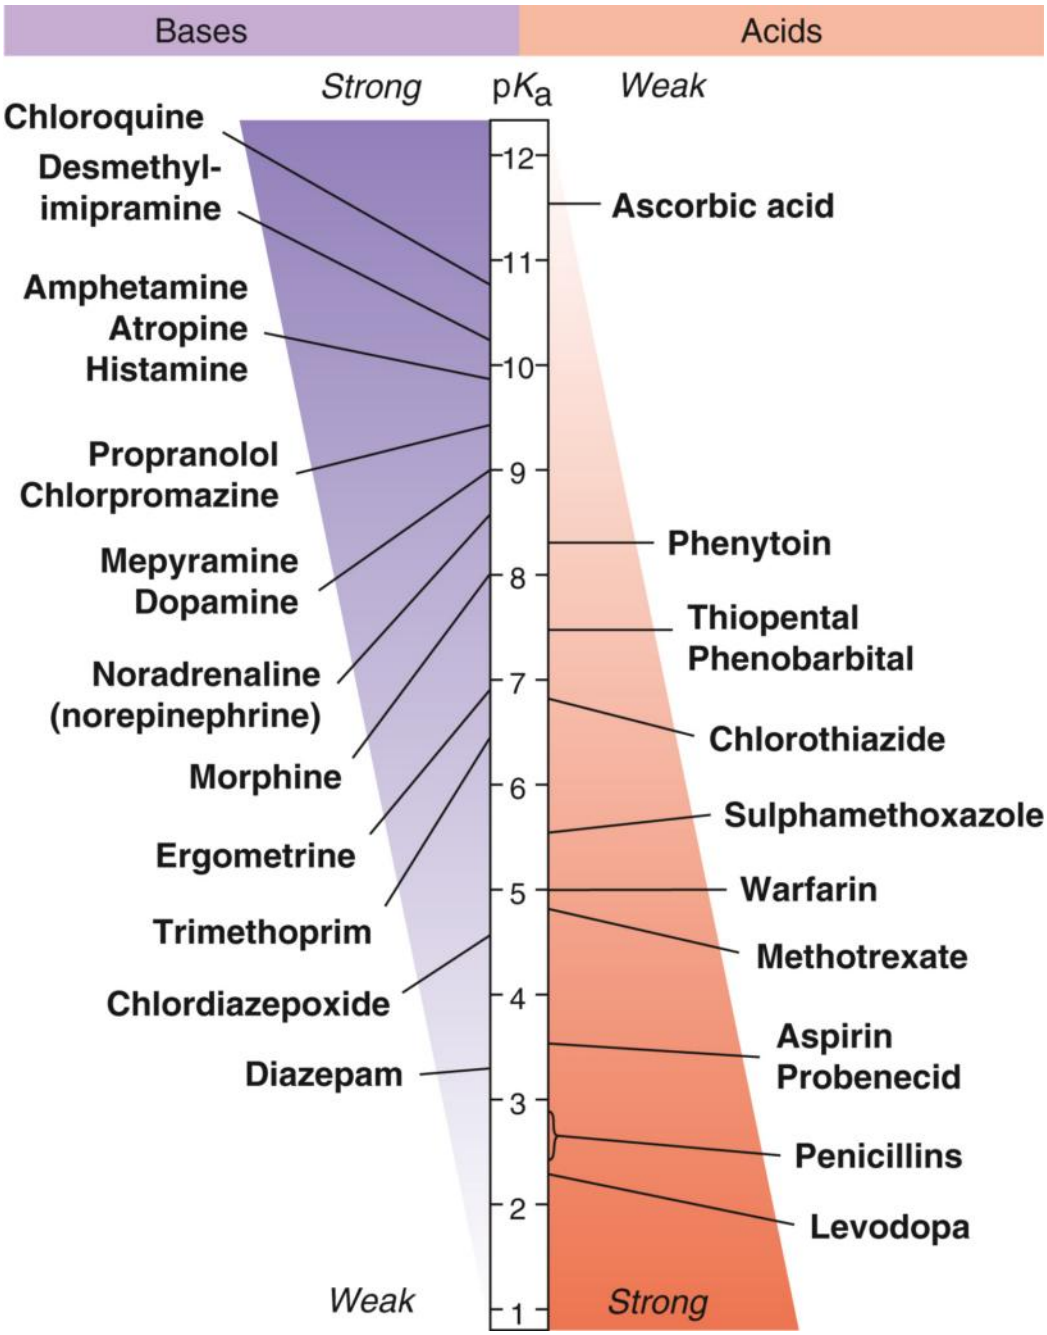

FIG. 9.4 p*K*a values for some acidic and basic drugs.

Carriers of this type are ubiquitous, and many pharmacological effects are the result of interference with them. Thus some nerve terminals have transport mechanisms that accumulate specific

neurotransmitters or their precursors, and there are many examples of drugs that act by inhibiting these transport mechanisms (see Chs **14**, **15**, **37**, **48** and **49**). From a general pharmacokinetic point of view, however, the main sites where SLCs, including OCTs and OATs, are expressed and carrier-mediated drug transport is important are:

- the blood–brain barrier
- the gastrointestinal tract
- the renal tubule
- the biliary tract
- the placenta

P-glycoprotein transporters

P-glycoproteins (P-gp; P for 'permeability'), which belong to the ABC transporter superfamily, are the second important class of transporters and are responsible for multidrug resistance in cancer cells, many of which express an ATP-dependent pump with broad specificity called multidrug resistance protein 1 (mdr1) – see **Chapter 57**. This is expressed in animals, fungi and bacteria and may have evolved as a defence mechanism against toxins. P-gps are present in renal tubular brush border membranes, in bile canaliculi, in astrocyte foot processes in brain microvessels [1] and in the gastrointestinal tract. They play an important part in the absorption, distribution and elimination of many drugs, and are often co-located with SLC drug carriers, so that a drug that has been concentrated by, for example, an OAT transporter in the basolateral membrane of a renal tubular cell may then be extruded by a P-gp in the lumenal membrane (see **Ch. 29**).

Polymorphic variation in the genes coding SLCs and P-gp contributes to individual genetic variation in responsiveness to different drugs, and competition between drugs for the same transporter cause drug–drug interactions (see **Lund et al., 2017**, **Nosaki and Izumi, 2020** and **Yoshida et al., 2013**, for reviews). OCT1 transports several drugs, including **metformin** (used to treat type 2 diabetes; see **Ch. 31**), into hepatocytes (in contrast to OCT2 which is expressed in renal proximal tubular cells, see previously). Metformin acts partly through effects within hepatocytes, and single nucleotide polymorphisms (SNPs) that impair the function of OCT1 influence its effectiveness (**Fig. 9.6**). This is but one example of many genetic influences on drug effectiveness or toxicity via altered activity of carriers that influence drug disposition. Furthermore, induction or competitive inhibition of transporter molecules can occur in the presence of a second ligand that binds the carrier, so there is a potential for drug–drug interaction (see **Fig. 9.5** and **Ch. 12**).

Plasma protein and tissue partition of drugs

In addition to the processes so far described, which govern the transport of drug molecules across the barriers between different aqueous compartments, two additional factors have a major influence on drug distribution and elimination. These are:

- binding to plasma proteins
- partition into body fat and other tissues

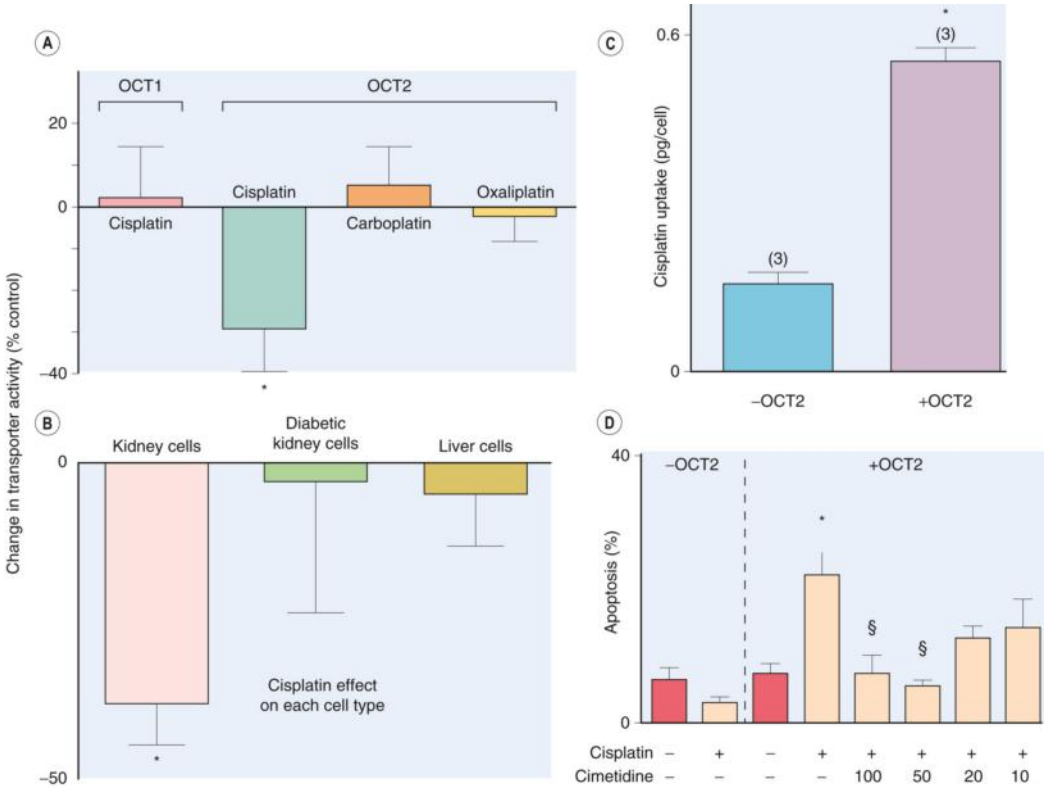

FIG. 9.5 Human organic cation transporter 2 (OCT2) mediates cisplatin nephrotoxicity.OCT2 is expressed in kidney whereas OCT1 is expressed in liver. Cisplatin (100 μmol/L) influences the activity of OCT2 but not of OCT1, each expressed in a cultured cell line (A), whereas the less nephrotoxic drugs carboplatin and oxaliplatin do not. Cisplatin similarly influences OCT2 activity in fresh human kidney tubule cells but not in fresh hepatocytes or kidney cells from patients with diabetes who are less susceptible to cisplatin nephrotoxicity (B). Cisplatin accumulates in cells that express OCT2 (C) and causes cell death (D). Cimetidine competes with cisplatin for OCT2 and

concentration dependently protects against cisplatin-induced apoptosis (D) – cimetidine concentrations are in μmol/L. Data redrawn from Ciarimboli, G., et al., 2005. Am. J. Pathol. 167, 1477–1484.

Movement of drugs across cellular barriers

- To traverse cellular barriers (e.g. gastrointestinal mucosa, renal tubule, blood–brain barrier, placenta), drugs have to cross lipid membranes.
- Drugs cross lipid membranes mainly (a) by passive diffusional transfer and (b) by carrier-mediated transfer.
- The main factor that determines the rate of passive diffusional transfer across membranes is a drug's lipid solubility.
- Many drugs are weak acids or weak bases; their state of ionisation varies with pH according to the Henderson–Hasselbalch equation.
- With weak acids or bases, only the uncharged species (the protonated form for a weak acid, the unprotonated form for a weak base) can diffuse across lipid membranes; this gives rise to pH partition.
- pH partition means that weak acids accumulate in compartments of relatively high pH, whereas weak bases do the reverse.

- Carrier-mediated transport is mediated by solute carriers (SLCs), which include OCTs and OATs, and P-gps, which are ABC transporters in the renal tubule, blood–brain barrier and gastrointestinal epithelium. These are important in determining the distribution of many drugs, are prone to genetic variation and are targets for drug–drug interactions.

FIG. 9.6 Genetic variants of organic cation transporter 1 (OCT1) are associated with different responses to metformin in healthy humans.(A) An oral glucose tolerance test (OGTT) gave similar plasma glucose responses in control subjects with only reference *OCT1* alleles versus subjects with at least one reduced function *OCT1* allele. (B) In contrast, after metformin treatment, the OGTT response was less in the same reference subjects than in those with reduced function *OCT1* alleles – i.e. the effect of metformin was blunted in the variant-allele group. (C) Glucose exposure estimated by area under the glucose time curves was significantly lower in subjects with only reference *OCT1* alleles, $p = 0.004$. Data redrawn from Yan Shu, et al., 2007. J. Clin. Invest. 117, 1422–1431.

Binding of Drugs to Plasma Proteins

At therapeutic concentrations in plasma, many drugs exist mainly in bound form. The fraction of drug that is unbound and pharmacologically active in plasma can be less than 1%, the remainder being associated with plasma protein. Seemingly small differences in protein binding (e.g. 99.5% vs 99.0%) can have large effects on free drug concentration and drug effect. Such differences are common between human plasma and plasma from species used

in preclinical drug testing and must be taken into account when estimating a suitable dose for 'first time in human' studies during drug development. The most important plasma protein in relation to drug binding is albumin, which binds many acidic drugs (e.g. warfarin, non-steroidal anti-inflammatory drugs, sulfonamides) and a smaller number of basic drugs (e.g. tricyclic antidepressants and chlorpromazine). Other plasma proteins, including β-globulin and a circulating acid glycoprotein that increases in inflammatory disease, have also been implicated in the binding of certain basic drugs such as quinine.

The amount of a drug that is bound to protein depends on three factors:

- the concentration of free drug
- its affinity for the binding sites
- the concentration of protein

As a first approximation, the binding reaction can be regarded as a simple association of the drug molecules with a finite population of binding sites, analogous to drug–receptor binding (see **Ch. 2**):

$$\underset{\text{free drug}}{D} + \underset{\text{binding site}}{S} \rightleftharpoons \underset{\text{complex}}{DS}$$

The usual concentration of albumin in plasma is approximately 0.6 mmol/L (4 g/100 mL). With two sites per albumin molecule, the drug-binding capacity of plasma albumin would therefore be about 1.2 mmol/L. For most drugs, the total plasma concentration

required for a clinical effect is much less than 1.2 mmol/L, so with usual therapeutic doses the binding sites are far from saturated, and the concentration bound [DS] varies nearly in direct proportion to the free concentration [D]. Under these conditions, the fraction bound, [DS]/([D] + [DS]), is independent of the drug concentration. However, some drugs, for example, **tolbutamide** (see **Ch. 31**), act at plasma concentrations at which its binding to plasma albumin approaches saturation (i.e. on the flat part of the binding curve). This means that increasing the dose increases the free (pharmacologically active) concentration disproportionately. This is illustrated in **Fig. 9.7**.

Plasma albumin binds many different drugs at one or another of a limited number of binding sites, so competition can occur between drugs. If two drugs (A and B) compete in this way, administration of drug B can reduce the protein binding, and hence increase the free plasma concentration, of drug A. To do this, drug B needs to occupy an appreciable fraction of the binding sites. Few therapeutic drugs affect the binding of other drugs because they occupy, at therapeutic plasma concentrations, only a tiny fraction of the available sites. *Sulfonamides* (see **Ch. 52**) are an exception, because they occupy about 50% of the binding sites at therapeutic concentrations and so can cause harmful effects by displacing other drugs or, in premature babies, bilirubin (see later). Much has been made of binding interactions of this kind as a source of untoward drug interactions in clinical medicine, but this type of competition is less important than was once thought (see **Ch. 12**).

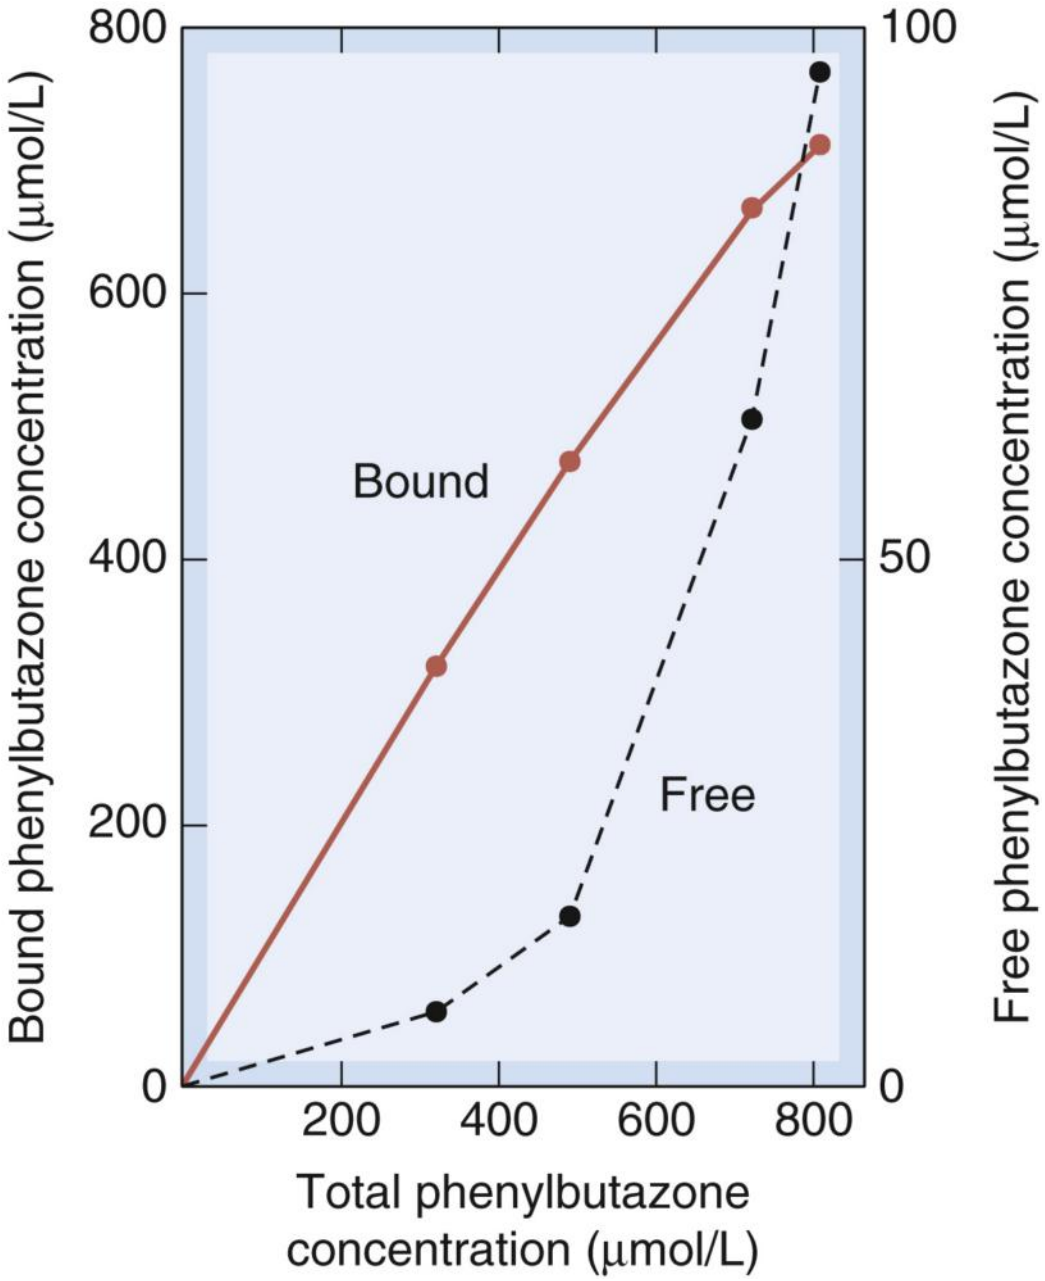

FIG. 9.7 Binding of phenylbutazone to plasma albumin.The graph shows the disproportionate increase in free concentration as the total concentration increases, owing to the binding sites approaching saturation. Data from Brodie, B., Hogben, C.A.M., 1957. J. Pharm. Pharmacol. 9, 345.

Binding of drugs to plasma proteins

- Plasma albumin binds mainly acidic drugs (approximately two molecules per albumin molecule).
- Saturable binding can lead to a non-linear relation between dose and free (active) drug concentration, but the effective concentration range of most therapeutic drugs is below that at which this would be important.
- Binding to plasma protein is a source of species variation, important in interpreting preclinical pharmacology studies and estimating the first-in-human dose.
- β-Globulin and acid glycoprotein also bind some drugs in plasma.
- Extensive protein binding slows drug elimination (metabolism and/or glomerular filtration).
- Competition between drugs for protein binding can lead to clinically significant drug interactions, but this is uncommon.

Partition into Body fat and other Tissues

Fat potentially provides a large reservoir for non-polar drugs. In practice, this is important for many general anaesthetics (see **Ch. 41**), which are relatively lipid soluble. In contrast, the effective fat:water partition coefficient is relatively low for many other drugs. Morphine, for example, although lipid-soluble enough to cross the blood–brain barrier, has a lipid:water partition coefficient of only

0.4, so sequestration of the drug by body fat is of little importance. **Thiopental** (a general anaesthetic [2]), by comparison, has a fat:water partition coefficient of approximately 10 and accumulates substantially in body fat. This has important consequences that limit its usefulness as an intravenous anaesthetic to short-term initiation ('induction') of anaesthesia, and it has been replaced by propofol even for this indication in many countries (see **Ch. 41**).

The second factor that limits the accumulation of drugs in body fat is its low blood supply – less than 2% of the cardiac output. Consequently, drugs are delivered slowly to body fat, and the theoretical equilibrium distribution between fat and body water is delayed. For practical purposes, therefore, partition into body fat when drugs are given acutely is important only for a few highly lipid-soluble drugs, notably the general anaesthetics as mentioned previously. When lipid-soluble drugs are given *chronically*, however, accumulation in body fat is more often clinically important (e.g. benzodiazepines; see **Ch. 45**). Some drugs and environmental contaminants (such as insecticides), if ingested intermittently, accumulate slowly but progressively in body fat.

Fat is not the only tissue in which drugs can accumulate. **Chloroquine** – an antimalarial drug (see **Ch. 55**) – has a high affinity for melanin and is taken up by the retina, which is rich in melanin granules, accounting for chloroquine's ocular toxicity. Tetracyclines (see **Ch. 52**) accumulate slowly in bones and teeth, because they have a high affinity for calcium, and should not be used in children for this reason. Very high concentrations of **amiodarone** (an antidysrhythmic drug; see **Ch. 20**) accumulate in

liver and lung during chronic use, causing hepatitis and interstitial pulmonary fibrosis.

Drug Absorption and Routes of Administration

The main routes of drug administration and elimination are shown schematically in **Fig. 9.8**. Absorption is defined as the passage of a drug from its site of administration into the plasma. It is important for all routes of administration except intravenous injection, where it is complete by definition. There are instances, such as topical administration of a steroid cream to skin or inhalation of a bronchodilator aerosol to treat asthma (see **Ch. 28**), where absorption as just defined is not required for the drug to act, but in most cases the drug must enter plasma before reaching its site of action.

The main routes of administration are:

- oral (drug is swallowed)

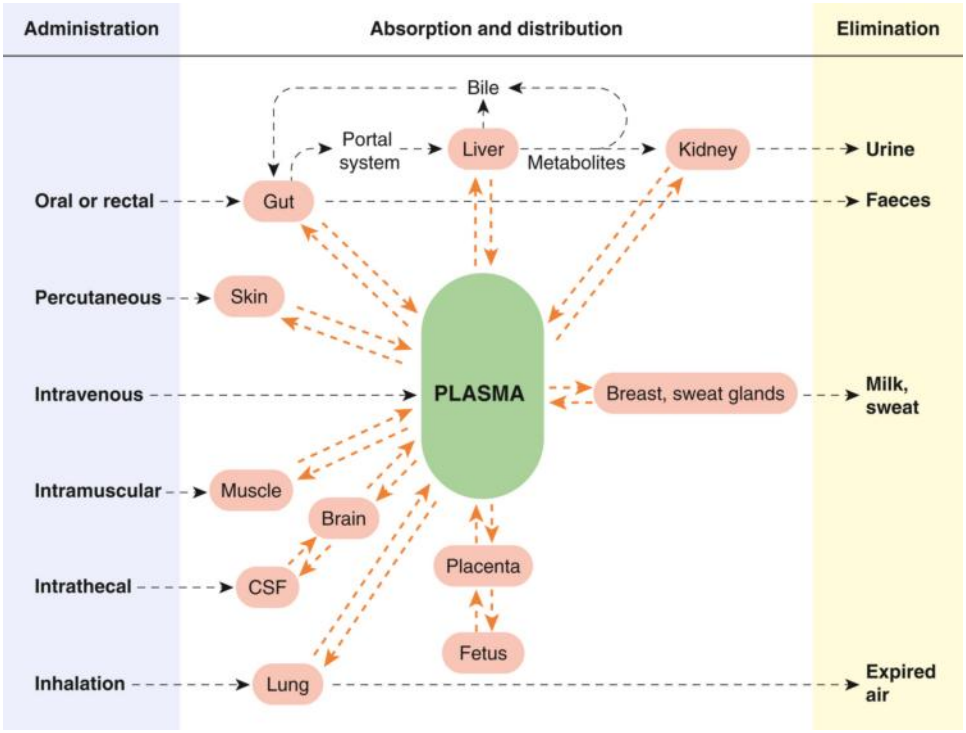

FIG. 9.8 The main routes of drug administration and elimination. *CSF,* Cerebrospinal fluid.

- sublingual or buccal (drug is kept in contact with the oral mucosa)
- rectal
- application to other epithelial surfaces (e.g. skin, conjunctiva, vagina and nasal mucosa)
- inhalation
- injection
    - subcutaneous
    - intramuscular
    - intravenous
    - intrathecal
    - intravitreal

Oral Administration

Most small molecule drugs are taken by mouth and swallowed. Little absorption occurs until the drug enters the small intestine, although non-polar drugs applied to the buccal mucosa or under the tongue are absorbed directly from the mouth (e.g. organic nitrates, see **Ch. 20**, and buprenorphine, see **Ch. 42**). Peptides and proteins are subject to digestion, so the oral route is not generally suitable to biopharmaceuticals, and despite ingenious pharmaceutical approaches to circumvent these problems, success has been limited (**Dubey et al., 2021**).

Drug Absorption from the Intestine

For most drugs, the mechanism of absorption is the same as for other epithelial barriers, namely, passive transfer at a rate determined by the ionisation and lipid solubility of the drug molecules. **Fig. 9.9** shows the absorption of various weak acids and bases as a function of pK_a. As expected, strong bases of pK_a 10 or higher are poorly absorbed, as are strong acids of pK_a less than 3, because they are fully ionised. The arrow poison **curare** used by South American indigenous tribes contains quaternary ammonium compounds that block neuromuscular transmission (see **Ch. 14**). These strong bases are poorly absorbed from the gastrointestinal tract, so the meat from animals killed in this way was safe to eat.

In some instances, intestinal drug absorption depends on carrier-mediated transport rather than simple lipid diffusion. Examples include **levodopa**, used in treating Parkinson's disease (see **Ch. 40**), which is taken up by the carrier that normally transports phenylalanine, and **fluorouracil** (see **Ch. 57**), a cytotoxic drug

that is transported by the carrier for pyrimidines (thymine and uracil). Iron is absorbed via specific carriers in the epithelial cell membranes of jejunal mucosa, and calcium is absorbed by a vitamin D–dependent carrier.

Factors Affecting Gastrointestinal Absorption

Typically, about 75% of a drug given orally is absorbed in 1–3 h, but numerous factors alter this, some physiological and some to do with the formulation of the drug. The main factors are:

- gut content (e.g. fed vs fasted)
- gastrointestinal motility
- splanchnic blood flow
- particle size and formulation
- physicochemical factors, including some drug–drug interactions

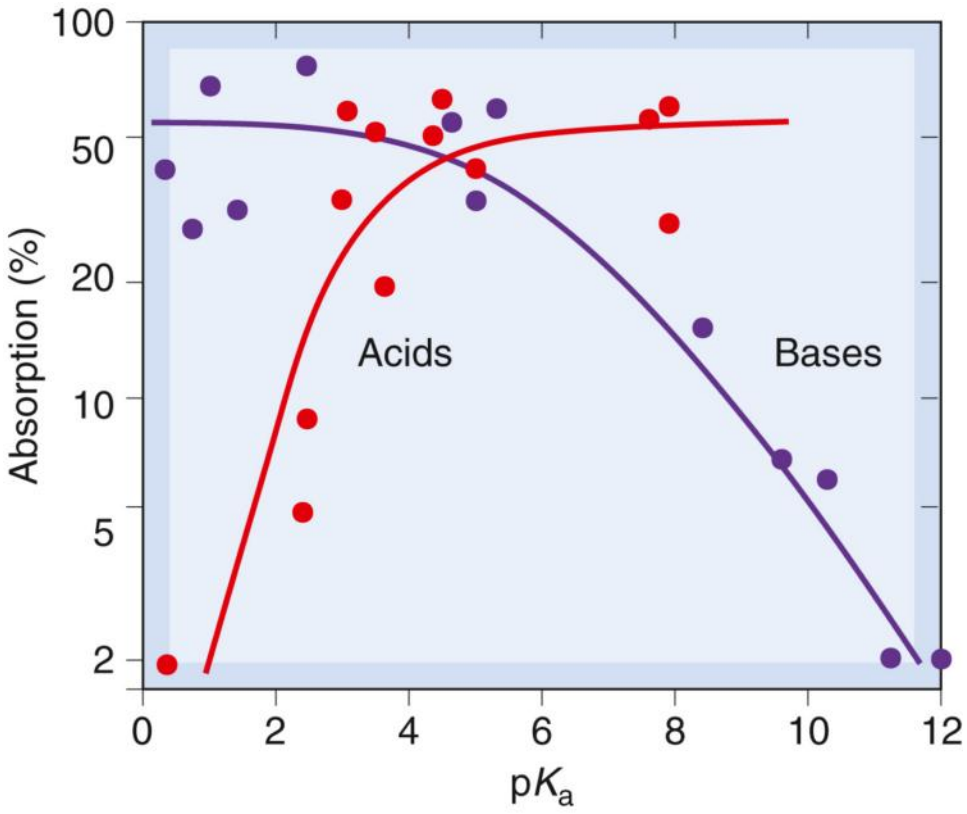

FIG. 9.9 Absorption of drugs from the intestine, as a function of p*K*a, for acids and bases.Weak acids and bases are well absorbed; strong acids and bases are poorly absorbed. Redrawn from Schanker, L.S., et al., 1957. J. Pharmacol. Exp. Therap. 120, 528.

- genetic polymorphisms in, and drug–drug competition for, transporters

The influence of feeding, which influences both gut content and splanchnic blood flow, is routinely examined in early phase clinical trials (the pharmacokinetic measure of interest is T_{max}, the time after dosing at which the plasma concentration of the drug is

maximal, C_{max}), and prescribing advice tailored accordingly. Gastrointestinal motility has a large effect. Many disorders (e.g. migraine, diabetic neuropathy) cause gastric stasis and slow drug absorption. Drug treatment can also affect motility, either reducing it (e.g. drugs that block muscarinic receptors; see **Ch. 14**) or increasing it (e.g. **metoclopramide**, an antiemetic used in migraine to facilitate absorption of analgesic; see Chs **16**, **30** and **42**). Excessively rapid movement of gut contents (e.g. in some forms of diarrhoea) can impair absorption. Several drugs (e.g. **propranolol**) reach a higher plasma concentration if they are taken after a meal, probably because food increases splanchnic blood flow. Conversely, splanchnic blood flow is greatly reduced by exercise and by hypovolaemia or heart failure, with a resultant reduction of drug absorption.

Particle size and formulation have major effects on absorption. In 1971, patients in a New York hospital were found to require unusually large maintenance doses of **digoxin** (see **Ch. 20**). In a study on healthy volunteers, it was found that standard digoxin tablets from different manufacturers resulted in different plasma concentrations (**Fig. 9.10**), even though the digoxin content of the tablets was the same, probably in part because of differences in particle size.

Therapeutic drugs are formulated to produce desired absorption characteristics. Capsules may be designed to remain intact for some hours after ingestion in order to delay absorption, or tablets may have a resistant coating to give the same effect. In some cases, a mixture of slow- and fast-release particles is included in a capsule to produce rapid but sustained absorption. More elaborate

pharmaceutical systems include modified-release preparations that permit less frequent dosing. Such preparations not only permit an increased dose interval but also reduce adverse effects related to high peak plasma concentration (C_{max}) following administration of a conventional formulation.

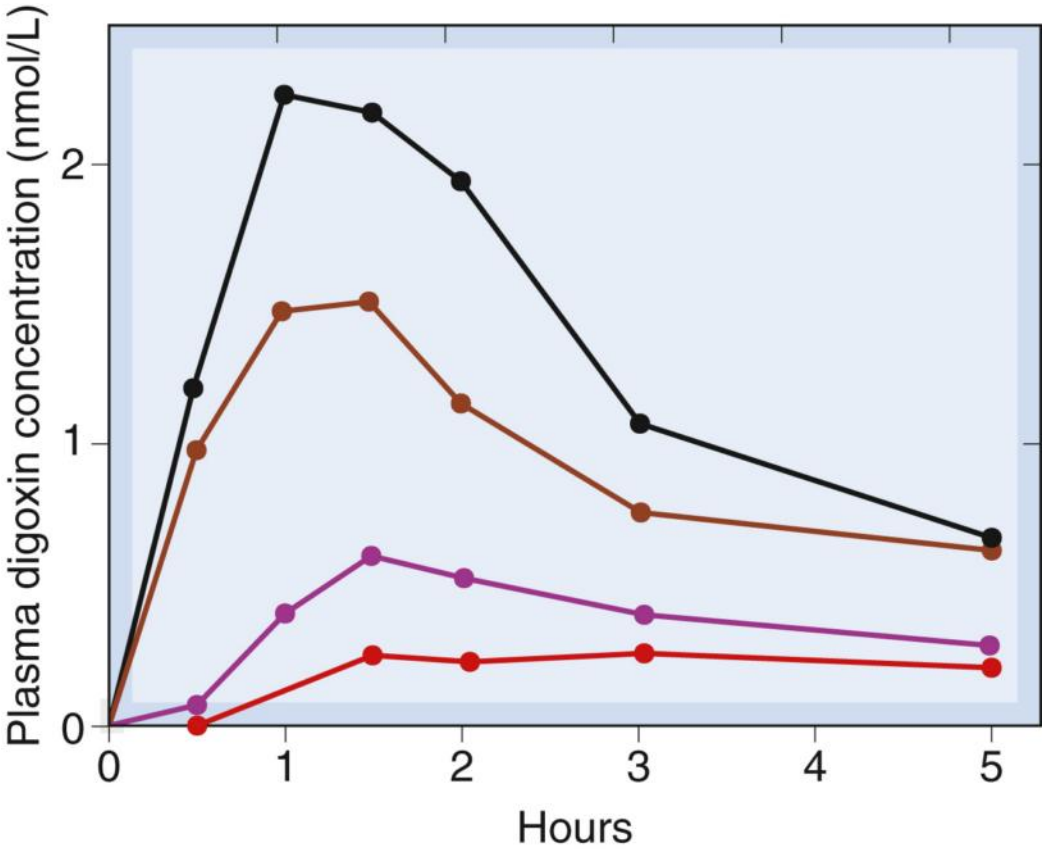

FIG. 9.10 Variation in oral absorption among different formulations of digoxin.The four curves show the mean plasma concentrations attained for the four preparations, each of which was given on separate occasions to four subjects. The large variation has caused the formulation of digoxin tablets to be standardised since this study was published. From Lindenbaum, J., et al., 1971. N. Engl. J. Med. 285, 1344.

When drugs are swallowed, the intention is usually that they should be absorbed and cause a systemic effect, but there are exceptions. **Vancomycin** is very poorly absorbed and is administered orally to eradicate toxin-forming *Clostridium difficile*

from the gut lumen in patients with pseudomembranous colitis (an adverse effect of broad-spectrum antibiotics caused by appearance of this organism in the bowel). **Mesalazine** is a formulation of 5-aminosalicylic acid in a pH-dependent acrylic coat that degrades in the terminal ileum and proximal colon, and is used to treat inflammatory bowel disease affecting this part of the gut. **Olsalazine** is a prodrug (see later) consisting of a dimer of two molecules of 5-aminosalicylic acid that is cleaved by colonic bacteria in the distal bowel and is used to treat patients with distal colitis.

Bioavailability and bioequivalence

To access the systemic circulation, a drug given orally must not only penetrate the intestinal mucosa, it must also run a gauntlet of inactivating enzymes in the gut wall and liver, referred to as 'presystemic' or 'first-pass' metabolism. The term *bioavailability* is used to indicate the fraction (F) of an orally administered dose that reaches the systemic circulation as intact drug, taking into account both absorption and local metabolic degradation. F is measured by determining the plasma drug concentration versus time curves in a group of subjects following oral and (on a separate occasion) intravenous administration (the fraction absorbed following an intravenous dose is 1 by definition). The area under the plasma concentration time curves (AUC) provides an integrated measure of drug exposure, taking into account time as well as concentration, and F is estimated as $AUC_{oral}/AUC_{intravenous}$. Bioavailability is not a characteristic solely of the drug preparation: variations in enzyme activity of gut wall or liver, in gastric pH or intestinal motility all affect it. Because of this, one cannot speak strictly of the

bioavailability of a particular preparation, but only of that preparation in a given individual on a particular occasion, and *F* determined in a group of healthy volunteer subjects may differ substantially from the value determined in patients with diseases of gastrointestinal or circulatory systems.

Bioavailability relates only to the total proportion of the drug that reaches the systemic circulation and neglects the rate of absorption. If a drug is completely absorbed in 30 min, it will reach a much higher peak plasma concentration (and have a more dramatic effect) than if it were absorbed over several hours. Regulatory authorities – which have to make decisions about the licensing of products that are 'generic equivalents' of patented products – require evidence of 'bioequivalence' based on the maximum concentration achieved (C_{max}) and time between dosing and C_{max} (T_{max}) as well as $AUC_{(0–t)}$. For most drugs, $AUC_{(0–t)}$ and C_{max} must each lie between 80% and 125% of a marketed preparation for the new generic product to be accepted as bioequivalent to the comparator, which is usually the market leader (**EMEA, 2010**).

Oromucosal (Sublingual or Buccal) Administration

Absorption directly from the oral cavity is sometimes useful when a rapid response is required, particularly when the drug is either unstable at gastric pH or rapidly metabolised by the liver. **Glyceryl trinitrate** and **buprenorphine** (mentioned earlier) are examples of drugs that are often given sublingually (see Chs **20** and **42**, respectively). Buccal midazolam is as effective and safe as intravenous or rectal diazepam in terminating early *status epilepticus* (see **Ch. 46**) in children (**Brigo et al., 2015**). Times

from arrival in the emergency department to drug administration and to seizure cessation are shortened and the drug is easier to administer. Drugs absorbed from the mouth pass directly into the systemic circulation without entering the portal system, and so escape first-pass metabolism by enzymes in the gut wall and liver.

Rectal Administration

Rectal administration is used for drugs that are required to produce either a local effect (e.g. anti-inflammatory drugs such as **mesalazine** suppositories or enemas for use in ulcerative colitis; see **Ch. 30**) or systemic effects. Absorption following rectal administration may be unreliable but can be rapid and more complete than following oral administration, since only a fraction of the capillary drainage returns to the systemic circulation via the portal vein. This route can be useful in patients who are vomiting or are unable to take medication by mouth (e.g. postoperatively or during palliative care), but rectal administration has not been widely adopted even when there is a seemingly good rationale and suppositories are commercially available, for example, ergotamine-containing suppositories for treating migraine attacks – a condition where gastric stasis and vomiting can limit the effectiveness of oral tablets (see **Ch. 42**).

Application to Epithelial Surfaces

Cutaneous Administration

Cutaneous administration is used when a local effect on the skin is required (see **Ch. 26**). Appreciable absorption may nonetheless occur and lead to systemic effects; absorption is sometimes

exploited therapeutically, for example, in local application of rub-on gels of non-steroidal anti-inflammatory agents such as **ibuprofen** (see **Ch. 25**).

Most drugs are absorbed very poorly through unbroken skin. However, a number of organophosphate insecticides (see **Ch. 14**), which need to penetrate an insect's cuticle to work, are absorbed through skin, and accidental poisoning occurs in farm workers.

A case is recounted of a 35-year-old florist in 1932. 'While engaged in doing a light electrical repair job at a work bench he sat down in a chair on the seat of which some "Nico-Fume liquid" (a 40% solution of free nicotine) had been spilled. He felt the solution wet through his clothes to the skin over the left buttock, an area about the size of the palm of his hand. He thought nothing further of it and continued at his work for about 15 min, when he was suddenly seized with nausea and faintness … and found himself in a drenching sweat. On the way to hospital he lost consciousness.' He survived, just, and then 4 days later: 'On discharge from the hospital he was given the same clothes that he had worn when he was brought in. The clothes had been kept in a paper bag and were still damp where they had been wet with the nicotine solution.' The sequel was predictable. He survived again but felt thereafter 'unable to enter a greenhouse where nicotine was being sprayed'. Transdermal dosage forms of nicotine are now used to reduce the withdrawal symptoms that accompany stopping smoking (see **Ch. 50**).

Transdermal dosage forms, in which the drug is incorporated in a stick-on patch applied to the skin, are used increasingly, and several drugs – for example **oestrogen** and **testosterone** for hormone

replacement (see **Ch. 35**) – are available in this form. Such patches produce a steady rate of drug delivery and avoid presystemic metabolism. **Fentanyl** is available in a patch to treat intermittent breakthrough pain (see **Ch. 43**). However, the method is suitable only for lipid-soluble drugs and is relatively expensive.

Nasal Sprays

Some peptide hormone analogues, for example, **antidiuretic hormone** (see **Ch. 33**) and **gonadotrophin-releasing hormone** (see **Ch. 35**), are given as nasal sprays, as is **calcitonin** (see **Ch. 36**). Absorption is believed to take place through mucosa overlying nasal-associated lymphoid tissue. This is similar to the mucosa overlying Peyer's patches in the small intestine, which is also unusually permeable.

Eye Drops

Many drugs are applied as eye drops (see **Ch. 27**), relying on absorption through the epithelium of the conjunctival sac to produce their effects. Desirable local effects within the eye can be achieved without causing systemic side effects; for example, **dorzolamide** is a carbonic anhydrase inhibitor that is given as eye drops to lower ocular pressure in patients with glaucoma. It achieves this without affecting the kidney (see **Ch. 29**), thus avoiding the acidosis that is caused by oral administration of acetazolamide. Some systemic absorption from the eye occurs, however, and can result in unwanted effects (e.g. bronchospasm in asthmatic patients using **timolol** eye drops for glaucoma).

Administration by Inhalation

Inhalation is the route used for volatile and gaseous anaesthetics, the lung serving as the route of both administration and elimination (see **Ch. 41**). The rapid exchange resulting from the large surface area and blood flow makes it possible to achieve rapid adjustments of plasma concentration. The pharmacokinetic behaviour of inhalation anaesthetics is discussed in **Chapter 41**.

Drugs used for their effects on the lung are also given by inhalation, usually as an aerosol mist of liquid droplets or sometimes of solid particles. Glucocorticoids (e.g. **beclometasone dipropionate**) and bronchodilators (e.g. **salbutamol** and **formoterol**; see **Ch. 28**) are given in this way to achieve high local concentrations in the lung while minimising systemic effects. However, drugs given by inhalation in this way are usually partly absorbed into the circulation, and systemic side effects (e.g. tremor following salbutamol) can occur. Chemical modification of a drug may minimise such absorption. For example, **ipratropium**, a muscarinic-receptor antagonist (see Chs **14** and **28**), is a quaternary ammonium ion analogue of atropine. It is used as an inhaled bronchodilator because its poor absorption prolongs its local action and reduces the likelihood of systemic adverse effects.

Administration by Injection

Intravenous injection is the fastest and most certain route of drug administration. Bolus injection rapidly produces a high concentration of drug, first in the right heart and pulmonary vessels and then in the systemic circulation. The peak concentration reaching the tissues depends critically on the rate of injection. Administration by intravenous infusion using a mechanical pump

avoids the uncertainties of absorption from other sites, while avoiding high peak plasma concentrations caused by bolus injection.

Subcutaneous or intramuscular injection of drugs usually produces a faster effect than oral administration, but the rate of absorption depends greatly on the site of injection and on local blood flow. The rate-limiting factors in absorption from the injection site are:

- diffusion through the tissue
- removal by local blood flow

Absorption from a site of injection (sometimes but not always desirable, see later) is increased by increased blood flow. *Hyaluronidase* (an enzyme that breaks down the intercellular matrix, thereby increasing diffusion) also increases drug absorption from the site of injection. Conversely, absorption is reduced in patients with circulatory failure (shock) in whom tissue perfusion is reduced (see **Ch. 21**).

Methods for Delaying Absorption

It may be desirable to delay absorption, either to produce a local effect or to prolong systemic action. For example, addition of adrenaline (epinephrine) to a local anaesthetic reduces absorption of the anaesthetic into the general circulation, usefully prolonging the anaesthetic effect (see **Ch. 44**). Formulation of insulin with protamine and zinc produces a long-acting form (see **Ch. 31**). Even longer-acting insulin analogues are now available that can provide basal insulin levels with once daily dosing. These include **insulin glargine**, **insulin detemir** and **insulin degladec.** The longest

acting of these, insulin degladec, has one amino acid deleted and a lysine residue is conjugated to a long-chain fatty acid via a g-L-glutamyl spacer. This analogue provides basal insulin for up to 42 h after a single injection – a useful property in managing diabetic patients with cognitive impairment at home via visiting nurses who may not be able to call at the same time each day. Procaine penicillin (see **Ch. 52**) is a poorly soluble salt of **penicillin**; when injected as an aqueous suspension, it is slowly absorbed and exerts a prolonged action. Esterification of steroid hormones (e.g. medroxyprogesterone acetate, testosterone propionate; see **Ch. 35**) and antipsychotic drugs (e.g. fluphenazine decanoate; see **Ch. 47**) increases their solubility in oil and slows their absorption when they are injected in an oily solution.

Another method used to achieve slow and continuous absorption of certain steroid hormones (e.g. **oestradiol**; see **Ch. 35**) is the subcutaneous implantation of the drug substance formulated as a solid pellet. The rate of absorption is proportional to the surface area of the implant.

Intrathecal Injection

Injection of a drug into the subarachnoid space via a lumbar puncture needle is used for some specialised purposes. **Methotrexate** (see **Ch. 57**) is administered in this way in the treatment of certain childhood leukaemias to prevent relapse in the CNS. Regional anaesthesia can be produced by intrathecal administration of a local anaesthetic such as **bupivacaine** (see **Ch. 44**); opioid analgesics can also be used in this way (see **Ch. 43**). **Baclofen** (a GABA analogue; see **Ch. 38**) is used to treat disabling

muscle spasms. It has been administered intrathecally to minimise its adverse peripheral effects. Some antibiotics (e.g. aminoglycosides) cross the blood–brain barrier very slowly, and in rare clinical situations where they are essential (e.g. nervous system infections with bacteria resistant to other antibiotics) can be given intrathecally or directly into the cerebral ventricles via a reservoir. **Nusinersen**, an antisense oligonucleotide used to treat spinal muscular atrophy (see Chs **5** and **40**), is administered intrathecally and this route may become increasingly important in view of the therapeutic potential of biopharmaceuticals in neurological disorders and the access problem posed to these agents by the blood–brain barrier.

Intravitreal Injection (see Ch. 27)

Ranibizumab (monoclonal antibody fragment that binds to vascular endothelial growth factor; see **Ch. 21**) or a fusion protein, **aflibercept,** are given by intravitreal injection by ophthalmologists treating patients with wet age-related macular degeneration, macular oedema and choroidal neovascularisation. Intravitreal implants that slowly release corticosteroids (such as **fluocinolone** or **dexamethasone**) over a period of months are used in macular oedema.

Drug absorption and bioavailability

- Drugs of very low lipid solubility, including those that are strong acids or bases, are generally poorly absorbed from the gut.

- Exceptions (e.g. **levodopa**) are absorbed by carrier-mediated transfer.
- Absorption from the gut depends on many factors, including:
  - gastrointestinal motility
  - gastrointestinal pH
  - particle size
  - physicochemical interaction with gut contents (e.g. chemical interaction between calcium and tetracycline antibiotics)
  - genetic polymorphisms in drug transporters and competition for transporters.
- Bioavailability is the fraction of an ingested dose of a drug that gains access to the systemic circulation. It may be low because absorption is incomplete, or because the drug is metabolised in the gut wall or liver before reaching the systemic circulation ('pre-systemic metabolism').
- Bioequivalence implies that if one formulation of a drug is substituted for another, no clinically untoward consequences will ensue.

Distribution of Drugs in the Body

Body Fluid Compartments

Body water is distributed into four main compartments (**Fig. 9.11**). Water constitutes 50% to 70% of body weight, being rather less in women than in men.

Extracellular fluid comprises the blood plasma (about 4.5% of body weight), interstitial fluid (16%) and lymph (1.2%). Intracellular fluid (30%–40%) is the sum of the fluid contents of all cells in the body. Transcellular fluid (2.5%) includes the cerebrospinal, intraocular, peritoneal, pleural and synovial fluids and digestive secretions. The fetus may also be regarded as a special type of transcellular compartment. Within each of these aqueous compartments, drug molecules usually exist both in free solution and in bound form; furthermore, drugs that are weak acids or bases will exist as an equilibrium mixture of the charged and uncharged forms, the position of the equilibrium depending on the pH of the fluid and pK_a of the drug.

The equilibrium pattern of distribution between the various compartments will therefore depend on:

- permeability across tissue barriers
- binding within compartments
- pH partition
- fat:water partition

To enter the transcellular compartments from the extracellular compartment, a drug must cross a cellular barrier, a particularly important example being the blood–brain barrier.

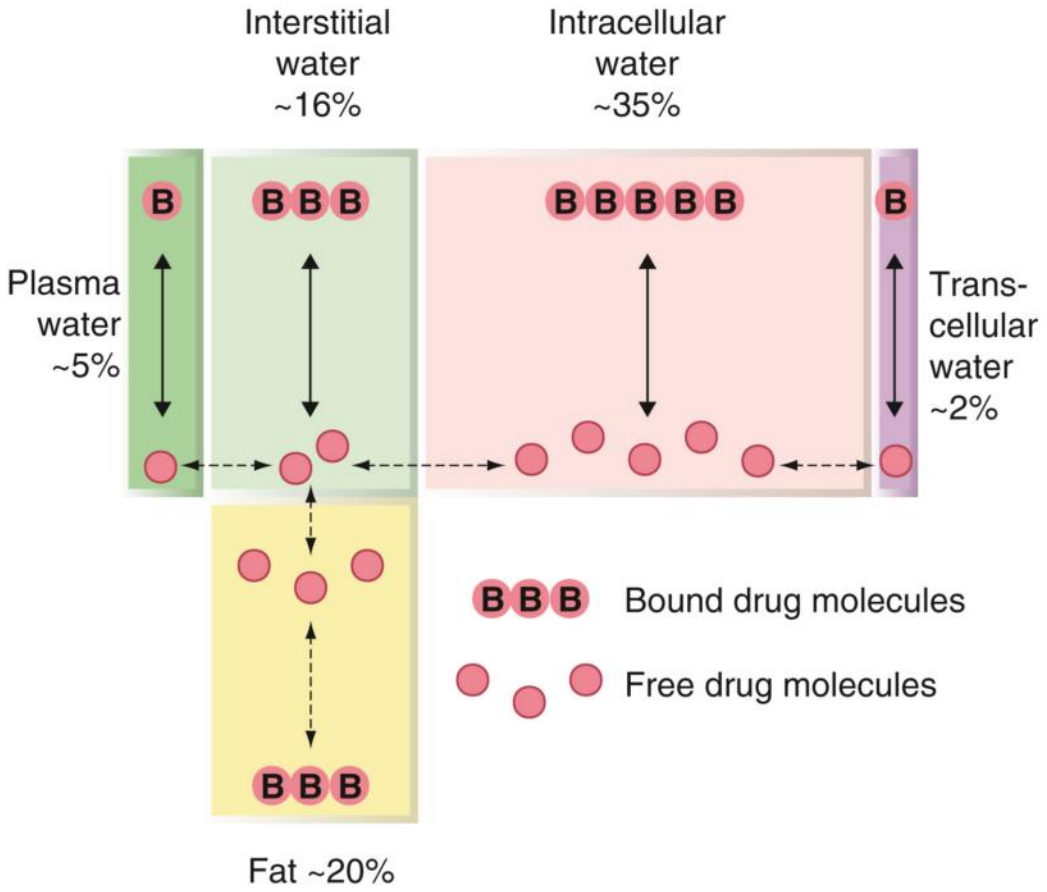

FIG. 9.11 The main body fluid compartments, expressed as a percentage of body weight.Drug molecules exist in bound or free form in each compartment, but only the free drug is able to move between the compartments.

The Blood–Brain Barrier

The concept of the blood–brain barrier was introduced by Paul Ehrlich to explain his observation that intravenously injected dye stained most tissues but not the brain. The barrier consists of a continuous layer of endothelial cells joined by tight junctions and surrounded by pericytes. Several efflux pumps extrude substrate molecules, including water-soluble drugs that penetrate into CSF.

The brain is consequently inaccessible to many drugs of low lipid solubility, and efforts have been made to improve central nervous sustem pharmacotherapy by modulating permeability proteins in the blood brain barrier (reviewed by **Miller et al 2008**). However, inflammation can disrupt the integrity of the blood–brain barrier (**Fig. 9.12**) and activity of efflux pumps; consequently, penicillin (see **Ch. 52**) can be given intravenously (rather than intrathecally) to treat bacterial meningitis, which is accompanied by intense inflammation. Loperamide, an opioid agonist used for its effect on the ileum in treating diarrhoea (see **Ch. 30**), is another drug that does cross the blood–brain barrier but is very rapidly pumped out so is in effect confined to the periphery. In some parts of the CNS, including the *chemoreceptor trigger zone*, the barrier is leaky. This enables **domperidone**, an antiemetic dopamine–receptor antagonist (see Chs **30** and **40**) that does not penetrate the blood–brain barrier but does access the chemoreceptor trigger zone, to be used to prevent the nausea caused by dopamine agonists such as **apomorphine** when these are used to treat advanced Parkinson's disease. This is achieved without loss of efficacy, because dopamine receptors in the basal ganglia are accessible only to drugs that have traversed the blood–brain barrier.

Methylnaltrexone bromide, naloxegol and **naldemedine** are peripherally acting μ-opioid–receptor antagonists which do not cross the blood–brain barrier. They are used in treating opioid-induced constipation in patients requiring opioids as part of palliative care (see **Ch. 43**). **Alvimopan** is similar and used in treating postoperative ileus. These drugs have limited

gastrointestinal absorption and do not cross the blood–brain barrier, so do not block the desired opioid effects in the CNS.

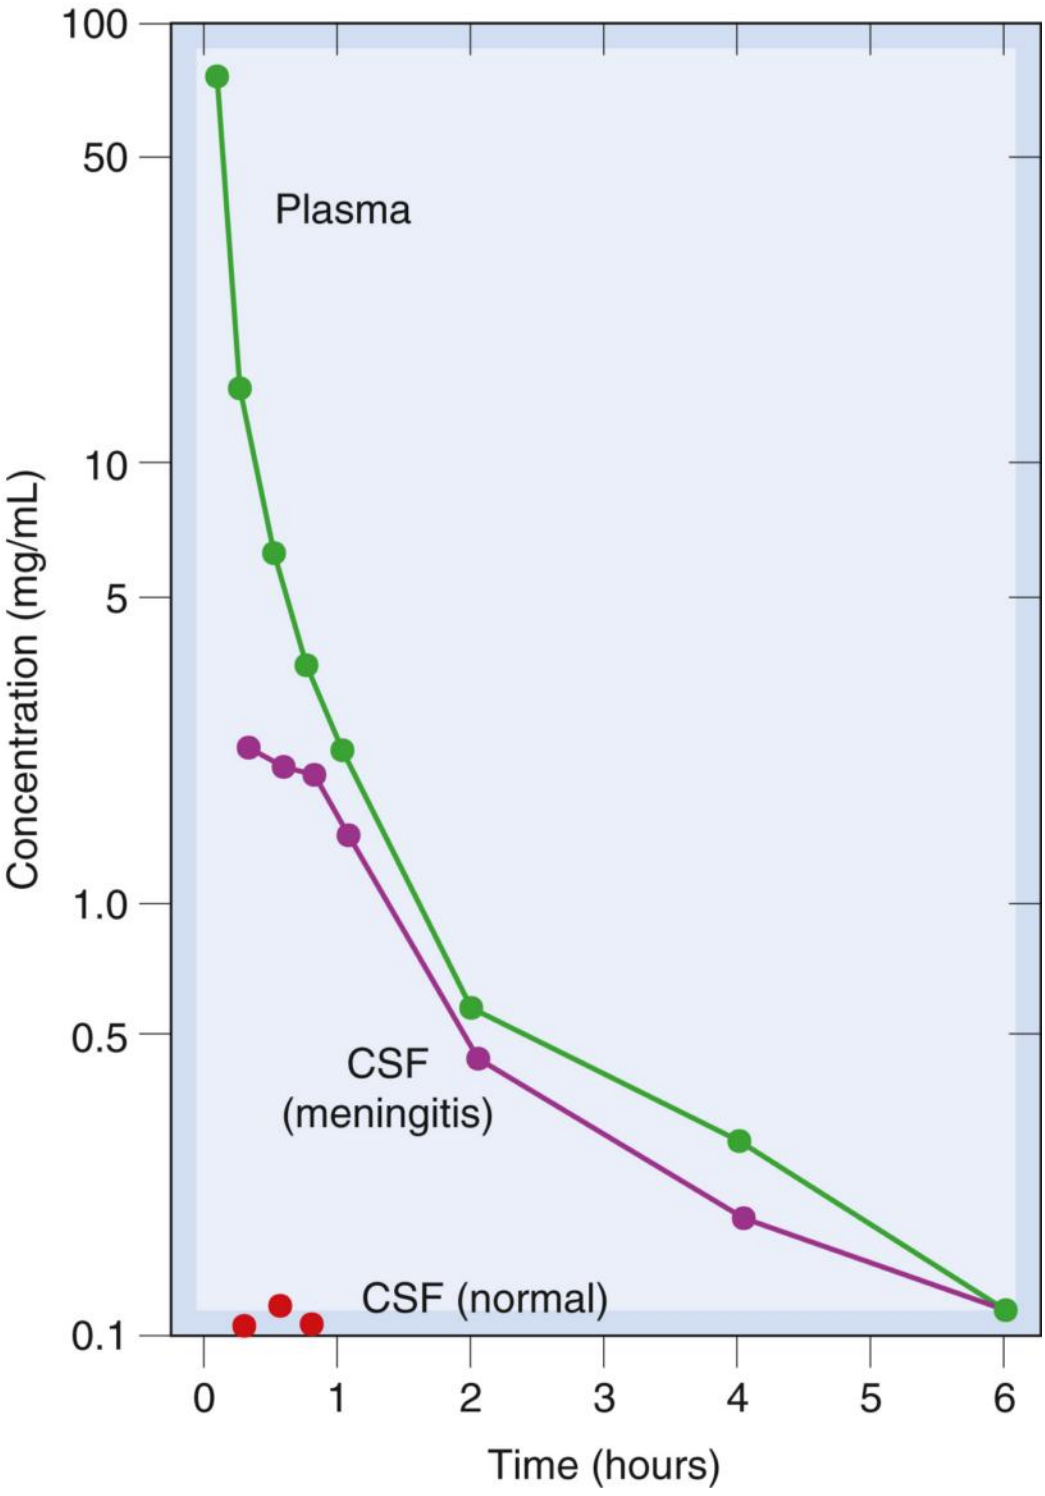

FIG. 9.12 Plasma and cerebrospinal fluid concentrations of an antibiotic (thienamycin) following an intravenous dose (25 mg/kg).In

normal rabbits, no drug reaches the cerebrospinal fluid (CSF), but in animals with experimental *Escherichia coli* meningitis the concentration of drug in CSF approaches that in the plasma. From Patamasucon, P., McCracken Jr, G.H., 1973. Antimicrob. Agents Chemother. 3, 270.

Several peptides, including bradykinin, increase blood–brain barrier permeability. There is interest in exploiting this and other possible interventions to improve penetration of anticancer drugs during treatment of brain tumours and other neurological diseases. Despite considerable ongoing effort (see e.g. **Marcucci et al., 2021**) this has not yet led to routine clinical application.

Volume of Distribution

The apparent volume of distribution, V_d (see **Ch. 11**), is defined as the volume that would contain the total body content of the drug (Q) at a concentration equal to that present in the plasma (C_p):

$$V_d = \frac{Q}{C_p}$$

It is important to avoid identifying a given range of V_d too closely with a particular anatomical compartment. Drugs may act at very low concentrations in the key compartment that provides access to their receptors. For example, insulin has a measured V_d similar to the volume of plasma water but exerts its effects on muscle, fat and

liver cells via receptors that are exposed to interstitial fluid but not to plasma (see **Ch. 31**).

Drugs Largely Confined to the Plasma Compartment

The plasma volume is about 0.05 L/kg body weight. A few drugs, such as **heparin** (see **Ch. 23**), are confined to plasma because the molecule is too large to cross the capillary wall easily. More often, retention of a drug in the plasma following a single dose reflects strong binding to plasma protein. It is, nevertheless, the free drug in the interstitial fluid that exerts a pharmacological effect. Following repeated dosing, equilibration occurs and measured V_d increases. Some dyes bind exceptionally strongly to plasma albumin, as with Evans blue, such that its V_d has been used experimentally to measure plasma volume.

Drugs Distributed in the Extracellular Compartment

The total extracellular volume is about 0.2 L/kg body weight, and this is the approximate V_d for many polar compounds, such as vecuronium (see **Ch. 14**), **gentamicin** and **carbenicillin** (see **Ch. 52**). These drugs cannot easily enter cells because of their low lipid solubility, and they do not traverse the blood–brain or placental barriers freely. Many macromolecular biopharmaceuticals, notably monoclonal antibodies (see **Ch. 5**), distribute in the extracellular space and access receptors on cell surfaces but do not readily enter cells. Nucleic acid-based biopharmaceuticals work intracellularly and are often provided with special delivery systems (see **Ch. 5**) that facilitate access to the cell interior.

Distribution Throughout the Body Water

Total body water represents about 0.55 L/kg. This approximates the distribution of many drugs that readily cross cell membranes, such as **phenytoin** (see **Ch. 46**) and **ethanol** (see **Ch. 50**). The binding of drugs outside the plasma compartment, or partitioning into body fat, increases V_d beyond the volume of total body water. Consequently, there are also many drugs with V_d greater than the total body volume, such as morphine (see **Ch. 43**), tricyclic antidepressants (see **Ch. 48**) and **haloperidol** (see **Ch. 47**). Such drugs are not efficiently removed from the body by haemodialysis, which filters blood plasma and is therefore unhelpful in managing overdose with such agents.

Drug distribution

- The major compartments are:
  - plasma (5% of body weight)
  - interstitial fluid (16%)
  - intracellular fluid (35%)
  - transcellular fluid (2%)
  - fat (20%).
- Volume of distribution (V_d) is defined as the volume of solvent that would contain the total body content of the drug (Q) at a concentration equal to the measured plasma concentration (C_p), $V_d = Q/C_p$.
- Lipid-insoluble drugs are mainly confined to plasma and interstitial fluids; most do not enter the brain following acute dosing.

- Lipid-soluble drugs reach all compartments and may accumulate in fat.
- For drugs that accumulate outside the plasma compartment (e.g. in fat or by being bound to tissues), V_d may exceed total body volume.

Drug Interactions Caused by Altered Absorption (see Ch. 12 for a General Approach to Drug–Drug Interactions)

Gastrointestinal absorption is slowed by drugs that inhibit gastric emptying, such as atropine or opiates, or accelerated by drugs that hasten gastric emptying (e.g. metoclopramide; see **Ch. 30**). Alternatively, drug A may interact physically or chemically with drug B in the gut in such a way as to inhibit absorption of B. For example, Ca^{2+} and Fe^{2+} each forms insoluble complexes with **tetracycline** that retard their absorption; **colestyramine**, a bile acid-binding resin, binds several drugs (e.g. warfarin, digoxin), preventing their absorption if administered close in time to one another. The addition of **adrenaline** (**epinephrine**) to local anaesthetic injections causes vasoconstriction which slows the absorption of the anaesthetic, thus prolonging its local effect (see **Ch. 44**). Physiologically based modelling is now beginning to be used to predict quantitatively the effects of genetic polymorphisms of drug transporters in intestine and hepatocytes and of drug–drug interactions due to competition for these transporters (see e.g. **Nosaki and Izumi, 2020**; **Yoshida et al., 2013**).

Drug Interactions Caused by Altered Distribution (see Ch. 12 for a General Approach to Drug Interactions)

Altered distribution as a consequence of altered protein binding

One drug may alter the distribution of another, by competing for a common binding site on plasma albumin or tissue protein, but such interactions are seldom clinically important unless accompanied by a separate effect on drug elimination (see Chs **10** and **12**). Displacement of a drug from binding sites in plasma or tissues transiently increases the concentration of free (unbound) drug, but this is followed by increased elimination, so a new steady state results in which total drug concentration in plasma is reduced but the free drug concentration is similar to that before introduction of the second 'displacing' drug. Consequences of potential clinical importance include:

- Harm from the transient increase in concentration of free drug before the new steady state is reached.
- If dose is being adjusted according to measurements of total plasma concentration, it must be appreciated that the target therapeutic concentration range will be altered by co-administration of a displacing drug.
- When the displacing drug additionally reduces elimination of the first, so that the free concentration is increased not only acutely but also chronically at the new steady state, severe toxicity may ensue.

Although many drugs have appreciable affinity for plasma albumin, and therefore might potentially be expected to interact in these ways, there are rather few instances of clinically important interactions of this type. Protein-bound drugs that are given in large

enough dosage to act as displacing agents include various *sulfonamides* and **chloral hydrate**; trichloroacetic acid, a metabolite of chloral hydrate, binds very strongly to plasma albumin. Displacement of bilirubin from albumin by such drugs in jaundiced premature neonates can have clinically disastrous consequences: bilirubin metabolism is undeveloped in the premature liver, and unbound bilirubin can cross the immature blood–brain barrier and cause kernicterus (staining of the basal ganglia by bilirubin). This causes a distressing and permanent disturbance of movement known as choreoathetosis, characterised by involuntary writhing and twisting movements in the child.

Phenytoin dose is adjusted according to measurement of its concentration in plasma, and such measurements do not routinely distinguish bound from free phenytoin (i.e. they reflect the total concentration of drug). Introduction of a displacing drug in an epileptic patient whose condition is stabilised on phenytoin (see **Ch. 46**) reduces the total plasma phenytoin concentration owing to increased elimination of free drug, but there is no loss of efficacy because the concentration of unbound (active) phenytoin at the new steady state is unaltered. If it is not appreciated that the therapeutic range of plasma concentrations has been reduced in this way, an increased dose may be prescribed, causing harm.

Drugs that alter protein binding sometimes additionally reduce elimination of the displaced drug, causing clinically important interactions. *Salicylates* displace **methotrexate** from binding sites on albumin and reduce its secretion into the nephron by competition with the OAT (see **Ch. 10**). **Quinidine** and several other antidysrhythmic drugs including **verapamil** and

amiodarone (see **Chs 20 and 21**) displace digoxin from tissue-binding sites while simultaneously reducing its renal excretion; they consequently can cause severe dysrhythmias through digoxin toxicity.

Altered distribution as a consequence of competition for shared transporters

Drugs may compete for shared transport mechanisms (see earlier). Carrier mediated transport by SLC and ABC mechanisms is implicated not only in drug distribution (e.g. the OAT that excludes penicillin from the CNS; and see **Ch. 12**) but also in drug absorption, excretion and access to metabolising enzymes in the liver (e.g. Figs **9.5** and **9.6** and see **Ch. 10**). There is currently a major interest in new approaches better to predict transporter-mediated drug–drug interactions such as measurement of endogenous substrates as biomarkers for transporter function (see **Muller et al., 2018**, for a review).

Special Drug Delivery Systems

Several approaches are used or in development to improve drug delivery to the target tissue. They include:

- prodrugs
- antibody–drug conjugates
- packaging in liposomes
- coated implantable devices

Prodrugs

Prodrugs are inactive precursors that are metabolised to active metabolites; they are described in **Chapter 10** and are reviewed by **Huttunen et al. 2011**. Some of the examples in clinical use confer no obvious benefits and have been found to be prodrugs only retrospectively, not having been designed with this in mind. However, some do have advantages. For example, the cytotoxic drug **cyclophosphamide** (see **Ch. 57**) becomes active only after it has been metabolised in the liver; it can therefore be taken orally in therapeutic doses without causing serious damage to the gastrointestinal epithelium. Levodopa is absorbed from the gastrointestinal tract and crosses the blood–brain barrier via an amino acid transport mechanism before conversion to active dopamine in nerve terminals in the basal ganglia (see **Ch. 40**). **Zidovudine** is phosphorylated to its active triphosphate metabolite only in cells containing the appropriate viral enzyme, hence conferring selective toxicity towards cells infected with HIV (see **Ch. 53**). **Valaciclovir** and **famciclovir** are each ester prodrugs, respectively of **aciclovir** and of **penciclovir**. Their bioavailability is greater than that of aciclovir and penciclovir, which are themselves prodrugs that are converted into active metabolites in virally infected cells (see **Ch. 53**). **Diacetyl morphine** ('heroin') is a prodrug that penetrates the blood–brain barrier even faster than its active metabolites morphine and 6-monoacetyl morphine (see **Ch. 43**), accounting for increased 'buzz' and hence abuse potential.

Delivering nucleic acid-based drugs (antisense oligonucleotides and small interfering RNA drugs) to their intracellular sites of action is a major issue with this class of biopharmaceutical (see **Ch. 5**). Conjugating these agents with *N*-acetylgalactosamine (GalNAc)

that binds to specific surface transporters permits drug delivery to hepatocytes. The asialoglycoprotein receptor (ASGR) is a lectin that is abundantly expressed on the cell surface of hepatocytes and binds terminal galactose and *N*-acetylgalactosamine (GalNAc) residues (as part of the host defence mechanism against gram-negative bacteria), leading to selective hepatocyte uptake of the conjugated drug which is converted to the oligonucleotide in the cytoplasm (**Prakash et al., 2016**).

Other problems could theoretically be overcome by using suitable prodrugs, for example, instability of drugs at gastric pH, direct gastric irritation (aspirin was synthesised in the 19th century in a deliberate attempt to produce a prodrug of salicylic acid that would be tolerable when taken by mouth), failure of a drug to cross the blood–brain barrier and so on. While the optimistic prodrug designer 'will have to bear in mind that an organism's normal reaction to a foreign substance is to burn it up for food', the successes mentioned previously in delivering nucleic acid drugs to hepatocytes are notable (see **Ch. 5**).

Antibody–Drug Conjugates

One of the aims of cancer chemotherapy is to improve the selectivity of cytotoxic drugs (see **Ch. 57**). One approach which has led to a surge of licensed agents (12 currently licensed by the FDA and counting) is to attach the drug or toxin to an antibody directed against a tumour-specific antigen, which will bind selectively to tumour cells (**Thomas et al., 2016**). **Ado-trastuzumab emtansine, brentuximab vedotin** and **gemtuzumab ozogamicin** are three examples which have now been in clinical

use for some years (see **Ch. 57**). Ado-trastuzumab emtansine is trastuzumab, a HER2-targeted antibody, covalently complexed via a linker molecule with a microtubule inhibitor, DM1. It is used, as a single agent, for the treatment of selected patients with HER2-positive, metastatic breast cancer. Trastuzumab binds to HER2 in the tumour, inhibiting HER2 receptor signalling and delivering the microtubule inhibitory drug DM1 (a maytansine derivative) to its site of action in the tumour. Randomised clinical trials demonstrated improved progression-free and overall survival compared with an active comparator group. Brentuximab vedotin is an antibody–drug conjugate used to treat selected lymphomas. It selectively targets tumour cells expressing the CD30 antigen, a defining marker of Hodgkin's disease and some other T-cell lymphomas. Likewise, gemtuzumab ozogamicin is a CD33 mAb-cytotoxic agent conjugate targeting myeloid progenitor cells for treatment of CD33-positive relapsed or refractory acute myeloid leukaemia. It has been reintroduced into the clinic after earlier safety concerns were addressed, resulting in its reappearance on the market.

Packaging in Liposomes

Liposomes are vesicles 0.1–1 μm in diameter produced by sonication of an aqueous suspension of phospholipids. They can be filled with non-lipid-soluble drugs, which are retained until the liposome is disrupted. Liposomes are taken up by reticuloendothelial cells, especially in the liver. They are also concentrated in malignant tumours, and several liposomal chemotherapeutic formulations are commercially available (see

Yingchoncharoeu et al., 2016). Amphotericin, an antifungal drug used to treat systemic mycoses (see **Ch. 54**), is available in a liposomal formulation that is less nephrotoxic and better tolerated than the conventional form, albeit considerably more expensive. A long-acting form of doxorubicin encapsulated in liposomes is available for the treatment of malignancies (including ovarian cancer and myeloma), and paclitaxel is available in an albumin nanoparticle preparation used to treat breast cancer (see **Ch. 57**). A liposomal preparation of cytarabine is available for intrathecal treatment of lymphomatous meningitis, and a liposomal formulation of vincristine is available for selected patients with acute lymphoblastic leukaemia.

Coated Implantable Devices

Impregnated coatings have been developed that permit localised drug delivery from implants. Examples include hormonal delivery to the endometrium from intrauterine devices (see **Ch. 35**) or Depo-Provera subcutaneous protection, and delivery of antithrombotic and antiproliferative agents (drugs or radiopharmaceuticals) to the coronary arteries from *stents* (expansile tubular devices inserted via a catheter after a diseased coronary artery has been dilated with a balloon – see **Ch. 21**). Stents reduce the occurrence of re-stenosis, but this can still occur at the margin of the device. Coating stents with drugs such as **sirolimus** (a potent immunosuppressant; see **Ch. 25**) embedded in a surface polymer prevents this important clinical problem.

QUESTIONS

QUESTION 9.1

The chemical properties of a drug have a significant impact on its bioavailability.

Which of the following has the most impact on the bioavailability of a small molecule drug?

OPTIONS:

A. Displacement of plasma protein binding by competing drugs

B. The partition coefficient of the drug

C. Its rate of diffusion through aqueous pores

D. The diffusion coefficient of the drug

E. The pH of the compartment

QUESTION 9.2

The route of administration of a drug has a significant impact on its bioavailability.

Which of the following is NOT a major factor of consideration when choosing the most effective route of administration of a drug?

OPTIONS:

A. The first-pass effect

B. The degree of systemic absorption

C. Patient compliance

D. The degree of plasma protein binding

E. The absorption rate of the drug from the site of administration

QUESTION 9.3

Many drugs require facilitated mechanisms to enable them to reach their desired site of action.

Which of the following statements about the facilitated transport of cisplatin is correct?

OPTIONS:

A. The facilitated uptake of cisplatin into cells requires an ATP-driven organic cation transporter (OCT).

B. Liver and kidney cells show equal sensitivity to cisplatin due to the ubiquitous expression of the OCTs.

C. Co-administration of cimetidine reduces the effects of cisplatin.

D. Single nucleotide polymorphisms in ATP-binding cassette (ABC) transporters influence cisplatin uptake into hepatocytes.

E. Cisplatin effects are prolonged by probenecid.

QUESTION 9.4

Consideration of the effects of pH partition on absorption rates is important in the safe administration of weak acid and base drugs.

Following aspirin overdose, which of the following treatment regimens would be most suitable?

OPTIONS:

A. Metoclopramide and bicarbonate

B. Propantheline and bicarbonate

C. Metoclopramide and acetazolamide

D. Propantheline and acetazolamide

E. Bicarbonate and acetazolamide

ANsWERS

ANSWER 9.1

RATIONALE:

A. Few therapeutic drugs affect the binding of other drugs because they occupy, at therapeutic plasma concentrations, only a tiny fraction of the available sites and so plasma protein binding is not saturated and has the capacity to bind a large proportion of the circulating drug.

B.

C. Diffusion through aqueous pores (aquaporins) is probably important in the transfer of gases such as carbon dioxide, but the pores are too small in diameter (about 0.4 nm) to allow most drug molecules (which usually exceed 1 nm in diameter) to pass through.

D. Diffusion coefficient – The rate of diffusion of a substance depends mainly on its molecular size, the diffusion coefficient being inversely proportional to the square root of molecular weight. Consequently, while large molecules diffuse more slowly than small ones, the variation with molecular weight is modest.

E. pH differences between body compartments can alter the steady-state distribution of drugs that are weak acids or weak bases via its influence on their ionisation as this reduces lipid solubility. However, although theoretically this could have a large impact on distribution, some permeability of ionised forms and the failure to reach equilibrium lessen the impact.

CORRECT ANSWER WITH EXPLANATION:

B. The partition coefficient of the drug

The most important determinant of membrane permeability for conventional low-molecular-weight drugs is the partition coefficient.

ANSWER 9.2

RATIONALE:

A. Many drugs given orally undergo a high level of metabolism in the liver or gut wall prior to reaching systemic circulation which may reduce the bioavailability.

B. Many drugs are only required to reach a localised target and therefore systemic absorption would not be desired as could lead to greater side effects.

C. Oral drugs are often preferred although achievement of an effective therapeutic dose is of greater importance.

D.

E. The absorption rate of the drug is affected by the properties of the drug and physiology/pathology at the site of administration.

CORRECT ANSWER WITH EXPLANATION:

D. Plasma protein binding

A high level of binding of drugs to plasma proteins occurs irrespective of the initial route of administration.

ANSWER 9.3

RATIONALE:

A. Cation transporters do not require an energy source.

B. Liver and kidney cells express different isoforms of the OCT and are therefore differentially affected by cisplatin.

C.

D. Cisplatin uptake is mediated by OCT not ABC transporters.

E. Probenecid is transported by organic anion transporters (OATs) and therefore does not affect cisplatin uptake.

CORRECT ANSWER WITH EXPLANATION:

C. Co-administration of cimetidine reduces the effects of cisplatin.

Cimetidine competes with cisplatin for OCT2 and protects against/reduces cisplatin-mediated apoptosis.

ANSWER 9.4

RATIONALE:

A. Metoclopramide accelerates gastric emptying and promotes aspirin absorption.

B.

C. Metoclopramide accelerates gastric emptying and promotes aspirin absorption whilst acetazolamide alkalinises the urine but increases salicylate distribution to the central nervous system (CNS).

D. Propantheline slows gastric emptying and aspirin absorption and acetazolamide alkalinises the urine but increases salicylate distribution to the CNS.

E. Both increase excretion through alkalinisation of the urine but have no effect on gastric absorption.

CORRECT ANSWER WITH EXPLANATION:

B. Propantheline and bicarbonate

Propantheline slows gastric emptying and aspirin absorption and bicarbonate alkalises the urine to increase aspirin excretion whilst decreasing distribution to the CNS.

[1] This accounts for some strain and species differences. For example, Collie dogs lack the multidrug resistance gene (*MDR1*), that encodes a P-gp which extrudes toxins from the cerebrospinal fluid across the blood–brain barrier. This has consequences for veterinary medicine because **ivermectin** (an anthelminthic drug; see Ch. 56) is severely neurotoxic in the many breeds with Collie ancestry.

[2] Also known as sodium pentothal or 'truth serum'. This barbiturate, at sub-narcosis doses, can reduce an individual's resolve and make them more compliant to suggestions – at least in the movies.

10: Drug metabolism and elimination

OVERVIEW

We describe phases 1 and 2 of drug metabolism, emphasising the importance of the cytochrome P450 monooxygenase system. We then cover the processes of biliary excretion and enterohepatic recirculation of drugs and of drug–drug interactions caused by induction or inhibition of metabolism. Drug and drug metabolite elimination by the kidney and drug–drug interactions due to effects on renal elimination are then considered.

INTRODUCTION

Drug elimination is the irreversible loss of drug from the body. It occurs by two processes: *metabolism* and *excretion*. Metabolism consists of anabolism and catabolism, that is, respectively, the build-up and breakdown of substances by enzymic conversion of one chemical entity to another within the body, whereas excretion consists of elimination from the body of drug or drug metabolites. The main excretory routes are:

- the kidneys
- the hepatobiliary system

- the lungs (important for volatile/gaseous anaesthetics)

Most drugs leave the body in the urine, either unchanged or as polar metabolites. Some drugs are secreted into bile via the liver, but most of these are then reabsorbed from the intestine. There are, however, instances (e.g. **rifampicin**; see **Ch. 52**) where faecal loss accounts for the elimination of a substantial fraction of unchanged drug in healthy individuals, and faecal elimination of drugs such as **digoxin** that are normally excreted in urine (see **Ch. 20**) becomes progressively more important in patients with advancing renal impairment. Excretion via the lungs occurs only with highly volatile or gaseous agents (e.g. general anaesthetics; see **Ch. 41**). Small amounts of some drugs are also excreted in secretions such as milk or sweat. Elimination by these routes is quantitatively negligible compared with renal excretion, although excretion into milk can sometimes be important because of effects on the baby (**www.fpnotebook.com/ob/Pharm/MdctnsInLctn.htm**, Accessed 25 October 2021).

Lipophilic substances are not eliminated efficiently by the kidney (see later). Consequently, most lipophilic drugs are metabolised to more polar products, which are then excreted in urine. Drugs are metabolised predominantly in the liver, especially by the cytochrome P450 (CYP) system. Some P450 enzymes are extrahepatic and play an important part in the biosynthesis of steroid hormones (see **Ch. 33**) and eicosanoids (see **Ch. 17**), but here we are concerned with catabolism of drugs by the hepatic P450 system.

DRUG METABOLISM

Animals have evolved complex systems that detoxify foreign chemicals ('xenobiotics'), including carcinogens and toxins present in poisonous plants. Drugs are a special case of such xenobiotics and, like plant alkaloids, they often exhibit *chirality* (i.e. there is more than one stereoisomer), which affects their overall metabolism. Drug metabolism involves two kinds of reaction, known as phase 1 and phase 2, which often occur sequentially. Both phases decrease lipid solubility, thus increasing renal elimination.

PHASE 1 REACTIONS

Phase 1 reactions (e.g. oxidation, reduction or hydrolysis) are catabolic, and the products are often more chemically reactive and hence, paradoxically, sometimes more toxic or carcinogenic than the parent drug. Phase 1 reactions often introduce a reactive group, such as hydroxyl, into the molecule, a process known as 'functionalisation'. This group then serves as the point of attack for the conjugating system to attach a substituent such as glucuronide (**Fig. 10.1**), explaining why phase 1 reactions often precede phase 2 reactions. The liver is especially important in phase 1 reactions. Many hepatic drug-metabolising enzymes, including CYP enzymes, are embedded in the smooth endoplasmic reticulum. They are often called 'microsomal' enzymes because, on homogenisation and differential centrifugation, the endoplasmic reticulum is broken into very small fragments that sediment only after prolonged high-speed centrifugation in the microsomal fraction. To reach these metabolising enzymes in life, a drug must cross the plasma membrane. Polar molecules do this less readily than non-polar molecules except where there are specific transport mechanisms

(see **Ch. 9**), so intracellular metabolism is important for lipid-soluble drugs, while polar drugs are, at least partly, excreted unchanged in the urine.

THE P450 MONOOXYGENASE SYSTEM

Nature, classification and mechanism of P450 enzymes

Cytochrome P450 enzymes are the most versatile protective biocatalysts in nature, catalysing a vast array of reactions. They are haem proteins, comprising a large family ('superfamily') of related but distinct enzymes, each referred to as CYP followed by a defining set of numbers and a letter. P450 enzymes (reviewed by **Guengerich, 2019**, and **Nair et al., 2016**) differ from one another in amino acid sequence, in sensitivity to inhibitors and inducing agents (see later) and in the specificity of the reactions that they catalyse. Different members of the family have distinct, but often overlapping, substrate specificities. Purification and cloning of P450 enzymes form the basis of the current classification, which is based on amino acid sequence similarities. Not all 57 human CYPs are involved in drug metabolism, but it has been estimated that CYP enzymes in families 1–3 mediate 70%–80% of all phase 1-dependent metabolism of clinically used small-molecule drugs (**Ingelman-Sundberg, 2004**). Twelve CYPs accounted for 93.0% of drug metabolism of 1839 known drug-metabolising reactions in a large international database (**Preissner et al., 2013**). CYPs 1A2, 3A4, 2D6, 2C9 and 2C19 were responsible for approximately 60% of drug metabolism. Examples of therapeutic drugs that are substrates for some important P450 isoenzymes are shown in **Table 10.1**, and a useful table of drug substrates,

inhibitors and inducers of CYP subtypes is provided by Indiana University (Cytochrome P450 Drug Interaction Table – Drug Interactions (**iu.edu**): **https://drug-interactions.medicine.iu.edu/MainTable.aspx**, accessed 03 January 2023).

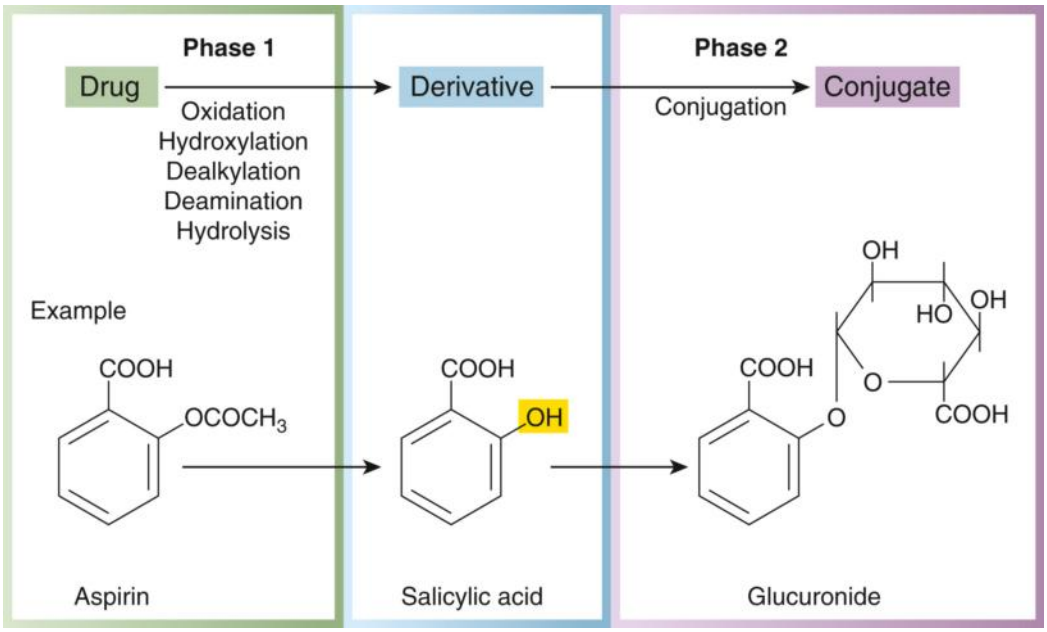

FIG. 10.1 The two phases of drug metabolism.In the example, *aspirin* reacts with water (H_2O) – a hydrolysis reaction – to form *salicylic acid* + acetic acid (CH_3COOH), and *glucuronide* is then transferred to salicylic acid by uridine diphosphate (UDP)-glucuronyl transferase to form the glucuronide product (details of the reactions not shown).

Drug oxidation by the monooxygenase P450 system requires drug (substrate, 'DH'), P450 enzyme, molecular oxygen, nicotinamide adenine dinucleotide phosphate (NADPH) and NADPH–P450

reductase (a flavoprotein). The mechanism involves a complex cycle (**Fig. 10.2**), but the outcome of the reaction is quite simple, namely the addition of one atom of oxygen (from molecular oxygen) to the drug to form a hydroxylated product (DOH), the other atom of oxygen being converted to water. (Hydroxylation is a chemical process that introduces a hydroxyl group into an organic molecule, whereas hydrolysis involves a reaction with a water molecule – see later.)

P450 enzymes have unique spectral properties, and the reduced forms combine with carbon monoxide to form a pink compound (hence 'P') with absorption peaks near 450 nm (range 447–452 nm). The first clue that there is more than one form of CYP came from the observation that treatment of rats with 3-methylcholanthrene (3-MC), an inducing agent (see later), causes a shift in the absorption maximum from 450 to 448 nm – the 3-MC-induced isoform of the enzyme absorbs light maximally at a slightly shorter wavelength than the un-induced enzyme.

P450 and biological variation

There are important variations in the expression and regulation of P450 enzymes between species. For instance, the pathways by which certain dietary heterocyclic amines (formed when meat is cooked) generate genotoxic products involves one member of the P450 superfamily (CYP1A2) that is constitutively present in humans and rats (which develop colon tumours after treatment with such amines) but not in cynomolgus monkeys (which do not). Such species differences have crucial implications for the choice of

species to be used for toxicity and carcinogenicity testing during the development of new drugs for use in humans.

Within human populations, there are major sources of inter-individual variation in P450 enzymes that are of great importance in therapeutics. These include genetic polymorphisms (alternative sequences at a locus within the DNA strand – alleles – that persist in a population through several generations; see **Ch. 12**). Environmental factors are also important, since enzyme inhibitors and inducers are present in the diet and environment. For example, a component of grapefruit juice inhibits drug metabolism (leading to potentially disastrous consequences, including cardiac dysrhythmias), whereas Brussels sprouts and cigarette smoke induce P450 enzymes. Components of the herbal medicine St John's wort (see **Ch. 48**) induce CYP450 isoenzymes as well as P-glycoprotein (P-gp; see **Ch. 9**). Drug interactions based on one drug altering the metabolism of another are common and clinically important (see **Ch. 12**). Predicting such potential interactions as an aid to personalising treatment (see **Ch. 12**) depends on the subject's phenotype at the time of treatment. Investigating this directly is difficult and expensive, so the simpler approach of genotyping has been advocated, but the correlation between genotype and phenotype is often poor (reviewed by **Waring, 2020**).

Not all drug oxidation reactions involve the hepatic P450 system. Some drugs are metabolised in plasma (e.g. hydrolysis of **suxamethonium** by plasma cholinesterase; see **Ch. 14**), lung (e.g. various prostanoids; see **Ch. 17**) or gut (e.g. **tyramine**, **salbutamol**; see Chs **15** and **28**). **Ethanol** (see **Ch. 50**) is

metabolised by a soluble cytoplasmic enzyme, alcohol dehydrogenase, in addition to CYP2E1. Other P450-independent enzymes involved in drug oxidation include xanthine oxidase, which inactivates **6-mercaptopurine** (see **Ch. 57**), and monoamine oxidase, which inactivates many biologically active amines (e.g. **noradrenaline**, tyramine, 5-hydroxytryptamine; see Chs **15** and **16**).

Table 10.1

Examples of drugs that are substrates of P450 isoenzymes

Isoenzyme P450	Drug(s)
CYP1A2	Caffeine, paracetamol (→NAPQI), tacrine, theophylline
CYP2B6	Cyclophosphamide, methadone
CYP2C8	Paclitaxel, repaglinide
CYP2C19	Omeprazole, phenytoin
CYP2C9	Ibuprofen, tolbutamide, warfarin
CYP2D6	Codeine, debrisoquine, S-metoprolol
CYP2E1	Alcohol, paracetamol
CYP3A4, 5, 7	Ciclosporin, nifedipine, indinavir, simvastatin

NAPQI, N-acetyl-*p*-amino-benzoquinone imine – the metabolite responsible for paracetamol toxicity in overdose.

Adapted from the Department of Medicine, Indiana University. Drug interactions: Flockhart table. **https://drug-interactions.medicine.iu.edu/MainTable.aspx**. Accessed 03 January 2023.

HYDROLYTIC REACTIONS

Hydrolysis, which is a chemical reaction in which water participates as nucleophile, breaking a chemical bond (e.g. hydrolysis of **aspirin**; see **Fig. 10.1**), occurs in plasma and in many tissues. Both ester and (less readily) amide bonds are susceptible to hydrolytic cleavage.

Reduction

Reduction is much less common in phase 1 metabolism than oxidation; keto- groups in **warfarin** (see **Ch. 23**) are, however, reduced to hydroxyl groups by CYP2A6, yielding inactive alcohols, in addition to oxidation by CYP2C9 with the production of inactive hydroxylated metabolites (the main route of its inactivation).

PHASE 2 REACTIONS

Phase 2 reactions are synthetic ('anabolic') and involve conjugation (i.e. attachment of a substituent group), which usually results in inactive products, although there are exceptions (e.g. the active sulphate metabolite of **minoxidil**, a potassium channel activator used to treat severe hypertension (see **Ch. 21**) and (as a cream) to promote hair growth (see **Ch. 26**)). Phase 2 reactions take place mainly in the liver. If a drug molecule or phase 1 product has a suitably reactive 'handle' (e.g. a hydroxyl, thiol or amino group), it is susceptible to conjugation. The chemical group inserted may be glucuronyl (**Fig. 10.3**), sulphate, methyl or acetyl. The tripeptide glutathione conjugates drugs or their phase 1 metabolites via its sulfhydryl group, as in the detoxification of **paracetamol** (see **Fig. 58.1**). Glucuronidation involves the formation of a high-energy phosphate ('donor') compound, uridine diphosphate glucuronic acid (UDPGA), from which glucuronic acid is transferred to an electron-

rich atom (N, O or S) on the substrate, forming an amide, ester or thiol bond. Uridine diphosphate (UDP)–glucuronyl transferase, which catalyses these reactions, has very broad substrate specificity embracing many drugs and other foreign molecules. Several important endogenous substances, including bilirubin and adrenal corticosteroids, are conjugated by the same pathway.

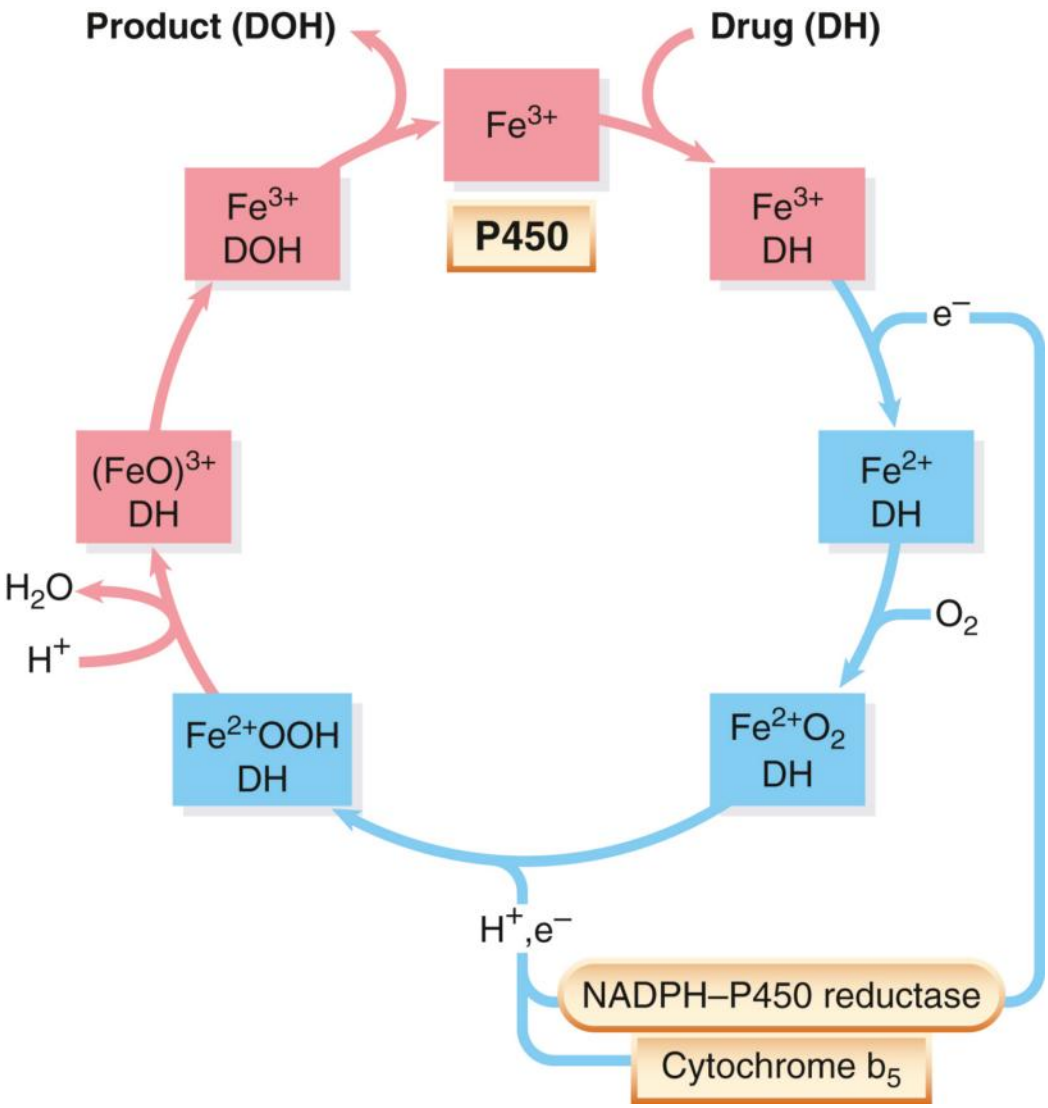

FIG. 10.2 The monooxygenase P450 cycle.Each of the *pink* or *blue* rectangles represents one single molecule of cytochrome P450 (P450) undergoing a catalytic cycle. Iron in P450 is in either the ferric *(pink rectangles)* or ferrous *(blue rectangles)* state. P450 containing ferric iron (Fe^{3+}) combines with a molecule of drug (DH) and receives an electron from NADPH–P450 reductase, which reduces the iron to Fe^{2+}. This combines with molecular oxygen, a

proton and a second electron (either from NADPH–P450 reductase or from cytochrome b_5) to form an $Fe^{2+}OOH$–DH complex. This combines with another proton to yield water and a ferric oxene $(FeO)^{3+}$–DH complex. $(FeO)^{3+}$ extracts a hydrogen atom from DH, with the formation of a pair of short-lived free radicals (see text), liberation from the complex of oxidised drug *(DOH)*, and regeneration of P450 enzyme. *NADPH*, Nicotinamide adenine dinucleotide phosphate.

Acetylation and methylation reactions occur with acetyl–coenzyme A (CoA) and S-adenosyl methionine, respectively, acting as the donor groups. Many conjugation reactions occur in the liver, but other tissues, such as lung and kidney, are also involved.

STEREOSELECTIVITY

Many clinically important drugs, such as **sotalol** (see **Ch. 20**), **warfarin** (see **Ch. 23**) and **cyclophosphamide** (see **Ch. 57**), are mixtures of stereoisomers, the components of which differ not only in their pharmacological effects but also in their metabolism, which may follow completely distinct pathways (**Campo et al., 2009**). Several clinically important drug interactions involve stereospecific inhibition of metabolism of one drug by another. In some cases, drug toxicity is mainly linked to one of the stereoisomers, not necessarily the pharmacologically active one. Where practicable, regulatory authorities urge that new drugs should consist of single isomers to lessen these complications. [1]

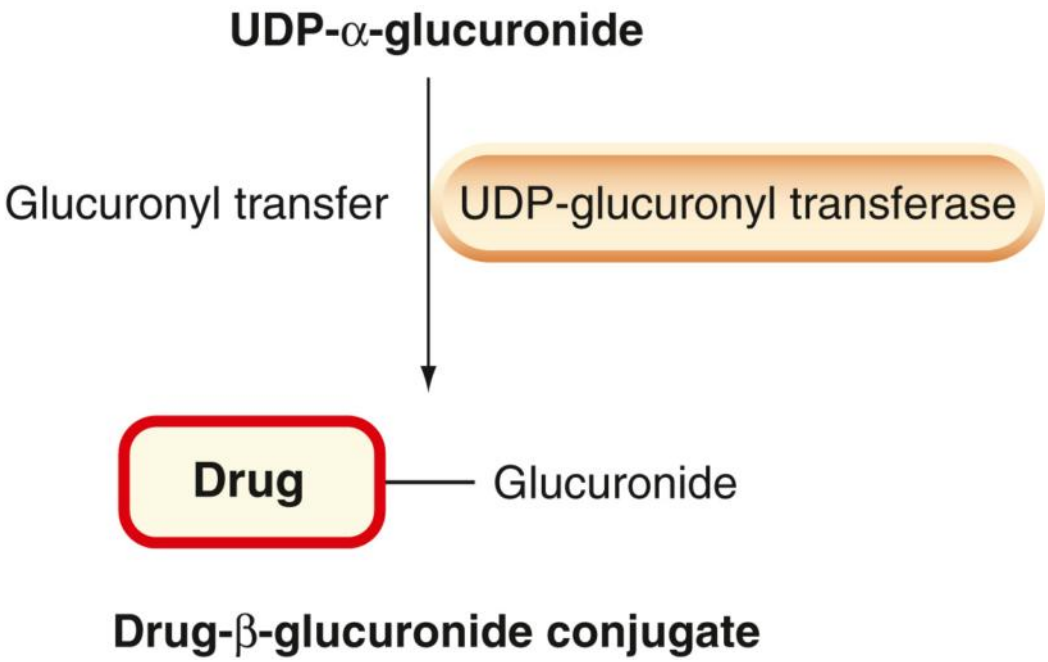

FIG. 10.3 The glucuronide conjugation reaction.A glucuronyl group is transferred from uridine diphosphate glucuronic acid to a drug molecule. *UDP*, Uridine diphosphate.

INHIBITION OF P450

Inhibitors of P450 differ in their selectivity towards different isoforms of the enzyme, and are classified by their mechanism of action. Some drugs compete for the active site but are not themselves substrates (e.g. **quinidine** is a potent competitive inhibitor of CYP2D6 but is not a substrate for it). Non-competitive inhibitors include drugs such as **ketoconazole**, which forms a tight complex with the Fe^{3+} form of the haem iron of CYP3A4, causing reversible non-competitive inhibition. So-called mechanism-based inhibitors require oxidation by a P450 enzyme. Examples include the oral contraceptive **gestodene** (CYP3A4) and

the anthelmintic drug **diethylcarbamazine** (CYP2E1). An oxidation product (e.g. a postulated epoxide intermediate of gestodene) binds covalently to the enzyme, which then destroys itself ('suicide inhibition'; see **Hakkola et al., 2020**).

INDUCTION OF MICROSOMAL ENZYMES

A number of drugs, such as **rifampicin** (see **Ch. 52**), **ethanol** (see **Ch. 50**) and **carbamazepine** (see **Ch. 46**), increase the activity of microsomal oxidase and conjugating systems, especially when administered repeatedly. Many carcinogenic chemicals, e.g. benzpyrene and 3-MC, also have this effect, which can be substantial; **Fig. 10.4** shows a nearly 10-fold increase in the rate of benzpyrene metabolism 2 days after a single dose. The effect is referred to as *induction* and is the result of increased synthesis and/or reduced breakdown of microsomal drug metabolising enzymes, notably CYP enzymes and UDP-glucuronyl transferase (**Hakkola et al., 2020**).

Enzyme induction can increase drug toxicity and carcinogenicity because several phase 1 metabolites are toxic or carcinogenic: paracetamol is an important example of a drug with a highly toxic CYP-metabolite *N*-acetyl-*p*-amino-benzoquinone imine (NAPQI; see **Ch. 58**, **Fig. 58.1**).

Enzyme induction is exploited therapeutically by administering **phenobarbital** to premature babies to induce glucuronyl transferase, thereby increasing bilirubin conjugation and reducing the risk of *kernicterus* (staining and neurological damage of the basal ganglia by bilirubin; see **Ch. 9**).

The first inducing agents to be studied were polycyclic aromatic hydrocarbons (e.g. 3-MC). These bind to the ligand-binding domain of a soluble cytoplasmic protein, termed the *aryl hydrocarbon receptor (AHR)*. Formation of this complex results in dissociation of chaperone molecules and transport of the activated receptor to the nucleus by an AHR nuclear translocator. In the nucleus it binds to response elements in the DNA, thereby promoting transcription of genes including *CYP1A1*. In addition to aryl hydrocarbons, AHR is also activated or inhibited by several endogenous indoles including kynurenine, and regulating CYP enzymes influences immunity, stem cell maintenance and cell differentiation. Activation of the AHR leads to down-regulation of proinflammatory cytokines, including interleukin-17 (IL-17), and influences skin barrier function. Consequently, AHR is a potential target for therapeutic drugs, and the FDA recently approved one agent (**tapinarof**) that binds and activates AHR as a topical therapy for plaque psoriasis (see **Ch. 26**).

In addition to enhanced transcription, some inducing agents (e.g. ethanol, which induces CYP2E1 in humans) also work by stabilising mRNA or P450 protein.

Recently, the constitutive androstane receptor (CAR) and pregnane X receptor (PXR) have been recognised as more important than AHR in the context of clinically important drug–drug interactions in humans. Like the AHR, these function as ligand activated transcription factors and have large flexible ligand-binding pockets, conferring promiscuity with regards to ligand binding. After transfer to the nucleus, they form heterodimers with the retinoid X receptor (RXR), bind DNA and act as transcription factors,

increasing transcription of mRNA coding for CYP3A4 and many other proteins important in drug metabolism (reviewed by **Hakkola et al., 2020**).

PRESYSTEMIC ('FIRST-PASS') METABOLISM

Following oral administration, some drugs are extracted so efficiently by the liver or gut wall that the amount reaching the systemic circulation is considerably less than the amount absorbed. This is known as presystemic (or 'first-pass') metabolism and reduces bioavailability (see **Ch. 9**), even when a drug is well absorbed. Presystemic metabolism is important for many therapeutic drugs (**Table 10.2** shows some examples), and is a problem because:

- A much larger dose of the drug is needed when it is taken by mouth than when it is given parenterally.
- Marked individual variations occur in the extent of first-pass metabolism, both in the activities of drug-metabolising enzymes and also as a result of variations in hepatic or intestinal blood flow. Hepatic blood flow can be reduced in disease (e.g. heart failure) or by drugs, such as β-adrenoceptor antagonists, which impair the clearance of chemically unrelated drugs, such as lidocaine, that are subject to presystemic metabolism due to a high hepatic extraction ratio. Intestinal blood flow is strongly influenced by eating and by the composition of the meal – especially by its fat content – and studies on the pharmacokinetic effects of food are routine in the development of orally administered drugs.

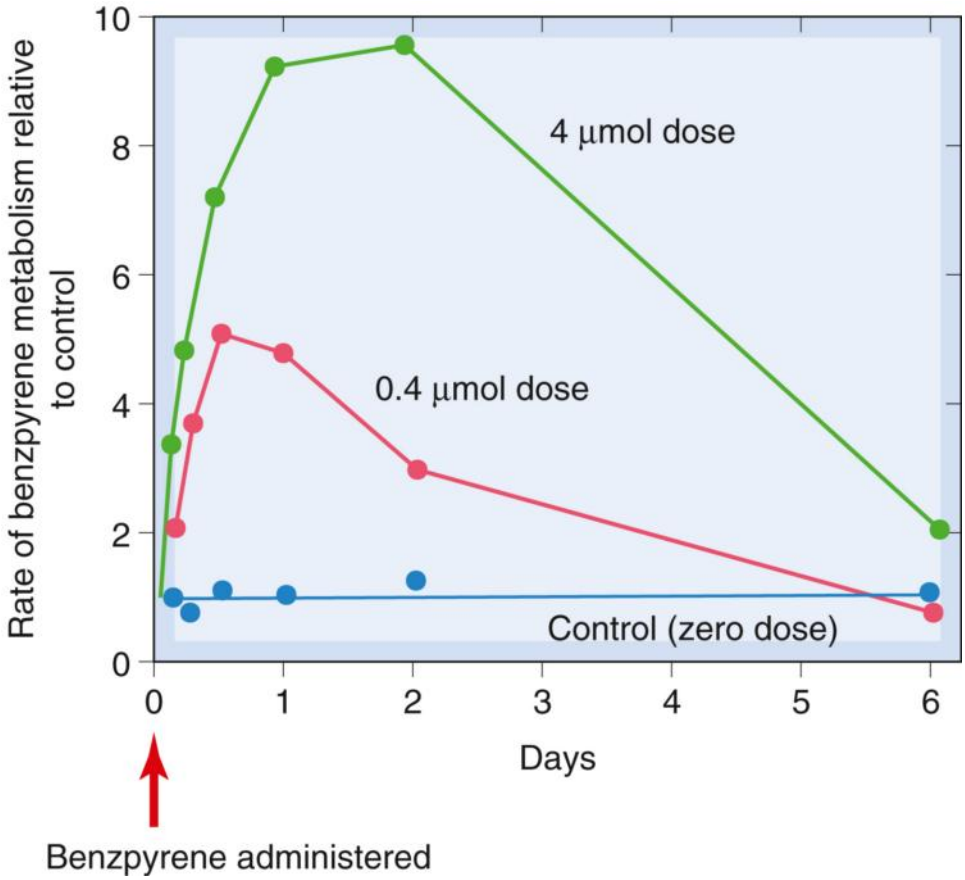

FIG. 10.4 Induction of hepatic metabolism of benzpyrene by substrate.Young rats were given benzpyrene (intraperitoneally) in the doses shown, and the benzpyrene-metabolising activity of liver homogenates was measured at times up to 6 days. From Conney, A.H., et al., 1957. J. Biol. Chem. 228, 753.

Table 10.2

Examples of drugs that undergo substantial pre-systemic ('first-pass') elimination

Aspirin	**Metoprolol**
Glyceryl trinitrate	Morphine
Isosorbide dinitrate	Propranolol
Levodopa	Salbutamol
Lidocaine	Verapamil

PHARMACOLOGICALLY ACTIVE DRUG METABOLITES

In some cases (**Table 10.3**), a drug becomes pharmacologically active only after it has been metabolised. For example, **azathioprine**, an immunosuppressant drug (see **Ch. 25**), is metabolised to **mercaptopurine**; and **enalapril**, an angiotensin-converting enzyme inhibitor (see **Ch. 21**), is hydrolysed to its active form **enalaprilat**. Such drugs, in which the parent compound lacks activity of its own, are known as *prodrugs*. These are sometimes designed deliberately to overcome problems of drug delivery (see **Ch. 9**). Metabolism can alter the pharmacological actions of a drug qualitatively. **Aspirin** inhibits platelet function and has anti-inflammatory activity (see Chs **23** and **25**). It is hydrolysed to salicylic acid (see **Fig. 10.1**), which has anti-inflammatory but not antiplatelet activity. In other instances, metabolites have pharmacological actions similar to those of the parent compound

(e.g. benzodiazepines, many of which form long-lived active metabolites that cause sedation to persist after the parent drug has disappeared; see **Ch. 45**). There are also cases in which metabolites are responsible for toxicity. Bladder toxicity of **cyclophosphamide**, which is caused by its toxic metabolite acrolein (see **Ch. 57**), is an example. Methanol and ethylene glycol both exert their toxic effects via metabolites formed by alcohol dehydrogenase. Poisoning with these agents is treated with ethanol (or with a more potent inhibitor), which competes for the active site of the enzyme.

Drug metabolism

- Phase 1 reactions involve oxidation, reduction and hydrolysis. They:
  - often form more chemically reactive products, which can be pharmacologically active, toxic or carcinogenic.
  - often involve a monooxygenase system in which cytochrome P450 (CYP) enzymes play a key role.
- Phase 2 reactions involve conjugation (e.g. glucuronidation) of a reactive group (often inserted during phase 1 reaction) and usually lead to inactive and polar products that are readily excreted in urine.
- Some conjugated products are excreted via bile and may be excreted in the faeces or may be reactivated in the intestine and reabsorbed ('enterohepatic circulation').
- Induction of P450 enzymes can greatly accelerate hepatic drug metabolism. It can increase the toxicity of drugs with toxic

metabolites and is an important cause of drug–drug interaction, as is enzyme inhibition.

- Presystemic metabolism in liver or gut wall reduces the bioavailability of several drugs when they are administered by mouth.

DRUG INTERACTIONS DUE TO ENZYME INDUCTION OR INHIBITION

INTERACTIONS CAUSED BY ENZYME INDUCTION

Enzyme induction is an important cause of drug interaction. The slow onset of induction and slow recovery after withdrawal of the inducing agent, together with the potential for selective induction of one or more CYP isoenzymes, contribute to the insidious nature of the clinical problems that induction presents. Adverse clinical outcomes from such interactions are very diverse, including graft rejection as a result of loss of effectiveness of immunosuppressive treatment, seizures due to loss of anticonvulsant effectiveness, unwanted pregnancy from loss of oral contraceptive action and thrombosis (from loss of effectiveness of warfarin) or bleeding (from failure to recognise the need to reduce warfarin dose when induction wanes after an inducing agent is discontinued). Over 200 drugs cause enzyme induction and thereby decrease the pharmacological activity of a range of other drugs. Some examples are given in **Table 10.4**, and further examples are given at the Indiana University website cited earlier. Because the inducing agent is often itself a substrate for the induced enzymes, the process can result in slowly developing tolerance. This pharmacokinetic kind of

tolerance is generally less marked than pharmacodynamic tolerance, for example, to opioids (see **Ch. 43**), but it is clinically important when starting treatment with the antiepileptic drug **carbamazepine** (see **Ch. 46**). Treatment starts at a low dose to avoid toxicity (because liver enzymes are not induced initially) and is gradually increased over a period of a few weeks, during which it induces its own metabolism.

Table 10.3

Some drugs that produce active or toxic metabolites

Inactive (prodrugs)	Active drug	Active metabolite	Toxic metabolite	See Chapter
Azathioprine →		Mercaptopurine		25
Cortisone →		Hydrocortisone		33
Prednisone →		Prednisolone		33
Enalapril →		Enalaprilat		21
Zidovudine →		Zidovudine trisphosphate		53
Cyclophosphamide →		Phosphoramide mustard →	Acrolein	57
	Diazepam ⇢	Oxazepam		45
	Morphine →	Morphine 6-glucuronide		43
	Halothane →		Trifluoroacetic acid	41
	Methoxyflurane →		Fluoride	41
	Paracetamol →		*N*-acetyl-*p*-amino-benzoquinone imine	25, 58

Table 10.4

Examples of drugs that induce drug-metabolising enzymes

Drugs inducing enzyme action	Examples of drugs with metabolism affected
Phenobarbital	Warfarin
Rifampicin	Oral contraceptives
Griseofulvin	Corticosteroids
Phenytoin	Ciclosporin
Ethanol	Paracetamol (increased toxicity)
Carbamazepine	Oral contraceptives, corticosteroids

Fig. 10.5 shows how the antibiotic **rifampicin**, given for 3 days, reduces the effectiveness of **warfarin** as an anticoagulant. Conversely, enzyme induction can increase the toxicity of a second drug if the toxic effects are mediated via an active metabolite. **Paracetamol** (**acetaminophen**) toxicity is a case in point (see **Fig. 58.1**): this is caused by its CYP metabolite *N*-acetyl-*p*-amino-benzoquinone imine (NAPQI). Consequently, the risk of serious hepatic injury following paracetamol overdose is increased in patients in whom CYP has been induced, for example, by chronic alcohol consumption.

INTERACTIONS CAUSED BY ENZYME INHIBITION

As with induction, interactions caused by enzyme inhibition are hard to anticipate from first principles. If in doubt about the

possibility of an interaction, it is best to look it up (e.g. in the *British National Formulary*, which has an invaluable appendix on drug interactions indicating which are of known clinical importance).

Enzyme inhibition, particularly of CYP enzymes, slows the metabolism and hence increases the action of other drugs inactivated by the enzyme. Such effects can be clinically important and are major considerations in the treatment of patients with HIV infection with combination therapy because several protease inhibitors are potent CYP inhibitors (see **Ch. 53**). Other examples of drugs that are enzyme inhibitors are shown in **Table 10.5**. To make life even more difficult, several inhibitors of drug metabolism influence the metabolism of different stereoisomers selectively. For example, **metronidazole** selectively inhibits the metabolism of the active (*S*) isomer of **warfarin**, while **omeprazole** selectively inhibits metabolism of the less active (*R*) isomer and **amiodarone** inhibits metabolism of both isomers similarly.

The therapeutic effects of some drugs are a direct consequence of enzyme inhibition (e.g. the xanthine oxidase inhibitor **allopurinol**, used to prevent gout; see **Ch. 25**). Xanthine oxidase metabolises several cytotoxic and immunosuppressant drugs, including **mercaptopurine** (the active metabolite of **azathioprine**), the action of which is thus potentiated and prolonged by allopurinol. **Disulfiram**, an inhibitor of aldehyde dehydrogenase that is used to produce an aversive reaction to ethanol (see **Ch. 50**), also inhibits metabolism of other drugs, including **warfarin**, which it potentiates. **Metronidazole**, an antimicrobial used to treat anaerobic bacterial infections and several protozoal diseases (see

Chs **52** and **55**), also inhibits this enzyme, and patients prescribed it are advised to avoid alcohol for this reason.

After the subject was given rifampicin (600 mg daily for a few days), the same dose of warfarin showed that the plasma half-life of warfarin decreased from approximately 2 days to <1 day *(green symbols)*. (B) The effect of each single dose of warfarin on prothrombin time, before *(red curve)* and after rifampicin *(green curve)* administration. The normal range of prothrombin time is shown by the *pink stripe*. Redrawn from O' Reilly, R.A., 1974. Ann. Intern. Med. 81, 337.

There are also examples of drugs that inhibit the metabolism of other drugs, even though enzyme inhibition is not the main mechanism of action of the offending agents. Thus, glucocorticosteroids and **cimetidine** potentiate a range of drugs, including some antidepressant and cytotoxic drugs.

Inhibition of the conversion of a prodrug to its active metabolite can result in *loss* of activity. Proton pump inhibitors (such as **omeprazole**; see **Ch. 30**) and the antiplatelet drug **clopidogrel** (see **Ch. 23**) have been widely co-prescribed, because clopidogrel is often used with other antithrombotic drugs predisposing to bleeding from the stomach – omeprazole reduces gastric acid secretion and the risk of gastric haemorrhage (see **Ch. 30**). Clopidogrel works

through an active metabolite formed by CYP2C19 which is inhibited by omeprazole, possibly thereby reducing the antiplatelet effect. It is unclear how clinically important this may be (**https://dig.pharmacy.uic.edu/faqs/2019-2/october-2019-faqs/what-is-the-clinical-relevance-of-the-clopidogrel-proton-pump-inhibitor-ppi-interaction/**, Accessed 1 November 2021), but the FDA continues to warn against concomitant use of these drugs for this reason.

DRUG AND METABOLITE EXCRETION

BILIARY EXCRETION AND ENTEROHEPATIC CIRCULATION

Liver cells transfer various substances, including drugs, from plasma to bile by transport systems analogous to those of the renal tubule; these include organic cation transporters (OCTs), organic anion transporters (OATs) and P-gps (see **Ch. 9**). Various hydrophilic drug conjugates (particularly glucuronides) are concentrated in bile and delivered to the intestine, where the glucuronide can be hydrolysed, regenerating active drug; free drug can then be reabsorbed and the cycle repeated, a process referred to as *enterohepatic circulation*. The result is a 'reservoir' of recirculating drug that can amount to about 20% of total drug in the body, prolonging drug action. Examples where this is important include **morphine** (see **Ch. 43**) and **ethinylestradiol** (see **Ch. 35**). Several drugs are excreted to an appreciable extent in bile. **Vecuronium** (a non-depolarising muscle relaxant; see **Ch. 14**) is an example of a drug that is excreted mainly unchanged in bile. **Rifampicin** (see **Ch. 52**) is absorbed from the gut and slowly

deacetylated, retaining its biological activity. Both forms are secreted in the bile, but the deacetylated form is not reabsorbed, so eventually most of the drug leaves the body in this form in the faeces.

RENAL EXCRETION OF DRUGS AND METABOLITES

RENAL CLEARANCE

Elimination of drugs by the kidneys is best quantified by the renal clearance (CL_{ren}; see **Ch. 11**). This is defined as the volume of plasma which contains the amount of drug that is removed from the body by the kidneys in unit time. It is calculated from the plasma concentration, C_p, the urinary concentration, C_u, and the rate of flow of urine, V_u, by the equation:

$$CL_{ren} = (C_u \times V_u) / C_p$$

CL_{ren} varies greatly for different drugs, from less than 1 mL/min to the theoretical maximum set by the renal plasma flow, which is approximately 700 mL/min, measured

by *p*-aminohippuric acid (PAH) clearance (renal extraction of PAH approaches 100%).

Drugs differ greatly in the rate at which they are excreted by the kidney, ranging from **penicillin** (see **Ch. 52**), which is (like PAH) cleared from the blood almost completely on a single transit through the kidney, to **amiodarone** (see **Ch. 20**) and **risedronate** (see **Ch. 36**), which are cleared extremely slowly.

Most drugs fall between these extremes. Three fundamental processes account for renal drug excretion:

1. glomerular filtration
2. active tubular secretion
3. passive reabsorption (diffusion from the concentrated tubular fluid back across tubular epithelium)

Table 10.5

Examples of drugs that inhibit drug-metabolising enzymes

Drugs inhibiting enzyme action	Drugs with metabolism affected
Allopurinol	Mercaptopurine, azathioprine
Chloramphenicol	Phenytoin
Cimetidine	Amiodarone, phenytoin, pethidine
Ciprofloxacin	Theophylline
Corticosteroids	Tricyclic antidepressants, cyclophosphamide
Disulfiram	Warfarin
Erythromycin	Ciclosporin, theophylline
Monoamine oxidase inhibitors	Pethidine
Ritonavir	Saquinavir

Table 10.6

Important drugs and related substances secreted into the proximal renal tubule by either the organic anion transporter (OAT) or organic cation transporter (OCT)

OAT	OCT
***p*-Aminohippuric acid**	Amiloride
Furosemide	Dopamine
Glucuronic acid conjugates	Histamine
Glycine conjugates	Mepacrine
Indometacin	Morphine
Methotrexate	Pethidine
Penicillin	Quaternary ammonium compounds
Sulfate conjugates	Quinine
Thiazide diuretics	5-Hydroxytryptamine (serotonin)
Uric acid	Triamterene

GLOMERULAR FILTRATION

Glomerular capillaries allow drug molecules of molecular weight below about 20 kDa to pass into the glomerular filtrate. Plasma

albumin (molecular weight approximately 68 kDa) is almost completely impermeant, but most drugs – with the exception of macromolecules such as **heparin** (see **Ch. 23**) or biopharmaceuticals (see **Ch. 5**) – cross the barrier freely. If a drug binds to plasma albumin, only free drug is filtered. If, like **warfarin** (see **Ch. 23**), a drug is approximately 98% bound to albumin, the concentration in the filtrate is only 2% of that in plasma, and clearance by filtration is correspondingly reduced.

TUBULAR SECRETION

Approximately 20% of renal plasma flow is filtered through the glomerulus in a healthy human, leaving at least 80% of delivered drug to pass on to the peritubular capillaries of the proximal tubule. Here, drug molecules are transferred to the tubular lumen by two independent and relatively non-selective carrier systems (see **Ch. 9**). One of these, the OAT, transports acidic drugs in their negatively charged anionic form (as well as various endogenous acids, such as uric acid), while an OCT handles organic bases in their protonated cationic form. Some important drugs that are transported by these two carrier systems are shown in **Table 10.6**. The OAT carrier can transport drug molecules against an electrochemical gradient and can reduce the plasma concentration nearly to zero, whereas OCT facilitates transport down an electrochemical gradient. Because at least 80% of the drug delivered to the kidney is presented to the carrier, tubular secretion is potentially the most effective mechanism of renal drug elimination. Unlike glomerular filtration, carrier-mediated transport can achieve maximal drug clearance even when most of the drug is bound to plasma protein. [2] **Penicillin**

(see **Ch. 52**), for example, although about 80% protein-bound and therefore cleared only slowly by filtration, is almost completely removed by proximal tubular secretion, and is therefore rapidly eliminated.

Many drugs compete for the same transport systems (**Table 10.6**), leading to drug interactions. For example, **probenecid** was developed originally to potentiate penicillin by retarding its tubular secretion (see later).

DIFFUSION ACROSS THE RENAL TUBULAR EPITHELIUM

Water is reabsorbed as fluid traverses the tubule, the volume of urine emerging per unit of time being only about 1% of that of the glomerular filtrate. Consequently, if the tubule is freely permeable to drug molecules, some 99% of the filtered drug will be reabsorbed passively down the resulting concentration gradient. Lipid-soluble drugs are therefore excreted poorly, whereas polar drugs of low tubular permeability remain in the lumen and become progressively concentrated as water is reabsorbed. Polar drugs handled in this way include **digoxin** and aminoglycoside antibiotics. These exemplify a relatively small but important group of drugs (**Table 10.7**) that are not inactivated by metabolism, the rate of renal elimination being the main factor that determines their duration of action. These drugs have to be used with special care in individuals whose renal function may be impaired, including the elderly and patients with renal disease or any severe acute illness.

The degree of ionisation of many drugs – weak acids or weak bases – is pH dependent, and this markedly influences their renal excretion. The ion-trapping effect (see **Ch. 9**) means that a basic

drug is more rapidly excreted in an acid urine that favours the charged form and thus inhibits reabsorption. Conversely, acidic drugs are most rapidly excreted if the urine is alkaline (**Fig. 10.6**).

DRUG INTERACTIONS DUE TO ALTERED DRUG EXCRETION

The main mechanisms by which one drug can affect the rate of renal excretion of another are by:

- altering protein binding, and hence filtration
- inhibiting tubular secretion
- altering urine flow and/or urine pH

INHIBITION OF TUBULAR SECRETION

Probenecid (see **Ch. 25**) was developed to inhibit secretion of **penicillin** and thus prolong its action. It also inhibits the excretion of other drugs, including **zidovudine** (see **Ch. 53**). Other drugs have an incidental probenecid-like effect and can enhance the actions of substances that rely on tubular secretion for their elimination. **Table 10.8** gives some examples. Because diuretics, such as furosemide, act from within the tubular lumen, drugs that inhibit their secretion into the tubular fluid, such as non-steroidal anti-inflammatory drugs, reduce their effect.

Table 10.7

Examples of drugs that are excreted largely unchanged in the urine

Percentage	Drugs excreted
100–75	Furosemide, gentamicin, methotrexate, atenolol, digoxin
75–50	Benzylpenicillin, cimetidine, oxytetracycline, neostigmine
~50	Propantheline, tubocurarine

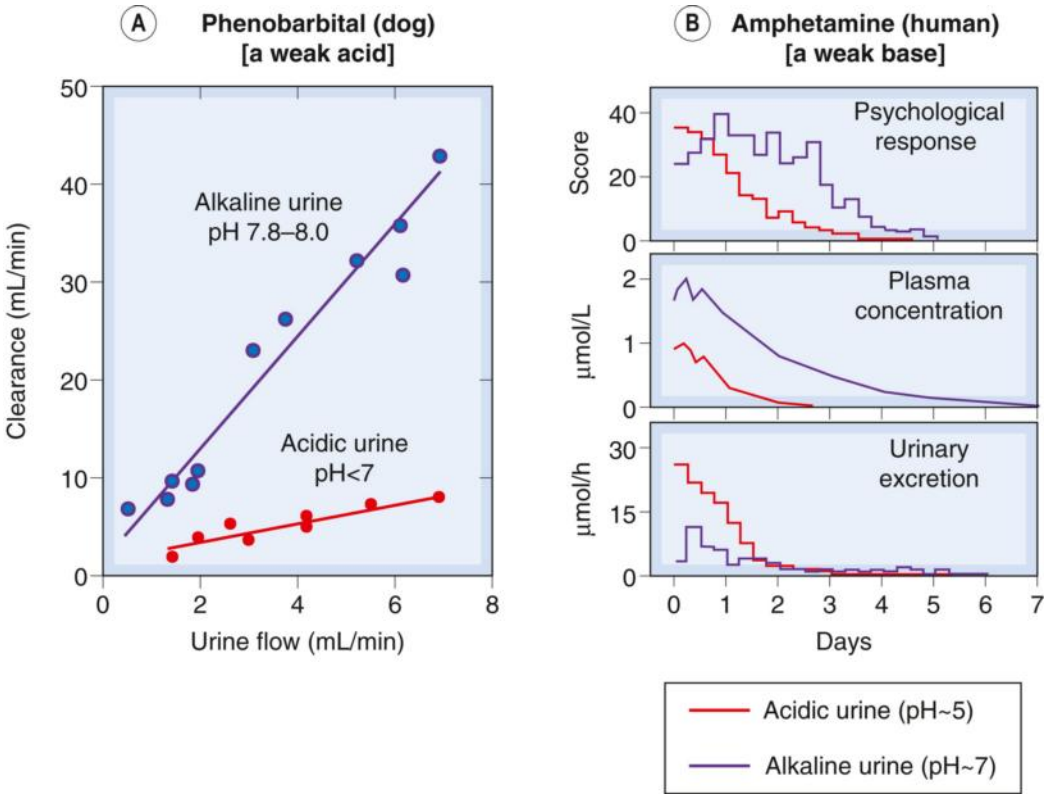

FIG. 10.6 The effect of urinary pH on drug excretion.(A) Phenobarbital clearance in the dog as a function of urine flow. Because phenobarbital is a weak acid, alkalinising the urine increases clearance about five-fold. (B) Amphetamine excretion in humans. Acidifying the urine increases the rate of renal elimination of amphetamine, reducing its plasma concentration and its effect on the subject's mental state. Data from Gunne and Anggard, 1974. In: Torrell, T., et al. (Eds). Pharmacology and Pharmacokinetics. Plenum, New York.

Table 10.8

Examples of drugs that inhibit renal tubular secretion

Drug(s) causing inhibition	Drug(s) affected
Probenecid	
Sulfinpyrazone	
Phenylbutazone	Penicillin
Sulfonamides	Azidothymidine
Aspirin	Indometacin
Thiazide diuretics	
Indometacin	
Verapamil	
Amiodarone	Digoxin
Quinidine	
Indometacin	Furosemide (frusemide)
Aspirin	
Non-steroidal anti-inflammatory drugs	Methotrexate

ALTERATION OF URINE FLOW AND pH

Diuretics tend to increase the urinary excretion of other drugs and their metabolites, but this is seldom immediately clinically important. Conversely, loop and thiazide diuretics indirectly *decrease* the excretion of **lithium**; they reduce body Na^+ content, to which the kidney responds by increased proximal tubular reabsorption of Na^+, and Li^+, which is handled in a similar way to Na^+. This can cause lithium toxicity in patients treated with lithium carbonate for mood disorders (see **Ch. 48**). The effect of urinary pH on the excretion of weak acids and bases is put to use in the treatment of poisoning with *salicylate*, but is not a cause of accidental interactions.

Elimination of drugs by the kidney

- Most drugs, unless highly bound to plasma protein or biopharmaceuticals, cross the glomerular filter freely.
- Many drugs, especially weak acids and weak bases are secreted, actively or by facilitated transport, into the renal tubule and rapidly excreted.
- Lipid-soluble drugs are passively reabsorbed down their concentration gradient across the tubular epithelium as water is reabsorbed, so are not efficiently excreted in the urine.
- Because of pH partition, weak acids are more rapidly excreted in alkaline urine, and vice versa.
- Several important drugs are removed predominantly by renal excretion and are liable to cause toxicity in elderly persons and patients with renal disease.

- There are instances of clinically important drug–drug interactions due to one drug reducing the renal clearance of another (examples include diuretics/lithium and indometacin/methotrexate), but these are less common than interactions due to altered drug metabolism.

QUESTIONS

QUESTION 10.1

Metabolism is the first stage in the elimination process of drugs from the body and involves two phases which decrease lipid solubility and increase renal elimination.

Which of the following statements about the mechanisms of the metabolism of drugs is correct?

OPTIONS:

A. The oxidation or hydrolysis of compounds during phase 1 metabolism inactivates the drug.

B. Phase 2 reactions are catabolic.

C. The toxicity of racemic mixtures is often due to the differing metabolism of the stereoisomers.

D. Lipophilic drugs are excreted more readily than polar drugs.

E. Microsomal enzymes mainly metabolise polar drugs.

QUESTION 10.2

Phase I reactions carried out by P450 enzymes are catabolic and carry out a process called functionalisation to introduce a reactive group to facilitate the conjugation in phase II.

Which of the following statement about the stages of phase I drug functionalisation is correct?

OPTIONS:

A. The iron in P450 is reduced by the acceptance of an electron from the drug.

B. The iron in P450 is oxidised by the addition of an atom of oxygen.

C. The drug is reduced by the addition of a single proton.

D. The drug is reduced by the loss of an electron.

E. The drug is oxidised by the addition of one atom of oxygen.

QUESTION 10.3

To aid the absorption or reduce toxicity, some drugs are given in an inactive prodrug form requiring metabolism in the body to release the active component.

Which of the following may reduce the therapeutic efficacy of a prodrug?

OPTIONS:

A. Alcohol

B. Smoking

C. Genetic polymorphisms in the cytochrome P450 enzymes leading to enhanced metabolism

D. Grapefruit juice

E. St. John's Wort

QUESTION 10.4

Some drugs can induce, inhibit or compete for the P450 enzymes, affecting the rate of metabolism not only of themselves but also of co-administered drugs and substances.

Which of the following situations could result in toxicity due to drug effects on microsomal enzyme function?

OPTIONS:

A. Paracetamol intake in patients with alcohol use disorder

B. Rifampicin administration to patients taking warfarin

C. Phenobarbital administration to newborns

D. Increasing doses of carbamazepine given to treat epilepsy

E. Omeprazole prescribed concomitantly with clopidogrel

ANSWERS

ANSWER 10.1

RATIONALE:

A. Phase 1 reactions are catabolic, and the products are often more chemically reactive and hence, paradoxically, sometimes more toxic or carcinogenic than the parent drug.

B. Phase 2 reactions are synthetic ('anabolic') and involve conjugation (i.e. attachment of a substituent group), which usually results in inactive products.

C.

D. Lipophilic substances are not eliminated efficiently by the kidney. Therefore most lipophilic drugs are metabolised to more polar products, which are then excreted in urine.

E. Polar molecules cross membranes less efficiently than non-polar molecules, so intracellular metabolism by microsomal enzymes is important for lipid-soluble drugs, while polar drugs are, at least partly, excreted unchanged in the urine.

CORRECT ANSWER WIH EXPLANATION:

C. The toxicity of racemic mixtures is often due to the differing metabolism of the stereoisomers.

Many drugs are mixtures of stereoisomers, the components of which differ not only in their pharmacological effects but also in

their metabolism, which may follow completely distinct pathways. In some cases, drug toxicity is mainly linked to one of the stereoisomers, not necessarily the pharmacologically active one.

ANSWER 10.2

RATIONALE:

A. The electron is donated to the iron from nicotinamide adenine dinucleotide phosphate (NADPH)-P450 reductase.

B. The iron combines with molecular oxygen (O2).

C. The ferrous ion gains two protons to form intermediary complexes and then releases a molecule of water.

D. Reduction is effected by electron gain.

E.

CORRECT ANSWER WIH EXPLANATION:

E. The drug is oxidised by the addition of one atom of oxygen.

Following phase I metabolism the drug, DH, is oxidised to form DOH.

ANSWER 10.3

RATIONALE:

A. Alcohol can induce the activity of CyP450 enzymes increasing the rate of activation of the prodrug.

B. Smoking can induce the activity of P450 enzymes, increasing the rate of metabolism.

C. Genetic polymorphisms that cause faster rates of metabolism of prodrugs will enhance their activation.

D.

E. St. John's Wort can induce the activity of CyP450 enzymes increasing the rate of activation of the prodrug.

CORRECT ANSWER WIH EXPLANATION:

D. Grapefruit juice

Grapefruit juice inhibits the P450 enzymes and as such reduces the rate of generation of the active component. (This can paradoxically lead to toxicity in drugs requiring effective metabolism to inactivate them.)

ANSWER 10.4

RATIONALE:

A.

B. Due to the induction of liver enzymes, the effectiveness of warfarin is decreased as its rate of metabolism is increased.

C. Phenobarbital induces enzyme activity and so is given to increase the conjugation and breakdown of bilirubin in newborn babies to prevent kernicterus.

D. Carbamazepine is a potent inducer of microsomal enzymes and hence increases its own metabolism. Doses are increased over several weeks to maintain a therapeutic effect.

E. Omeprazole reduces the activity of P450 enzymes so reducing the conversion of clopidogrel to its active metabolite and hence its efficacy as an antithrombotic.

CORRECT ANSWER WIH EXPLANATION:

A. Paracetamol intake in patients with alcohol use disorder

Ethanol induces enzyme activity resulting in an increase in the metabolism of paracetamol to its toxic metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI).

[1] Well intentioned – although the usefulness of expensive 'novel' entities that are actually just the pure active isomer of well-established and safe racemates has been questioned, and enzymic interconversion of stereoisomers may subvert such sophisticated chemical design.

[2] Because filtration involves isosmotic movement of both water and solutes, it does not affect the free concentration of drug in the plasma. Thus, the equilibrium between free and bound drug is not disturbed, and there is no tendency for bound drug to dissociate as blood traverses the glomerular capillary. The rate of clearance of a drug by filtration is therefore reduced directly in proportion to the fraction of the drug that is bound. In the case of active tubular secretion, this is not so because the carrier transports drug molecules unaccompanied by water. As free drug molecules are taken from the plasma, therefore, the free plasma concentration falls, causing dissociation of bound drug from plasma albumin. Secretion is only retarded slightly, even though the drug is mostly bound, because effectively 100% of the drug, both bound and free, is available to the carrier.

11: Pharmacokinetics

OVERVIEW

We explain the importance of pharmacokinetic (PK) analysis and present a simple approach to this topic. We explain how drug clearance determines the steady-state plasma concentration during constant-rate drug administration and how the characteristics of absorption and distribution (considered in **Ch. 9**) plus metabolism and excretion (considered in **Ch. 10**) determine the time course of drug concentration in blood plasma during and following drug administration. The effect of different dosing regimens on the time course of drug concentration in plasma is explained. Population PK is mentioned briefly, and a final section considers limitations to the PK approach.

Introduction: Definition and uses of Pharmacokinetics

PK is the branch of pharmacology dedicated to determining the fate of chemical substances administered to a living organism – 'what the body does to the drug'. In practice this involves the measurement and formal interpretation of changes with time of drug and drug metabolite concentrations in plasma, urine and sometimes other accessible regions of the body, in relation to dosing. It provides a framework for understanding what happens to

a drug when given to an animal or human, where it goes in the body and how quickly, that enables one to understand the effects that it produces. In contrast, pharmacodynamics (PD: 'what the drug does to the body') describes events consequent on interaction of the drug with its receptor or other molecular target. The distinction is useful, although the words cause dismay to etymological purists.

Pharmacodynamic received an entry in a dictionary of 1890 ('relating to the powers or effects of drugs') whereas PK studies became possible only in the latter part of the 20th century with the development of sensitive, specific and accurate physicochemical analytical techniques, especially high-performance chromatography and mass spectrometry, for measuring drug concentrations in biological fluids. Latterly, '*in silico*' computer modelling of PK has become increasingly important as the discipline has evolved. The time course of drug concentration following dosing depends on the processes of absorption, distribution, metabolism and excretion (ADME) that we have considered qualitatively in **Chapters 9** and 10.

In practice, PK usually focuses on concentrations of drug in *blood plasma*, which is easily sampled via venepuncture, since plasma concentrations are assumed usually to bear a clear relation to the concentration of drug in extracellular fluid surrounding cells that express the receptors or other targets with which drug molecules combine. This underpins what is termed the *target concentration strategy*, where biological effect is related to the *concentration* of the drug in plasma, as surrogate for the liquid environment of the target, rather than to the *dose* administered. Concentration-effect relationships can be studied directly in cell or tissue preparations

in vitro, whereas in whole animal pharmacology (including human pharmacology) it is usually the dose rather than the concentration that is under direct control. Individual variation in response to a given dose of a drug is often greater than variability in response to the *plasma concentration* after that dose because plasma concentration (C_p) accounts for the individual variations in absorption, distribution and elimination. Measurements of C_p are especially useful in the early stages of drug development (see later). Concentrations of drug or drug metabolites in other body fluids (e.g. urine, [1] saliva, cerebrospinal fluid, milk) may add useful information.

For a few therapeutic drugs, plasma drug concentrations are also used in routine clinical practice to individualise dosage to achieve the desired therapeutic effect while minimising adverse effects in each individual patient – an approach known as *therapeutic drug monitoring*, often abbreviated TDM. **Table 11.1** shows examples of drugs where a therapeutic range of plasma concentrations has been established, enabling TDM. Clinicians use this approach when there is a steep dose–effect relationship and little separation between doses needed to cause desired versus adverse effects – referred to as a narrow therapeutic range. However, they much prefer to use drugs where a large margin of safety permits the use of a standard dose without the discomfort, inconvenience and expense of monitoring, which entails sequential blood sampling and dose adjustment. While warfarin therapy (which relies on pharmacodynamic monitoring to optimise efficacy while minimising the risk of bleeding) was used for chronic anticoagulation for many decades, the introduction of direct oral anticoagulants that are administered

in standard dose and do not require such intensive monitoring has rapidly altered practice (see **Ch. 23**), and analogous improvements of other drugs currently monitored by measuring their plasma concentrations (**Table 11.1**) will hopefully be introduced. The drugs of choice will vary according to local analytical capabilities as well as economic considerations for many years to come.

Formal interpretation of PK data consists of fitting concentration-versus-time data to a model (whether abstract or physiologically-based) and determining parameters that describe the observed behaviour. The parameters can then be used to adjust the dose regimen to achieve a desired target plasma concentration. The pharmacologically active concentration range is estimated from preclinical experiments on cells, tissues or laboratory animals, and modified as data emerge from early-phase human pharmacology trials. These often start by testing single doses of the new drug administered to successive groups of volunteers in progressively increasing doses – single ascending dose (SAD) studies (see **Ch. 60**). Some descriptive PK parameters can be estimated directly by inspecting the time course of drug concentration in plasma following dosing – important examples, [2] illustrated more fully later, are the *maximum plasma concentration* following a given dose of a drug administered in a defined dosing form (C_{max}) and the *time* (T_{max}) between drug administration and achieving C_{max}. Other PK parameters are estimated mathematically from experimental data; examples include *volume of distribution* (V_d) and *clearance* (*CL*), concepts that have been introduced in **Chapters 9** and 10, respectively, and to which we return later. This approach applies both to classical low-molecular-weight drugs and

to macromolecular biopharmaceuticals (see **Ch. 5**), although qualitative aspects of absorption, distribution and elimination are, of course, very different and PK parameters differ markedly – for example, antibodies have evolved to persist for long periods after exposure to antigen, and therapeutic antibodies commonly have low rates of clearance and long elimination half-lives in consequence.

Table 11.1

Examples of drugs where therapeutic drug monitoring of plasma concentrations is used clinically

Category	Example(s)	See chapter
Immunosuppressants	Ciclosporin, tacrolimus	25
Cardiovascular	Digoxin	20
Respiratory	Theophylline	28
Central nervous system	Lithium, phenytoin	48, 46
Antibacterials	Aminoglycosides	52
Anticancer drugs	Methotrexate	57

Uses of Pharmacokinetics

Knowledge of the PK behaviour of drugs in animals and man is crucial in drug development, both to make sense of preclinical toxicological and pharmacological data [3] and to decide on an

appropriate dose and dosing regimen for clinical trials (see **Ch. 60**). In particular, where possible, dose escalation during early-phase human trials of new chemical entities is now informed by real-time data on drug exposure to make decisions safely. Relevant parameters of exposure are C_{max} (especially for events related to peak concentration such as dysrhythmias) and the area under the concentration–time curve (*AUC* – introduced in **Ch. 9**, in the context of bioavailability, and see later) which may be more relevant to cumulative toxicity, for example hepatotoxicity.

Drug regulators have additionally developed concepts such as *bioavailability* and *bioequivalence* (see **Ch. 9**) to support the licensing of generic versions of drugs produced when originator products lose patent protection. These do not extend to biopharmaceuticals which can undergo subtle but significant post-translational modification in the cells in which they are manufactured, leading to the distinct but parallel regulatory concept of *biosimilars* (see **Ch. 60**).

Understanding the general principles of PK is also important in clinical practice, to understand the rationale of recommended dosing regimens, to time blood sampling correctly in relation to dosing and interpret drug concentrations for TDM, to adjust dose regimens rationally and to identify and evaluate possible drug interactions (see Chs **9** and **10**). In particular, intensive care specialists and anaesthetists dealing with a severely ill patient often need to individualise the dose regimen depending on the urgency of achieving a therapeutic plasma concentration, and whether the PK behaviour of the drug is likely to be affected by illness such as renal impairment or liver disease.

Scope of this Chapter

We describe:

- how total drug clearance determines steady-state plasma concentration during administration by intravenous infusion or repeated dosing;
- how drug concentration versus time can be predicted using a simple model in which the body is represented as a single well-stirred compartment, of volume V_d. This describes accumulation before steady state and the decline of concentration after dosing is discontinued, based on the elimination half-life ($t_{1/2}$);
- situations where this model is inadequate, and introduce a two-compartment model;
- situations where clearance of a drug varies with its concentration ('non-linear kinetics');
- situations (such as paediatrics) where only a few samples are available from each subject and population PK may be appropriate.

Finally, we consider some of the limitations inherent in the PK approach. More detailed accounts are provided by **Atkinson et al. (2012)**, **Birkett (2010)** and **Derendorf and Schmidt (2020)**.

Drug Elimination Expressed as Clearance

The overall clearance of a drug by all routes (CL_{tot}) is the fundamental PK parameter describing drug elimination. It is defined as the volume of plasma which contains the total amount of

drug that is removed from the body in unit time. It is thus expressed as volume per unit time, e.g. mL/min or L/h. Renal clearance (CL_{ren}), an important component of CL_{tot}, was described in **Chapter 10**.

The overall clearance of a drug (CL_{tot}) is the sum of clearance rates for each mechanism involved in eliminating the drug, usually renal clearance (CL_{ren}) and metabolic clearance (CL_{met}) plus any additional appreciable routes of elimination (faeces, breath, etc.). It relates the rate of elimination of a drug (in units of mass/unit time) to the plasma concentration, C_p:

$$\text{Rate of drug elimination} = C_p \times CL_{tot} \quad \textbf{(11.1)}$$

Drug clearance can be determined in an individual subject by measuring the plasma concentration of the drug (in units of, say, mg/L) at intervals during a constant-rate intravenous infusion (delivering, say, *X* mg of drug per hour), until a steady state is approximated (**Fig. 11.1A**). At steady state, the rate of *input to the body is equal to the rate of elimination*, so:

$$X = C_{ss} \times CL_{tot} \quad \textbf{(11.2)}$$

Rearranging this,

$$CL_{tot} = \frac{X}{\text{MATH}_{ss}} \quad \textbf{(11.3)}$$

where C_{SS} is the plasma concentration at steady state, and CL_{tot} is in units of volume/time (L/h in the example given). Note that this estimate of CL_{tot}, unlike estimates based on the elimination rate constant or half-life (see later), does not depend on the applicability of any particular compartmental model.

For many drugs, clearance in an individual subject is independent of dose (at least within the range of doses used therapeutically – but see the section on saturation kinetics later for exceptions), so knowing the clearance enables one to calculate the dose rate needed to achieve a desired steady-state ('target') plasma concentration from **Eq. 11.2**: if the infusion rate (X) is doubled the steady-state plasma concentration is also doubled, and a plot of X (ordinate) versus C_{SS} (abscissa) is a straight line through the origin with a slope of CL_{tot} – so-called *linear kinetics*.

CL_{tot} can also be estimated by measuring plasma concentrations at intervals following a single intravenous bolus dose of, say, Q mg (**Fig. 11.1B**). This provides a concentration–time curve. $AUC_{0-\infty}$ is the area under the full curve relating C_p to time following a bolus dose given at time $t = 0$ (**Fig 11.1B**) and provides an integrated measure of tissue exposure to the drug in units of time multiplied by drug concentration. In addition to its use in determining the bioavailabilities of different routes of administration of a drug and of different drug preparations described in **Chapter 9**, $AUC_{0-\infty}$ provides measures of clearance and drug exposure considered here. It can be estimated graphically by summing the areas of trapezia

(rectangles with a triangle on top) between adjacent data points (above) and the time axis (below) to the last measured point plus an area to account for the area after the last measured point to time zero using an estimate called the trapezoidal rule.

FIG. 11.1 Plasma drug concentration–time curves.(A) During a constant intravenous infusion at rate X mg/h, indicated by the horizontal bar, the plasma concentration (C_p) increases from zero to a steady-state value (C_{SS}); when the infusion is stopped, C declines from C_{SS} toward zero. The start times for the accumulation and the decay equations are set/re-set, respectively, to 0, so C_0 (C_p at time 0) is 0 for accumulation and is C_{SS} for the decline phase. (B) Following an intravenous bolus dose (Q mg), the plasma concentration rises abruptly and then declines towards zero. (C) Data from panel (B) plotted with plasma concentrations on a logarithmic scale. The straight line shows that concentration declines exponentially. Extrapolation back to the ordinate at zero time gives an estimate of C_0, the concentration at zero time, and hence of V_d, the volume of distribution.

From $AUC_{0-\infty}$, CL_{tot} is estimated from:

$$CL_{tot} = \frac{Q}{AUC_{0-\infty}} \tag{11.4}$$

If plasma concentration declines exponentially after an intravenous bolus (see later) $AUC_{0-\infty}$ can be calculated from the

negative of the slope of the linear decline in the natural logarithm of C_p ($\ln C_p$) versus time (see later). Since the slope is of declining concentration it is negative, so the negative of the slope is positive. It is the elimination rate constant k_{el}. $AUC_{0-\infty}$ is obtained from k_{el} and C_0 (C_p at time 0):

$$AUC_{0-\infty} = C_0/k_{el} \qquad \textbf{(11.5)}$$

In practice, C_0 is obtained by extrapolating the linear part of a semi-logarithmic plot of the plasma concentration–time curve back to the ordinate axis (**Fig 11.1C**). Note that AUC has units of time – on the abscissa – multiplied by concentration (mass/volume) – on the ordinate; so CL ($= Q/AUC_{0-\infty}$) has units of volume/time as it should.

Single-Compartment Model

Consider a highly simplified model of a human being, which consists of a single well-stirred compartment, of volume V_d (distribution volume), into which a quantity of drug Q is introduced rapidly by intravenous injection, and from which it is removed either by being metabolised or by being excreted (**Fig. 11.2**). For most drugs, V_d is an apparent volume rather than the volume of an anatomical compartment (see **Ch. 9**). It links the total amount of drug in the body to its concentration in plasma. The quantity of drug in the body immediately after it is administered as a single bolus is equal to the administered dose Q. The initial concentration, C_0, will therefore be given by:

$$C_0 = \frac{Q}{V_d} \quad \textbf{(11.6)}$$

In practice, as mentioned earlier, C_0 can be estimated by extrapolating the linear portion of a semilogarithmic plot of C_p against time back to its intercept at time 0 (**Fig. 11.1C**). C_p at any time 0 depends on CL_{tot} as well as on the dose and V_d. Many drugs exhibit linear kinetics (see earlier), where the clearance is constant (independent of plasma concentration). This occurs because the rate of elimination is directly proportional to drug concentration. This gives rise to the exponential decay 'die-away' curve characteristic of many natural processes such as cooling (described by Newton's law of cooling), radioactive decay and the oscillations of a released spring. In each case the rate of change of the variable at any time is directly proportional to the value of the variable at that time. In the case of PK the rate of change of plasma concentration (dC_p/dt), is directly proportional to C_p. This is the condition determining exponential decay:

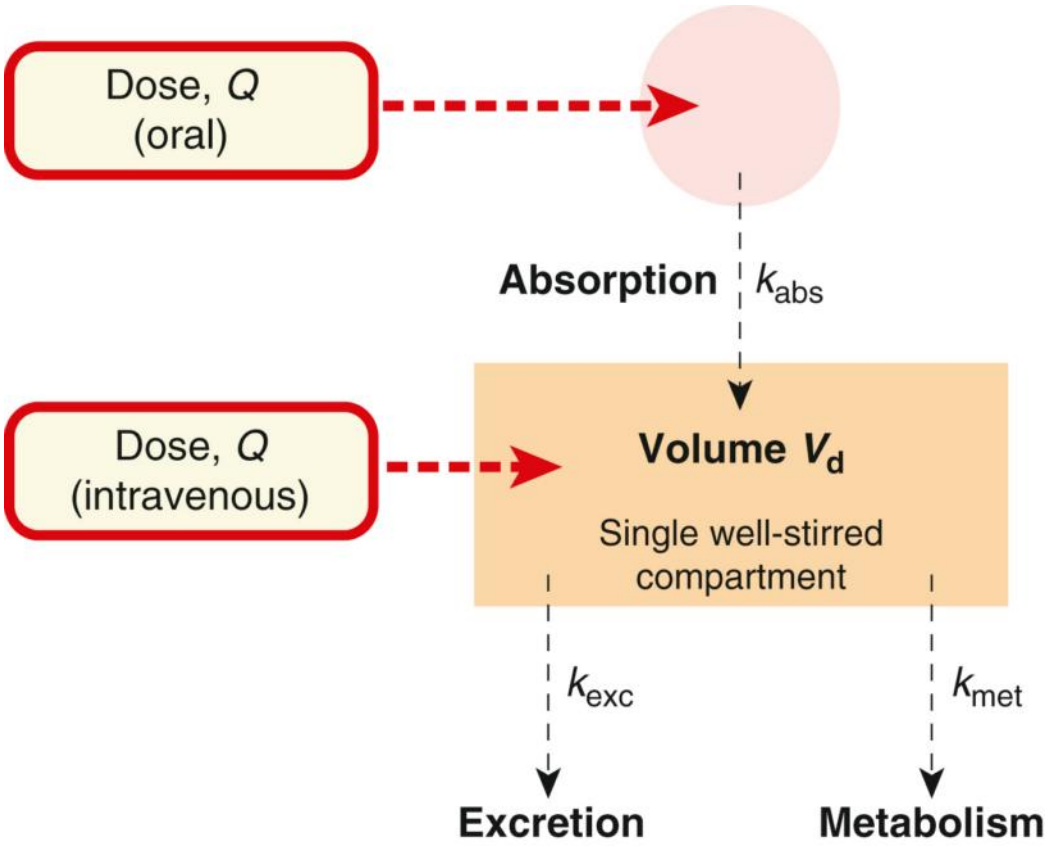

FIG. 11.2 Single-compartment pharmacokinetic model.This model is applicable if the plasma concentration falls exponentially after drug administration (as in Fig. 11.1).

$$C_t = C_0 \cdot e^{-kt} \qquad \textbf{(11.7)}$$

Where k is the *elimination rate constant* k_{el}. It will be seen from this equation that C_t falls from its initial maximum value of C_0 immediately after the bolus injection (when $C_t = C_0$), since when $t = 0$ $e^{-kt} = e^0 = 1$: first rapidly then slower and slower towards a value of 0 when $t = \infty$ so $e^{-kt} = 0$), as illustrated in **Fig. 11.1B** and

Fig. 11.3. Taking logarithms to the base e (written as ln) in **Eq. 11.7** gives:

$$\ln C_t = \ln C_0 - k_{el}t \quad \textbf{(11.8)}$$

This is the equation of a straight line ($y = c + mx$), so plotting $\ln C_t$ against time (t) yields a straight line with slope $-k_{el}$.

The elimination rate constant k_{el} has units of 1/time and is the *fraction* of the dose present in the body that is eliminated per unit time. For example, if the rate constant is 0.1/h this implies that at each time point the elimination rate is one-tenth of the drug remaining in the body at that time per hour. Since drug present in the body is distributed as in a volume V_d, and CL_{tot} is the volume of plasma from which drug is eliminated in unit time, k_{el} is equal to the clearance as a fraction of V_d:

$$k_{el} = CL_{tot}/V_d \quad \textbf{(11.9)}$$

The *elimination half-life*, $t_{1/2}$, is the time taken for C_p to decrease by half (to $C_p/2$) and is equal to $\ln 2/k_{el}$, since:

$$C_t/2 = Ct.e^{-kt_{1/2}} \quad \textbf{(11.10)}$$

Taking logarithms:

$$\ln C_t - \ln 2 = \ln C_t - k_{el}.t_{1/2} \quad \textbf{(11.11)}$$

So:

$$k_{el}.t_{1/2} = \ln 2 = 0.693 \quad \textbf{(11.12)}$$

And:

$$t_{1/2} = 0.693/k_{el} \quad \textbf{(11.13)}$$

The half-life has units of time and enables one conveniently to predict the time course of C_p after the start or end of an infusion or of the rate of drug accumulation during repeated bolus administration (see later), when C_p is rising to its steady-state level or declining to zero.

When a single-compartment model is applicable, a constant-rate drug infusion (see **Fig. 11.1A**) causes the drug concentration in plasma (C_t) to increase from 0 at time 0 toward the steady-state value C_{SS}, the accumulation equation being:

$$C_t = C_{SS}\left(1 - e^{-kt}\right) \quad \textbf{(11.14)}$$

FIG. 11.3 Predicted behaviour of single-compartment model following intravenous drug administration at time 0.Drugs *a* and *b* differ only in their elimination rate constant, k_{el}. Curve *b′* shows the plasma concentration time course for a smaller dose of *b*. Note that the half-life ($t_{1/2}$) (indicated by *broken lines*) does not depend on the dose. (A) Linear concentration scale. (B) Logarithmic concentration scale.

When the infusion is discontinued at a new time 0 after steady state has been approximated (so $C_0 = C_{SS}$), the concentration falls exponentially from C_{SS} towards 0, the decay equation being $C_t = C_0.e^{-kt}$ (**Eq. 11.7**).

TThe accumulation curve (**Eq. 11.14**) is the inverse of the die-away curve (**Eq. 11.7**) so the rate constants (k) for accumulation and elimination are the same, as are the half-lives ($t_{1/2}$) of elimination and accumulation. One half-life after stopping the infusion, the concentration will have fallen to half the initial concentration; after two half-lives, it will have fallen to one-quarter the initial concentration; after three half-lives, to one-eighth; and so on. It is intuitively obvious that the longer the half-life, the longer the drug will persist in the body after dosing is discontinued. It is less obvious, but nonetheless true, that during chronic drug administration, the longer the half-life, the longer it will take for the drug to accumulate to its steady-state level: one half-life to reach 50% of the steady-state value, two to reach 75%, three to reach 87.5% and so on. This is extremely helpful to a clinician deciding

how to start treatment. If the drug in question has a half-life of approximately 24 h, for example, it will take 3–5 days to approximate the steady-state concentration during a constant-rate infusion. If this is too slow in the face of the prevailing clinical situation, a *loading dose* may be used in order to achieve a therapeutic concentration of drug in the plasma more rapidly (see later). The size of such a dose is determined by the volume of distribution (**Eq. 11.6**).

Repeated Dosing

Drugs are usually given therapeutically as repeated doses rather than single injections or a constant infusion. Repeated injections (each of dose Q) give a more complicated pattern than the smooth exponential rise during intravenous infusion, but the principle is the same (**Fig. 11.4**). The mean concentration will rise to a mean steady-state concentration with the same time course as during a constant rate infusion, but C_p will oscillate around the mean (through a range Q/V_d if injections are intravenous so absorption is complete). The smaller and more frequent the doses, the more closely the situation approaches that of a continuous infusion, and the smaller the swings in concentration. The exact dosage schedule, however, does not affect the mean steady-state concentration, or the rate at which it is approached. In practice, a steady state is effectively achieved after three to five half-lives. Speedier attainment of the steady state can be achieved by starting with a larger dose, as mentioned earlier. Such a loading dose is sometimes used when starting treatment with a drug with a half-life that is long in the context of the urgency of the clinical situation, as may be

the case when treating cardiac dysrhythmias with drugs such as **amiodarone** or **digoxin** (see **Ch. 20**).

Effect of Variation in Rate of Absorption

If a drug is absorbed slowly from the gut or from an injection site into the plasma, it is (in terms of a compartmental model) as though it were being slowly infused at a variable rate into the bloodstream. For the purpose of kinetic modelling, the transfer of drug from the site of administration to the central compartment can be represented approximately by a rate constant, k_{abs} (see **Fig. 11.2**). This assumes that the rate of absorption is directly proportional, at any moment, to the amount of drug still unabsorbed, which is at best a rough approximation to reality. The effect of slow absorption on the time course of the rise and fall of the plasma concentration is shown in **Fig. 11.5**. The curves show the effect of spreading out the absorption of the same total amount of drug over different times. In each case, the drug is absorbed completely, but the peak concentration appears later and is lower and less sharp if absorption is slow. In the limiting case, a dosage form that releases drug at a constant rate as it traverses the ileum (see **Ch. 9**) approximates a constant-rate infusion. Once absorption is complete, the plasma concentration declines with the same half-time, irrespective of the rate of absorption.

For the kind of PK model discussed here, the $AUC_{0-\infty}$ is directly proportional to the total amount of drug introduced into the plasma compartment, irrespective of the rate at which it enters. Incomplete absorption, or destruction by presystemic metabolism before the drug reaches the plasma compartment, reduces $AUC_{0-\infty}$ after oral

administration (see **Ch. 9**). Changes in the rate of absorption, however, do not of themselves affect *AUC*. Again, it is worth noting that provided absorption is complete, the relation between the rate of administration and the steady-state plasma concentration (**Eq. 11.3**) is unaffected by k_{abs}, although the rate of rise of the increase of plasma concentration with each dose is reduced if absorption is slowed.

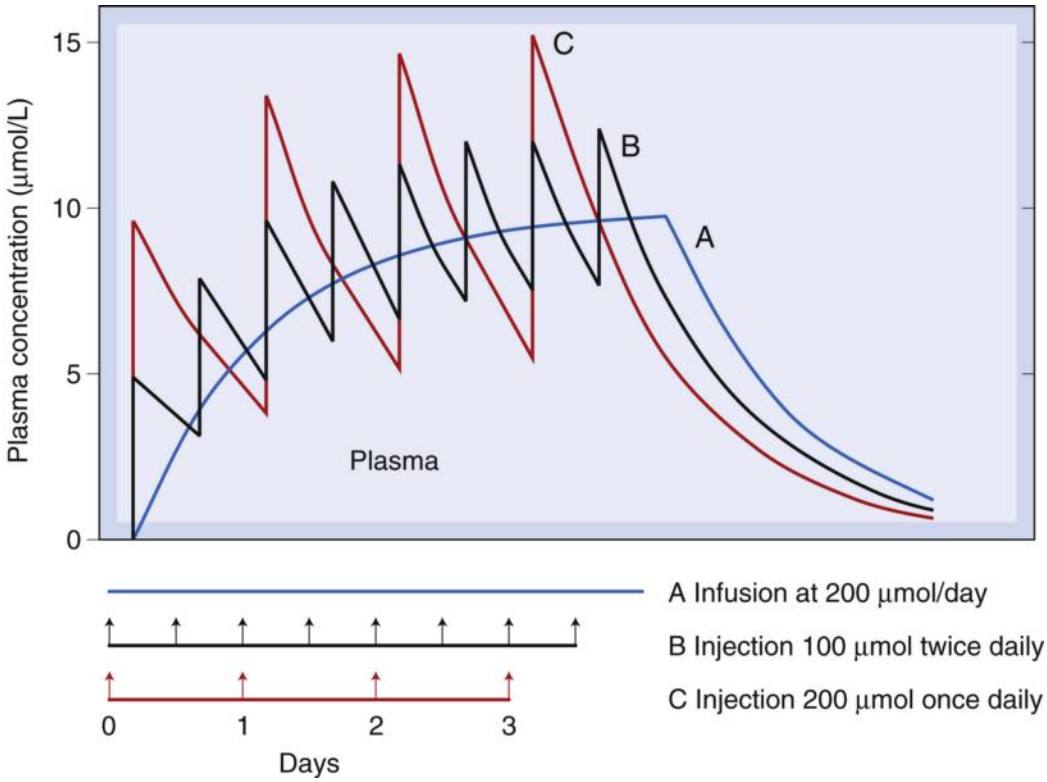

FIG. 11.4 Predicted behaviour of single-compartment model with continuous or intermittent drug administration.Smooth *curve A* shows the effect of continuous infusion for 4 days; *curve B,* the same total amount of drug given in eight equal doses; and *curve C,* the same total amount of drug given in four equal doses. The drug has a half-life of 17 h and a volume of distribution of 20 L. Note that in each case a steady state is effectively reached after about 2 days (about three half-lives), and that the mean concentration reached in the steady state is the same for all three schedules.

More Complicated Kinetic Models

So far, we have considered a single-compartment PK model in which the rates of absorption, metabolism and excretion are all assumed to be directly proportional to the concentration of drug in the compartment from which transfer is occurring. This is a useful way to illustrate some basic principles but is clearly a physiological oversimplification. The characteristics of different parts of the body, such as brain, body fat and muscle, are quite different in terms of their blood supply, partition coefficients for drugs and the permeability of their capillaries to drugs. These differences, which the single-compartment model ignores, can markedly affect the time courses of drug distribution and action, and much theoretical work has gone into the mathematical analysis of more complex models (see **Atkinson et al., 2012**; **Derendorf and Schmidt, 2020**).

The two-compartment model, which introduces a separate 'peripheral' compartment to represent the tissues, in communication with the 'central' plasma compartment, more closely resembles the real situation without involving excessive complications and is conceptually useful although non-compartmental analysis is now usually preferred in drug development.

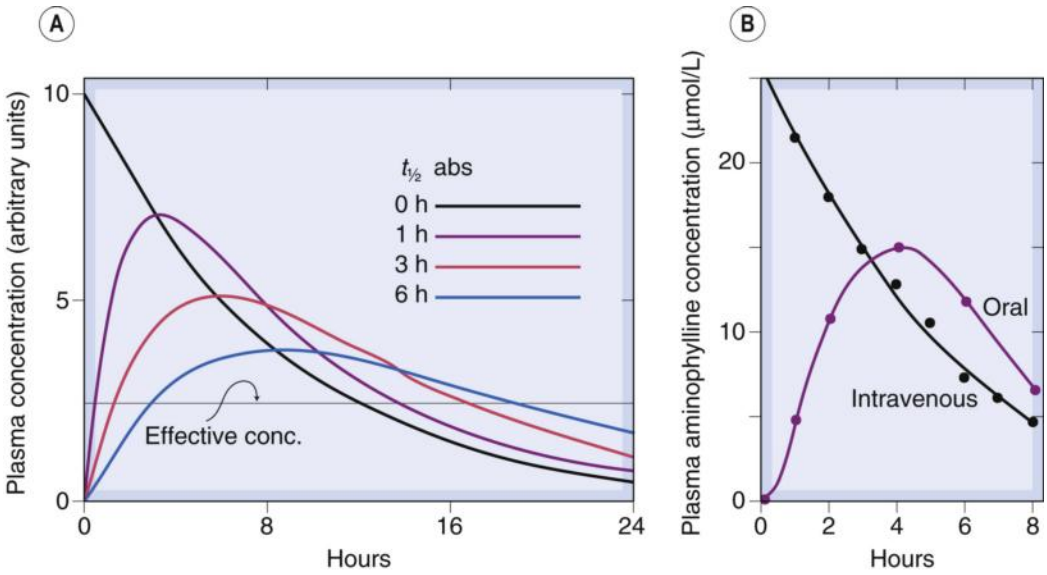

FIG. 11.5 The effect of slow drug absorption on plasma drug concentration.(A) Predicted behaviour of single-compartment model with drug absorbed at different rates from the gut or an injection site. The elimination half-time is 6 h. The absorption half-times ($t_{1/2}$ abs) are marked on the diagram. (Zero indicates instantaneous absorption, corresponding to intravenous administration.) Note that the peak plasma concentration is reduced and delayed by slow absorption, and the duration of action is somewhat increased. (B) Measurements of plasma aminophylline concentration in humans following equal oral and intravenous doses. Data from Swintowsky, J.V., 1956. J. Am. Pharm. Assoc. 49, 395.

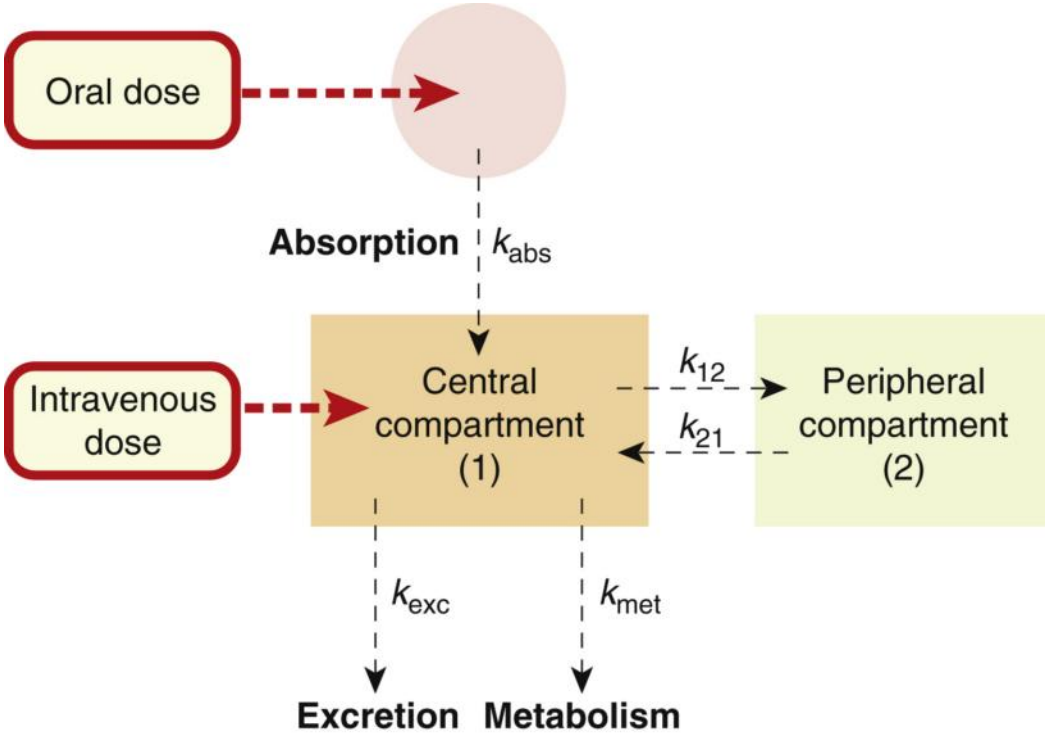

FIG. 11.6 Two-compartment pharmacokinetic model.

Two-Compartment Model

The two-compartment model is a widely used approximation in which the tissues are lumped together as a peripheral compartment. Drug molecules can enter and leave the peripheral compartment only via the central compartment (**Fig. 11.6**), which usually represents the plasma. The effect of adding a second compartment to the model is to introduce a second exponential component into the predicted time course of the plasma concentration, so that it comprises a fast and a slow phase. This pattern is often observed experimentally and is most clearly revealed when the concentration data are plotted semi-logarithmically (**Fig. 11.7**). If, as is often the case, the transfer of drug between the central and peripheral

compartments is relatively fast compared with the rate of elimination, then the fast phase (often called the *α phase*) can be taken to represent the redistribution of the drug (i.e. drug molecules passing from plasma to tissues, thereby rapidly lowering the plasma concentration). The plasma concentration reached when the fast phase is complete, but before appreciable elimination has occurred, allows a measure of the combined distribution volumes of the two compartments; the half-time for the slow phase (the *β phase*) provides an estimate of k_{el}. If a drug is rapidly metabolised or excreted, the α and β phases are not well separated, and the calculation of separate V_d and k_{el} values for each phase is not straightforward. Problems also arise with drugs (e.g. very fat-soluble drugs) for which it is unrealistic to lump all the peripheral tissues together.

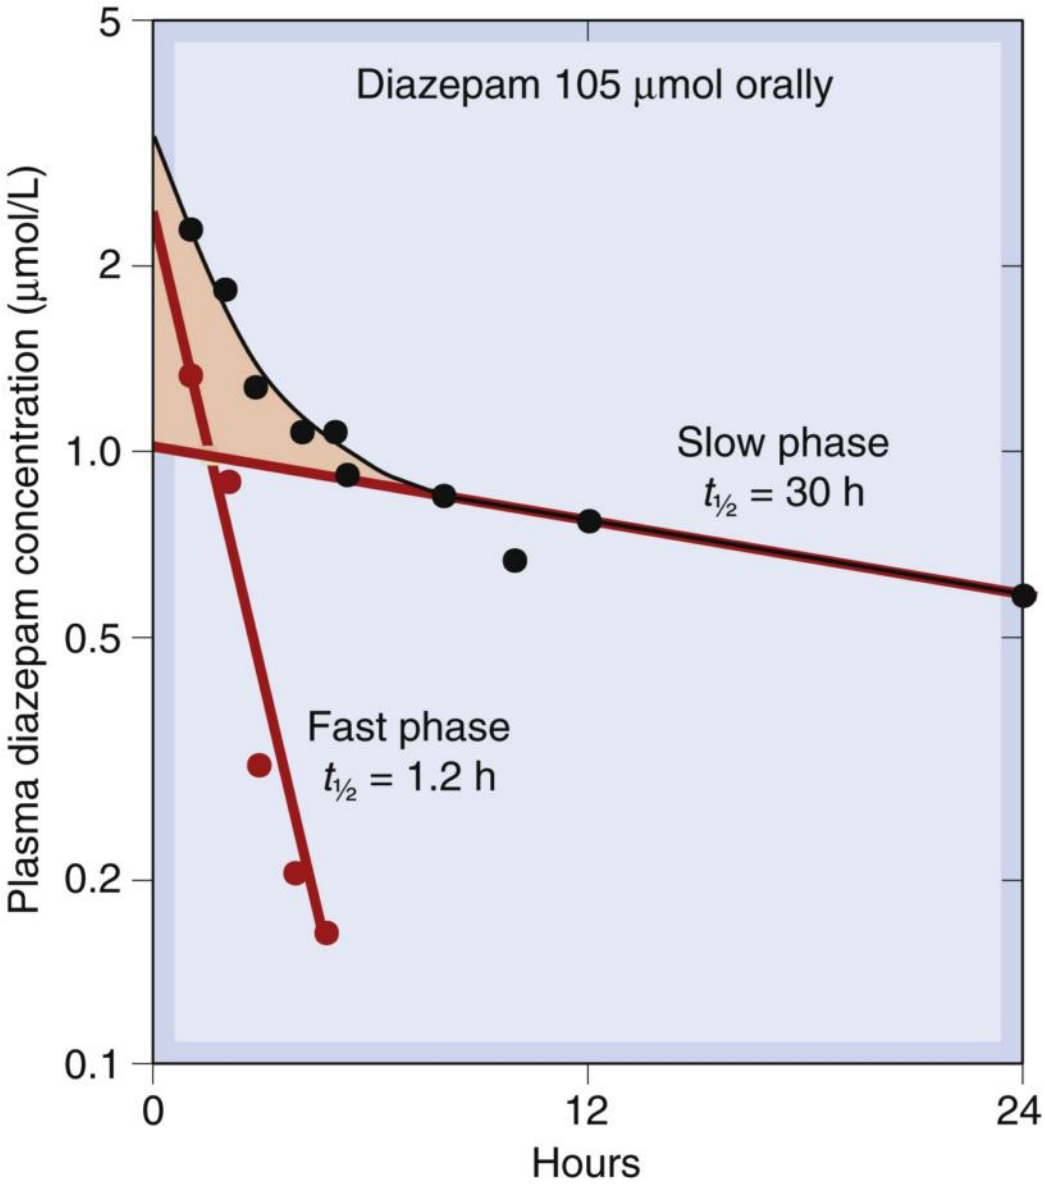

FIG. 11.7 Kinetics of diazepam elimination in humans following a single oral dose.The graph shows a semilogarithmic plot of plasma concentration versus time. The experimental data *(black symbols)* follow a curve that becomes linear after about 8 h (slow phase). Plotting the deviation of the early points *(pink shaded area)* from this line on the same

coordinates *(red symbols)* reveals the fast phase. This type of two-component decay is consistent with the two-compartment model (see Fig. 11.6) and is obtained with many drugs. Data from Curry, S.H., 1980. Drug Disposition and Pharmacokinetics. Blackwell, Oxford.

Saturation Kinetics

In the case of some drugs, including **ethanol**, **phenytoin** and **salicylate**, the time course of disappearance of drug from the plasma does not follow the exponential or bi-exponential patterns shown in Figs **11.3** and **11.7** but is initially linear (i.e. drug is removed at a constant rate that is independent of plasma concentration). This is often called *zero-order kinetics* to distinguish it from the usual first-order kinetics that we have considered so far (these terms have their origin in chemical kinetic theory). *Saturation kinetics* is a better term, because it conveys the underlying mechanism, namely that a carrier or enzyme saturates and so as the concentration of drug substrate increases, the rate of elimination approaches a constant value. **Fig. 11.8** shows the example of ethanol. It can be seen that the rate of disappearance of ethanol from the plasma is constant at approximately 4 mmol/L per hour, irrespective of dose or of the plasma concentration of ethanol. The explanation for this is that the rate of oxidation by the enzyme alcohol dehydrogenase reaches a maximum at low ethanol concentrations, because of limited availability of the cofactor NAD^+ (see **Ch. 49**, **Figs 49.5 and 49.6)**.

Saturation kinetics has several important consequences (**Fig. 11.9** and see **Ch. 46**, **Fig. 46.4**). One is that the duration of action is more strongly dependent on dose than is the case with drugs that do not show metabolic saturation. Another consequence is that the relationship between dose and steady-state plasma concentration is steep and unpredictable, and it does not obey the proportionality rule implicit in **Eq. 11.3** for non-saturating drugs (see **Fig. 49.6** for another example related to ethanol). The maximum rate of metabolism sets a limit to the rate at which the drug can be administered; if this rate is exceeded, the amount of drug in the body will, in principle, increase indefinitely and never reach a steady state (see **Fig. 11.9**). This does not actually happen, because there is always some dependence of the rate of elimination on the plasma concentration (usually because other, non-saturating metabolic pathways or renal excretion contribute significantly at high concentrations). Nevertheless, the steady-state plasma concentrations of drugs of this kind vary widely and unpredictably with dose. Similarly, variations in the rate of metabolism (e.g. through enzyme induction) cause disproportionately large changes in the plasma concentration. These problems are well recognised for drugs such as phenytoin, an anticonvulsant for which plasma concentration needs to be closely controlled to achieve an optimal clinical effect (see **Ch. 46**, **Fig. 46.4**). Drugs showing saturation kinetics are less predictable in clinical use than ones with first-order kinetics, so may be rejected during drug development if a pharmacologically similar candidate with first-order kinetics is available (see **Ch. 60**).

The opposite kind of non-linearity is also encountered during drug development, where plasma concentration increases less (rather than more than) in proportion with dose increment. This can occur when drugs are administered by mouth and an absorption carrier becomes saturated or (more commonly) when the pharmaceutical formulation fails to disperse adequately with higher doses.

Clinical applications of PK are summarised in the clinical box.

Uses of pharmacokinetics

- Pharmacokinetic studies performed during drug development underpin the standard dose regimens approved by regulatory agencies.
- Clinicians sometimes need to individualise dose regimens to account for individual variation in a particular patient (e.g. a neonate, a patient with impaired and changing renal function or a patient taking drugs that interfere with drug metabolism; see **Ch. 10**).
- Drug effect (PD) is often used for such individualisation, but there are drugs (including some anticonvulsants, immunosuppressants and antineoplastics) where a therapeutic range of plasma concentrations has been defined, and for which it is useful to adjust the dose to achieve a concentration in this range.
- Knowledge of kinetics enables rational dose adjustment. For example:

  - the frequency of dosing of a drug such as **gentamicin** eliminated by renal excretion may need to be markedly reduced in a patient with renal impairment (see **Ch. 52**);
  - the dose increment needed to achieve a target plasma concentration range of a drug such as **phenytoin** with saturation kinetics (see **Ch. 46**, **Fig. 46.4**) is much less than for a drug with linear kinetics.
- Knowing the approximate $t_{1/2}$ of a drug can be very useful, even if a therapeutic concentration is not known:
  - in correctly interpreting adverse events that occur some considerable time after starting regular treatment (e.g. benzodiazepines; see **Ch. 45**);
  - in deciding on the need or otherwise for an initial loading dose when starting treatment with drugs such as **digoxin** and **amiodarone** (see **Ch. 20**).
- The volume of distribution (V_d) of a drug determines the size of loading dose needed. If V_d is large (as for many tricyclic antidepressants), haemodialysis will not be an effective way of increasing the rate of elimination in treating overdose.

Population Pharmacokinetics

In some situations, for example when a drug is intended for use in chronically ill children, it is desirable to obtain PK data in a patient population rather than in healthy adult volunteers. Such studies in children are inevitably limited and samples for drug analysis are often obtained opportunistically during clinical care, with limitations as to quality of the data and on the number of samples

collected from each patient. Population PK addresses how best to analyse such data. Fitting data from all subjects as if there were no kinetic differences between individuals and fitting each individual's data separately and then combining the individual parameter estimates, each has obvious shortcomings. A better method is to use non-linear mixed effects modelling (NONMEM). How population studies relate to the individual requires the use of such mathematical modelling. Such analysis is used to predict individual variation whether in clinical trial or clinical practice. The uncertainties and the statistical technicalities are considerable and beyond the scope of this chapter: the interested reader is referred to **Sheiner et al. (1997)**.

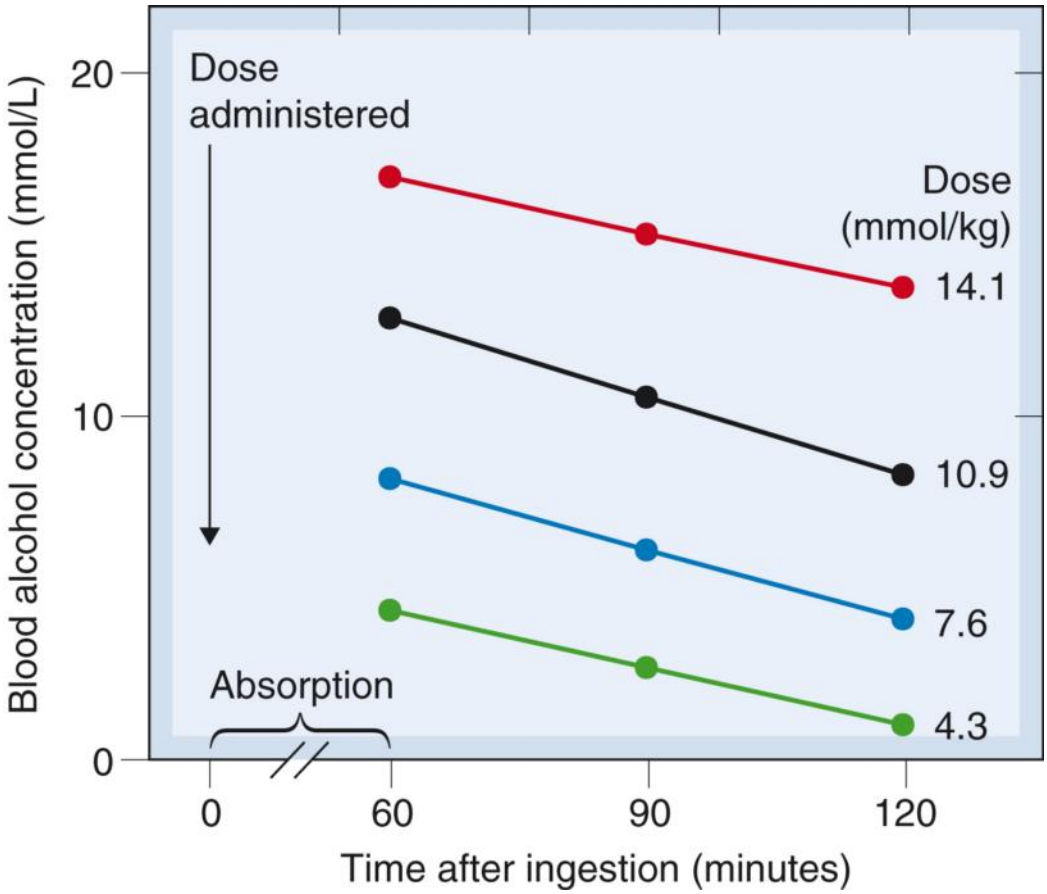

FIG. 11.8 Saturating kinetics of alcohol elimination in humans.The blood alcohol concentration falls linearly rather than exponentially, and the rate of fall does not vary with dose. From Drew, G.C., Colquhoun, W.P., Long, H.A., 1958. Effects of small doses of alcohol on a skill resembling driving. Br. Med. J. 2, 5103.

Pharmacokinetics

- Total clearance (CL_{tot}) of a drug is the fundamental parameter describing its elimination: the rate of elimination equals CL_{tot} multiplied by plasma concentration.
- CL_{tot} determines steady-state plasma concentration (C_{SS}): C_{SS} = rate of drug administration/CL_{tot}.
- For many drugs, disappearance from the plasma follows an approximately exponential time course. Such drugs can be described by a model where the body is treated as a single well-stirred compartment of volume V_d. V_d is an apparent volume linking the amount of drug in the body at any time to the plasma concentration.
- Elimination half-life ($t_{1/2}$) is directly proportional to V_d and inversely proportional to CL_{tot}.
- With repeated dosage or sustained delivery of a drug, the plasma concentration approaches a steady value within three to five plasma half-lives.
- In urgent situations, a loading dose may be needed to achieve therapeutic concentration rapidly.
- The loading dose (L) needed to achieve a desired initial plasma concentration C_{target} is determined by V_d: $L = C_{target} \times V_d$.
- A two-compartment model can be used when the observed kinetics are biexponential. The two components approximate the processes of transfer between plasma and tissues (α phase) and elimination from the body (β phase).
- Some drugs show non-exponential ‘saturation’ kinetics, with important clinical consequences, especially a

disproportionate increase in steady-state plasma concentration when dose is increased.

Limitations of Pharmacokinetics

Some limitations of the PK approach will be obvious from the earlier account, such as the proliferation of parameters in even quite conceptually simple models. There are also limitations in the usefulness of monitoring drug concentrations in plasma as an approach to reducing individual variability in drug response (see **Ch. 12**). Two main assumptions underpin the expectation that by relating response to a drug to its plasma concentration we can reduce variability of response by accounting for PK variation – that is, variation in ADME. They are:

1. That plasma concentration of a drug bears a precise relation to the concentration of drug in the immediate environment of its target (receptor, enzyme, etc.).
2. That drug response depends uniquely on the concentration of the drug in the immediate environment of its target.

While the first of these assumptions is plausible for those few drugs that work through a target in the circulating blood (e.g. a fibrinolytic drug working on intravascular fibrin) and reasonably plausible for a drug working on an enzyme, ion channel or G protein–coupled or kinase-linked receptor located in the cell membrane and accessed by drug molecules dissolved in the extracellular fluid, it is less likely to be true in the case of a nuclear receptor or when an active metabolite is involved. Because of the

blood–brain barrier, plasma concentrations rarely reflect local drug concentrations in the brain, so, with the exception of lithium (see **Ch. 48**) and of some antiepileptic drugs (see **Ch. 46**), monitoring of plasma concentrations has not proved to be clinically useful for drugs acting in the brain.

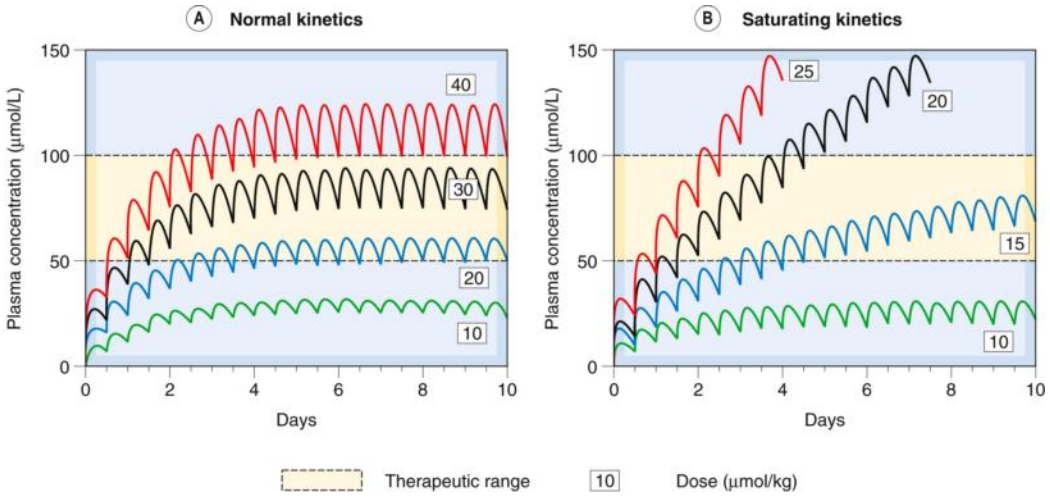

FIG. 11.9 Comparison of non-saturating and saturating kinetics for drugs given orally every 12 h.(A) The curves showing an imaginary drug, similar to the antiepileptic drug phenytoin at the lowest dose, but with linear kinetics. The steady-state plasma concentration is reached within a few days, and is directly proportional to dose. (B) Curves for saturating kinetics calculated from the known PK parameters of phenytoin (see **Ch. 46**). Note that no steady state is reached with higher doses of phenytoin, and that a small increment in dose results after a time in a disproportionately large effect on plasma concentration. Curves were calculated with the Sympak pharmacokinetic modelling program written by Dr. J.G. Blackman, University of Otago.

The second assumption is untrue in the case of drugs that form a stable covalent attachment with their target, and so produce an

effect that outlives their presence in solution. Examples include the antiplatelet effects of **aspirin** and **clopidogrel** (see **Ch. 23**) and the effect of some monoamine oxidase inhibitors (see **Ch. 48**) and proton pump inhibitors (see **Ch. 30**). In other cases, drugs in therapeutic use act only after delay (e.g. antidepressants; see **Ch. 48**), or gradually induce tolerance (e.g. opioids; see **Ch. 43**) or physiological adaptations (e.g. corticosteroids; see **Ch. 33**) that alter the relation between concentration and drug effect in a time-dependent manner such that drug effect is not uniquely determined by drug concentration in the plasma.

QUESTIONS

QUESTION 11.1

Knowledge of pharmacokinetics is crucial in drug development to enable estimations of drug efficacy, appropriate dosing and predicted toxicology. The single compartment model gives a simplified estimation of drug distribution.

In a single compartment model, which of the following statements is correct?

OPTIONS:

A. The initial concentration of the drug can be calculated by multiplying the bolus dose by the volume of distribution.

B. Most drugs exhibit zero-order kinetics such that the rate of elimination is directly proportional to the drug concentration.

C. The slope of the graph log CL_{tot} versus time will yield the elimination rate constant.

D. Chronic administration of a drug with a long half-life results in rapid achievement of steady state but a slow elimination profile.

E. The plasma concentration of the drug rises and falls approximately exponentially during constant intravenous infusion and on discontinuation.

QUESTION 11.2

Different dosing regimens have an effect on the time course of drug concentration in plasma.

Which of the following statements about the effects of different dosing regimens is correct?

OPTIONS:

A. The frequency of repeated injections will affect the rate at which mean steady-state concentration is achieved.

B. Loading doses are used to accelerate achievement of the mean steady-state concentration.

C. The rate of absorption of a drug from the gut is inversely proportional to the plasma concentration.

D. In a zero or saturation kinetic model, the clearance rate is entirely dependent upon drug dose.

E. Steady state is achieved in a linear fashion rather than exponentially for drugs exhibiting saturation kinetics.

QUESTION 11.3

Variations in plasma protein binding and metabolism affect the kinetics of elimination.

Which of the following statements about the pharmacokinetic profiles of the stated agents is correct?

OPTIONS:

A. As the plasma concentration of ethanol increases, the rate of elimination increases.

B. Clopidogrel response is dependent on the concentration of the drug at its target.

C. The time course of disappearance of low dose salicylate from the plasma is linear.

D. Small increments in phenytoin dose have little effect on plasma concentrations.

E. The frequency of dosing of a drug such as gentamicin must be increased in a patient with renal impairment.

ANSWERS

ANSWER 11.1

RATIONALE:

A. The dose is distributed evenly across the available volume and thus should be divided by the volume of distribution.

B. In zero-order kinetics the rate of elimination is constant and independent of concentration.

C. The log of the concentration at time t (C_t) against time will yield a slope – CL/V – equivalent to the elimination rate constant.

D. The longer the half-life of the drug, the longer it will take to achieve steady state.

E.

CORRECT ANSWER WITH EXPLANATION:

E. The plasma concentration of the drug rises and falls approximately exponentially during constant intravenous infusion and on discontinuation.

The profile follows first order kinetics approaching steady state, as shown in the plasma concentration plots on Figs 11.1 and 11.3.

ANSWER 11.2

RATIONALE:

A. The dosage schedule does not affect the mean steady state concentration or the rate at which this is approached.

B.

C. The rate of absorption is directly proportional to the amount of unabsorbed drug.

D. In a zero-order model the drug is cleared at a constant rate, independent of concentration.

E. For drugs exhibiting saturation kinetics, steady-state plasma concentrations often vary widely and unpredictably with dose and do not follow the proportionality rule.

CORRECT ANSWER WITH EXPLANATION:

B. Loading doses are used to accelerate achievement of the mean steady-state concentration.

Drugs with a long half-life can be too slow, when given by continuous infusion, to reach a therapeutic steady state. In such cases a larger loading dose may be used to reach a therapeutic dose more rapidly.

ANSWER 11.3

RATIONALE:

A. As the plasma concentration of ethanol increases, the rate of elimination approaches a constant value as the metabolising enzymes become saturated.

B. Clopidogrel forms a stable covalent attachment with its target, and so produces an effect that outlives its presence in solution.

C.

D. Phenytoin displays saturation kinetics so only a small dose increment is needed to achieve a target plasma concentration range.

E. The frequency of dosing of a drug such as gentamicin which is eliminated by renal excretion may need to be markedly reduced in a patient with renal impairment.

CORRECT ANSWER WITH EXPLANATION:

C. The time course of disappearance of low-dose salicylate from the plasma is linear.

Elimination of salicylate follows saturation kinetics and is initially linear, occurring at a constant rate that is independent of plasma concentration.

---

[1] *Clinical* pharmacology became at one time so associated with the measurement of drugs in urine that the canard had it that clinical pharmacologists were the new alchemists – they turned urine into airline tickets.

[2] Important because dose-related adverse effects often occur around C_{max}.

[3] For example, doses used in experimental animals often need to be much greater than those in humans on a 'per unit body weight' basis, because drug metabolism is commonly much more rapid in rodents – **methadone** (Ch. 43) is one of many such examples. When using animal data to estimate a 'human equivalent dose' in planning the first-in-human study, doses of low-molecular-weight drugs are normalised (so-called 'allometric scaling') to estimated body surface area rather than to body weight. Paediatricians commonly use the same approach, estimating appropriate doses for babies and young children from adult human doses in terms of dose/unit of estimated body surface area rather than dose/kg body weight.

12: Individual variation, pharmacogenomics and personalised medicine

OVERVIEW

This chapter addresses the sources of variation between individuals (inter-individual variation) in their responses to drugs. Important factors, including ethnicity, age, pregnancy, disease and drug interaction (i.e. modification of the action of one drug by another), are described. The concept of individualising drug therapy in light of genomic information ('personalised medicine') – a rapidly expanding area of clinical pharmacology – is introduced. We explain relevant elementary genetic concepts and describe briefly several single-gene pharmacogenetic disorders that affect drug responses. We then cover how pharmacogenomic tests can be used to guide the choice of therapy and adjustments to dosing regimens.

Introduction

Therapeutics would be a great deal easier if the same dose of drug always produced the same response. In reality, inter- and even intra-individual variation is often substantial and this can lead to important differences in the balance between benefit and harm of

treatment. Physicians need to be aware of the sources of such variation to prescribe drugs safely and effectively. Variation can be caused by different concentrations at sites of drug action or by different responses to the same drug concentration. The first kind is called *pharmacokinetic variation* and can occur because of differences in absorption, distribution, metabolism or excretion (ADME; Chs **9** and **10**). The second kind is called *pharmacodynamic variation*. Responses to some therapeutic agents, for example, most vaccines and oral contraceptives (see **Ch. 35**), are sufficiently predictable to permit a standard dose regimen, whereas treatment with **lithium** (see **Ch. 48**), antihypertensive drugs (see **Ch. 21**), anticoagulants (see **Ch. 23**) and many other drugs is individualised, doses being adjusted on the basis of monitoring the drug concentration in the plasma or a response such as change in blood pressure, together with any adverse effects.

Inter-individual variation in response to some drugs is a serious problem; if not taken into account, it can result in lack of efficacy or unexpected adverse effects. Whilst large-scale clinical trials may be able to predict the 'average' effect of a drug, clinicians also recognise that there are subgroups of individuals who have a greater likelihood for beneficial (or harmful) response than others. This is particularly relevant to life-threatening conditions (such as cancer) where optimised individual therapy guided by predictive markers may achieve striking gains in the benefit:harm ratio. Variation is partly caused by environmental factors, but studies comparing identical with non-identical twins suggest that much of the variation in response to certain drugs is genetically determined; for example, the elimination half-lives of antipyrine, a probe of hepatic

drug oxidation, and of **warfarin**, an oral anticoagulant (see **Ch. 23**), differ much less between identical than between fraternal twins.

Genes influence pharmacokinetics by altering the expression of proteins involved in drug ADME; pharmacodynamic variation reflects differences in drug targets, G proteins or other downstream pathways whilst individual susceptibility to uncommon qualitatively distinct adverse reactions (see **Ch. 58**) can result from genetically determined differences in enzymes or immune mechanisms. Here, the introduction of rapid, easily accessible methods to identify genetic differences between individuals is a key consideration. It is now possible to use genetic information specific to an individual patient to preselect a drug that will be effective and not cause excessive toxicity, rather than relying on trial and error supported by physiological clues as at present – an aspiration referred to as *personalised medicine*. Thus far, this approach, which was initially over-hyped, has faced hurdles in translation to patient benefit throughout daily clinical practice. Research continues at a breakneck pace however, and the US FDA has listed over 480 pharmacogenomic biomarkers for inclusion in drug labelling information – a doubling since the last edition of this book. As one might expect, the vast majority of recommendations for pharmacogenetic testing are in relation to the critically poised benefit:harm profiles of anticancer drugs.

The Genetic Testing Registry (**https://www.ncbi.nlm.nih.gov/gtr/**) in the United States accepts submissions from laboratories worldwide regarding the genetic tests that are made available for the purposes of screening,

diagnosis, drug/disease monitoring and treatment response. As of January 2023, the registry has recorded information on 76,531 tests covering 18,737 genes that are associated with 22,574 conditions. There is no doubt that pharmacogenetic testing can make an important contribution to therapeutics, but serious questions remain about the cost–benefit, and how this avalanche of genetic information could be effectively incorporated into daily clinical workflows.

In this chapter we first describe the most important epidemiological sources of variation in drug responsiveness, before revisiting some elementary genetics as a basis for understanding genetic disorders characterised by abnormal responses to drugs. We conclude with a brief account of currently available pharmacogenomic tests and how these are beginning to be applied to individualise drug therapy (*pharmacogenomics*). In particular, we will summarise four key roles of pharmacogenetic data in treatment decisions involving drug indication, dosage, safety and communication of risk.

Individual variation

- Variability is a serious problem; if not taken into account, it can result in:
  - lack of efficacy
  - unexpected harmful effects
- Types of variability may be classified as:
  - pharmacokinetic
  - pharmacodynamic

- The main causes of variability are:
  - age
  - genetic factors
  - immunological factors (see **Ch. 58**)
  - disease (especially when this influences drug elimination or metabolism, e.g. kidney or liver disease)
  - drug interactions

Epidemiological Factors and Inter-Individual Variation of Drug Response

Ethnicity

Ethnic means 'pertaining to race', and many anthropologists are sceptical as to the value of this concept (see, for example, **Cooper et al., 2003**). Members of racial groups share some characteristics on the basis of common genetic and cultural heritage, but there is enormous diversity within each group. Could an Asian Indian conceivably have the same drug response as an Asian Chinese, or Japanese? Coarse and inconsistent ethnic categories based on visual impressions of outward appearance are unlikely to help in personalising medicine for individuals within diverse populations (see **Po, 2007**). The expanding availability of comprehensive testing for individual genetic markers helps us to move away from outdated and imprecise concepts of ethnicity.

Age

The main reason that age affects drug action is that drug elimination is less efficient in newborn babies and in older people,

so that drugs commonly produce greater and more prolonged effects at the extremes of life. Other age-related factors, such as variations in pharmacodynamic sensitivity, are also important with some drugs. Body composition changes with age, fat contributing a greater proportion to body mass in the elderly, with consequent changes in distribution volume of drugs. Elderly people typically consume more drugs than do younger adults, so the potential for drug interactions is also increased. For fuller accounts of drug therapy in paediatrics and in the elderly, see the chapters on renal and hepatic disease in **Huang et al. (2021)**.

Effect of Age on Renal Excretion of Drugs

Glomerular filtration rate (GFR) in the newborn, normalised to body surface area, is only about 20% of the adult value. Accordingly, plasma elimination half-lives of renally eliminated drugs are longer in neonates than in adults (**Table 12.1**). In babies born at term, renal function increases to values similar to those in young adults in less than a week and continues to increase to a maximum of approximately twice the adult value at 6 months of age. Improvement in renal function occurs more slowly in premature infants. Renal immaturity in premature infants can have a substantial effect on drug elimination. For example, in premature newborn babies, the antibiotic **gentamicin** (see **Ch. 52**) has a plasma half-life of ≥18 h, compared with 1–4 h for adults and approximately 10 h for babies born at term. It is therefore necessary to reduce and/or space out doses to avoid toxicity in premature babies.

Table 12.1

[a] Even greater differences from mean adult values occur in premature babies.

Data from Reidenberg, M.M., 1971. Renal Function and Drug Action. Saunders, Philadelphia; and Dollery, C.T., 1991. Therapeutic Drugs. Churchill Livingstone, Edinburgh.

GFR declines slowly from about 20 years of age, falling by about 25% at 50 years and by 50% at 75 years. **Fig. 12.1** shows that the renal clearance of **digoxin** in young and elderly subjects is closely correlated with creatinine clearance, a measure of GFR. Consequently, chronic administration over the years of the same daily dose of digoxin to an individual as he or she ages leads to a progressive increase in plasma concentration, and this is a common cause of glycoside toxicity in elderly people (see **Ch. 20**).The age-related decline in GFR is not reflected by an increase in plasma creatinine *concentration,* as distinct from creatinine *clearance.* Plasma creatinine typically remains within the normal adult range in elderly persons despite substantially diminished GFR. This is because creatinine synthesis is reduced in elderly persons because of their reduced muscle mass. Consequently, a 'normal' plasma creatinine in an elderly person does not indicate that they have a normal GFR. Failure to recognise this and reduce the dose of drugs that are eliminated by renal excretion can lead to drug toxicity.

Effect of Age on Drug Metabolism

Several important enzymes, including hepatic microsomal oxidase, glucuronyltransferase, acetyltransferase and plasma esterases, have low activity in neonates, especially if premature. These enzymes take 8 weeks or longer to reach the adult level of activity. The relative lack of conjugating activity in the newborn can have serious consequences, as in *kernicterus* caused by drug displacement of bilirubin from its binding sites on albumin (see **Ch. 9**) and in the 'grey baby' syndrome caused by the antibiotic **chloramphenicol** (see **Ch. 52**). This sometimes-fatal condition, at first thought to be a specific biochemical sensitivity to the drug in young babies, actually results simply from accumulation of very high tissue concentrations of chloramphenicol because of slow hepatic conjugation. Chloramphenicol is no more toxic to babies than to adults, provided the dose is reduced to make allowance for this. Slow conjugation is also one reason why **morphine** (which is excreted mainly as the glucuronide, see **Ch. 43**) is not used as an analgesic in labour, because drug transferred via the placenta has a long half-life in the newborn baby and can cause prolonged respiratory depression.

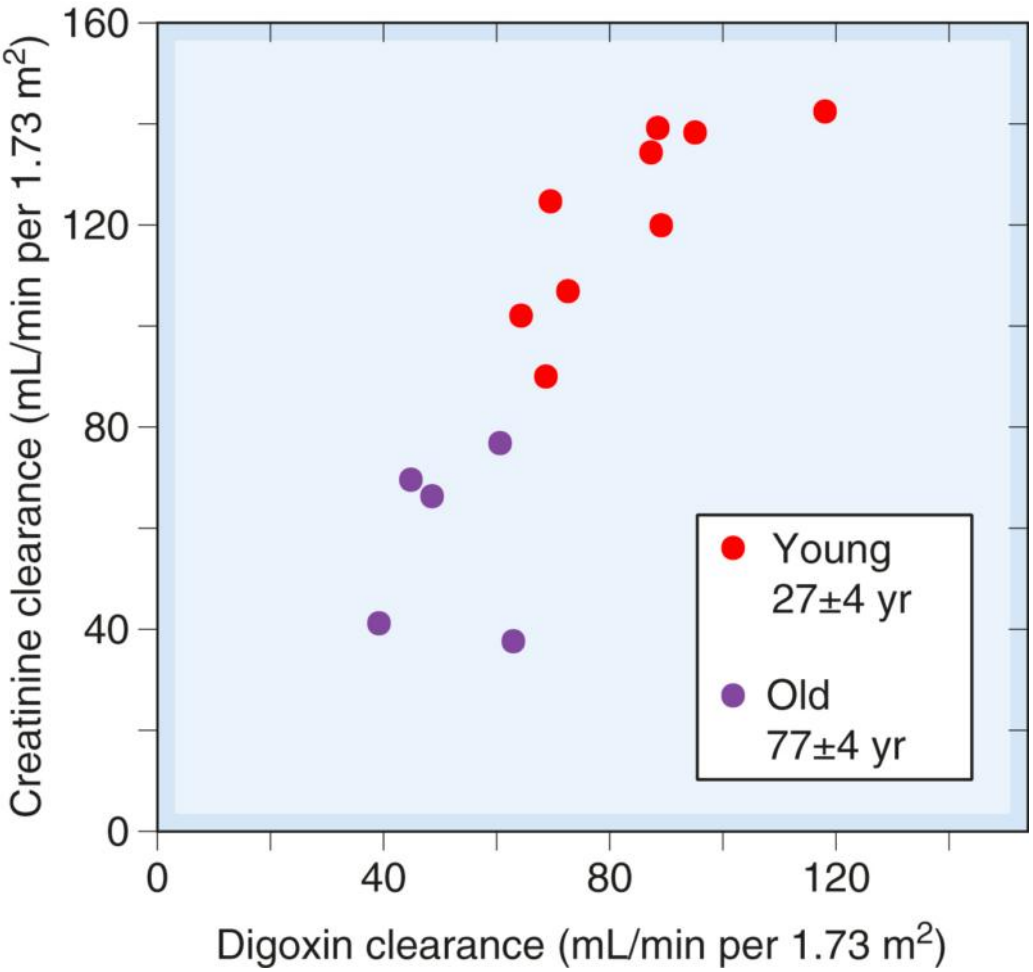

FIG. 12.1 Relationship between renal function (measured as creatinine clearance) and digoxin clearance in young and older subjects. From Ewy, G.A., et al., 1969. Circulation 34, 452.

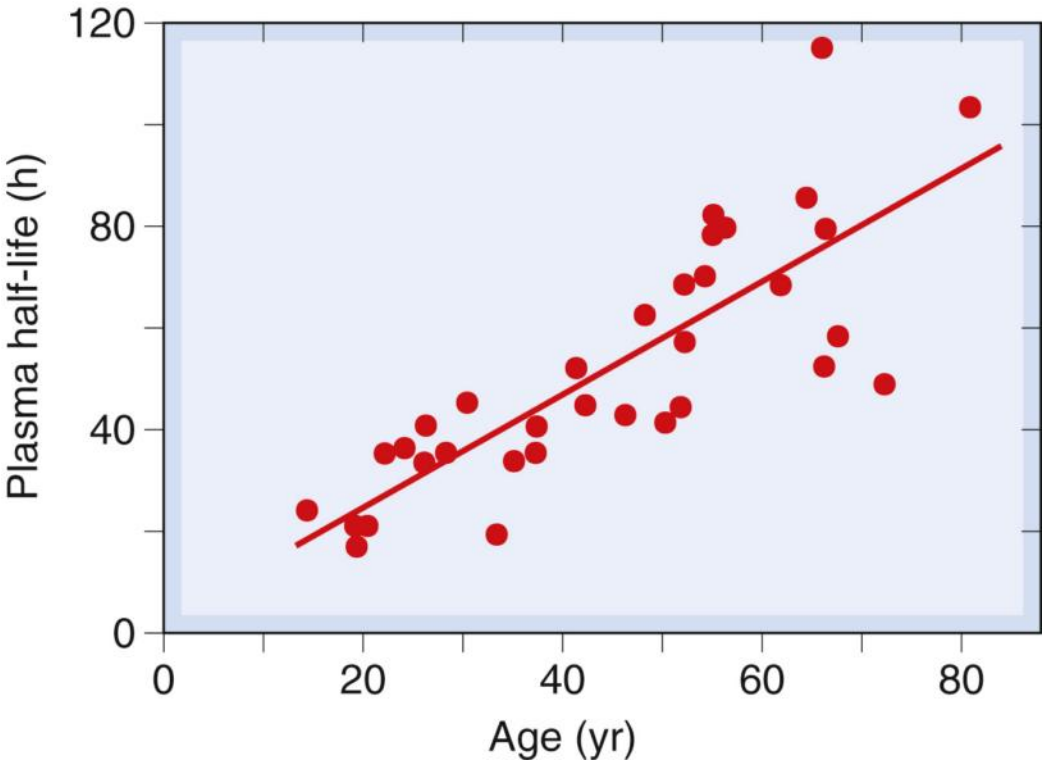

FIG. 12.2 Increasing plasma half-life for diazepam with age in 33 normal subjects. Note the increased variability as well as increased half-life with ageing. (From Klotz, U., et al., 1975. J. Clin. Invest. 55, 347.

The activity of hepatic microsomal enzymes declines slowly (and very variably) with age, and the distribution volume of lipid-soluble drugs increases, because the proportion of the body that is fat increases with advancing age. The increasing half-life of the anxiolytic drug **diazepam** with advancing age (**Fig. 12.2**) is one consequence of this. Some other benzodiazepines and their active metabolites show even greater age-related increases in half-life. Because half-life determines the time course of drug accumulation during repeated dosing (see **Ch. 11**), insidious effects, developing over days or weeks, can occur in elderly people and may be

misattributed to age-related memory impairment rather than to drug accumulation. Even if the mean half-life of a drug is little affected, there is often a striking increase in the *variability* of half-life between individuals with increasing age (as in **Fig. 12.2**). This is important, because a population of older people will contain some individuals with grossly reduced rates of drug metabolism, whereas such extremes do not occur so commonly in young adult populations. Drug regulatory authorities therefore usually require studies in elderly persons as part of the evaluation of drugs likely to be used in older people (similarly for potential use in children).

Age-Related Variation in Sensitivity to Drugs

The same plasma concentration of a drug can cause different effects in young and old subjects. Benzodiazepines (see **Ch. 45**) exemplify this, producing more confusion and less sedation in elderly than in young subjects; similarly, hypotensive drugs (see **Ch. 21**) cause postural hypotension more commonly in elderly than in younger adult patients.

Pregnancy

Pregnancy causes physiological changes that influence drug disposition in mother and fetus. Maternal plasma albumin concentration is reduced, influencing drug protein binding. Cardiac output is increased, leading to increased renal blood flow and GFR, and increased renal elimination of drugs. Lipophilic molecules rapidly traverse the placental barrier, whereas transfer of hydrophobic drugs is slow, limiting fetal drug exposure following a single maternal dose. The placental barrier excludes some drugs (e.g. low molecular-weight heparins; see **Ch. 23**) so effectively that

they can be administered chronically to the mother without causing effects in the fetus. However, drugs that are transferred to the fetus are eliminated more slowly than from the mother. The activity of most drug-metabolising enzymes in fetal liver is much less than in the adult. Furthermore, the fetal kidney is not an efficient route of elimination because excreted drug enters the amniotic fluid, which is swallowed by the fetus. For a fuller account, see **Huang et al. (2021)**.

Disease

Therapeutic drugs are prescribed to patients, so the effects of disease on drug response are very important, especially disease of the major organs responsible for drug metabolism and drug (and drug metabolite) excretion. Detailed consideration is beyond the scope of this book and interested readers should refer to a clinical text such as the chapters on renal and hepatic disease in **Huang et al. (2021)**. Disease can cause pharmacokinetic or pharmacodynamic variation. Common disorders such as impaired renal or hepatic function predispose to toxicity by causing unexpectedly intense or prolonged drug effects as a result of increased drug concentration following a 'standard' dose. Drug absorption is slowed in conditions causing gastric stasis (e.g. migraine, diabetic neuropathy) and may be incomplete in patients with malabsorption owing to ileal or pancreatic disease or to oedema of the ileal mucosa caused by heart failure or nephrotic syndrome. *Nephrotic syndrome* (characterised by heavy proteinuria, oedema and a reduced concentration of albumin in plasma) alters drug absorption because of oedema of intestinal mucosa; alters drug

disposition through changes in binding to plasma albumin; and causes insensitivity to diuretics such as **furosemide** that act on ion transport mechanisms in the lumenal surface of tubular epithelium (see **Ch. 29**), through drug binding to albumin in tubular fluid. *Hypothyroidism* is associated with increased sensitivity to several drugs (e.g. **pethidine**), for reasons that are poorly understood. *Hypothermia* (to which elderly persons, in particular, are predisposed) markedly reduces the clearance of many drugs.

Other disorders affect drug sensitivity by altering receptor or signal-transduction mechanisms (see **Ch. 3**). Examples include the following:

- Diseases that influence receptors:
  - *myasthenia gravis*, an autoimmune disease characterised by antibodies to nicotinic acetylcholine receptors (see **Ch. 14**) and increased sensitivity to neuromuscular-blocking agents (e.g. **vecuronium**) and other drugs that may influence neuromuscular transmission (e.g. *aminoglycoside antibiotics*; see **Ch. 52**);
  - *X-linked nephrogenic diabetes insipidus*, characterised by abnormal antidiuretic hormone (ADH; vasopressin) receptors (see **Ch. 29**) and insensitivity to ADH;
  - *familial hypercholesterolaemia*, an inherited disease of low-density lipoprotein receptors (see **Ch. 22**); the homozygous form is relatively resistant to treatment with statins (which act partly by causing increased hepatic expression of these receptors), whereas the

much commoner heterozygous form responds well to statins.

- Diseases that influence signal-transduction mechanisms:
  - *pseudohypoparathyroidism*, which stems from impaired coupling of G protein–coupled receptors with adenylyl cyclase;
  - *familial precocious puberty* and *hyperthyroidism* caused by functioning thyroid adenomas, which are each caused by mutations in G protein–coupled receptors that result in the receptors remaining 'turned on' even in the absence of the hormones that are their natural agonists.

Drug Interactions

Many patients, especially if elderly are treated continuously with one or more drugs for chronic diseases such as hypertension, heart failure, osteoarthritis and so on. Acute events (e.g. infections, myocardial infarction) are treated with additional drugs. The potential for drug interactions is therefore substantial, and drug interactions account for 5%–20% of adverse drug reactions. These may be serious (approximately 30% of fatal adverse drug reactions are estimated to be the consequence of drug interaction). Drugs can also interact with chemical entities in other dietary constituents (e.g. grapefruit juice, which down-regulates expression of CYP3A4 in the gut) and herbal remedies (such as St John's wort; see **Ch. 48**). The administration of one chemical entity (A) can alter the action of another (B) by one of two general mechanisms [1] :

1. Modifying the pharmacological effect of B without altering its concentration in the tissue fluid (pharmacodynamic interaction).
2. Altering the concentration of B at its site of action (pharmacokinetic interaction), as described in **Chapters 9** and 10.

Pharmacodynamic Interaction

Pharmacodynamic interaction can occur in many different ways (including those discussed under *Drug antagonism* in **Ch. 2**). There are many mechanisms, and some examples of practical importance are probably more useful than attempts at classification.

- β-Adrenoceptor antagonists diminish the effectiveness of β-adrenoceptor agonists such as **salbutamol** (see **Ch. 15**).
- Many diuretics lower plasma K^+ concentration (see **Ch. 29**), and thereby predispose to **digoxin** toxicity and to toxicity with *class III antidysrhythmic drugs* (see **Ch. 20**).
- **Sildenafil** inhibits the isoform of phosphodiesterase (type V) that inactivates cGMP (see Chs **19** and **35**); consequently, it potentiates organic nitrates, which activate guanylyl cyclase, and can cause severe hypotension in patients taking these drugs.
- *Monoamine oxidase inhibitors* increase the amount of noradrenaline stored in noradrenergic nerve terminals and interact dangerously with drugs, such as **ephedrine** or **tyramine**, which release stored noradrenaline. This can also occur with tyramine-rich foods – particularly fermented cheeses such as Camembert (see **Ch. 48**).

- **Warfarin** competes with vitamin K, preventing hepatic synthesis of various coagulation factors (see **Ch. 23**). If vitamin K production in the intestine is inhibited (e.g. by antibiotics), the anticoagulant action of warfarin is increased.
- The risk of bleeding, especially from the stomach, caused by warfarin is increased by drugs that cause bleeding by different mechanisms (e.g. **aspirin**, which inhibits platelet thromboxane A_2 biosynthesis and which can damage the stomach; see **Ch. 25**).
- *Sulfonamides* prevent the synthesis of folic acid by bacteria and other microorganisms; **trimethoprim** inhibits its reduction to its active tetrahydrofolate form. Given together, the drugs have a synergistic action of value in treating *Pneumocystis* infection (see Chs **54** and **55**).
- *Non-steroidal anti-inflammatory drugs* (NSAIDs; see **Ch. 25**), such as **ibuprofen** or **indometacin**, inhibit biosynthesis of prostaglandins, including renal vasodilator/natriuretic prostaglandins (prostaglandin E_2, prostaglandin I_2). If administered to patients receiving treatment for hypertension, they increase the blood pressure. If given to patients being treated with diuretics for chronic heart failure, they cause salt and water retention and hence cardiac decompensation. [2]
- Histamine H_1-receptor antagonists, such as **promethazine**, commonly cause drowsiness as an unwanted effect. This is more troublesome if such drugs are taken with alcohol, leading to accidents at work or on the road.

Pharmacokinetic Interaction

All the four major processes that determine pharmacokinetics – absorption, distribution, metabolism and excretion (ADME) – can be affected by drugs. For instance, absorption and distribution interactions can arise between compounds with shared transporters (see **Ch. 9**). Further details on pharmacokinetic interactions are covered in **Chapters 9** and 10.

Drug interactions

- These are many and varied: if in doubt, look it up.
- Interactions may be pharmacodynamic or pharmacokinetic.
- Pharmacodynamic interactions are often predictable from the actions of the interacting drugs.
- Pharmacokinetic interactions can involve effects on:
  - absorption (see **Ch. 9**)
  - distribution (e.g. competition for protein binding, see **Ch. 9**)
  - hepatic metabolism (induction or inhibition, see **Ch. 10**)
  - renal excretion (see **Ch. 10**)

Genetic Variation in Drug Responsiveness

A patient's response to a particular drug may be influenced by a rare genetic trait, or a complex multifactorial trait involving effects of several genetic and environmental factors. Complex traits may not adhere to typical Mendelian or familial inheritance because they

involve the additive or synergistic influence of multiple gene variants that can interact with environmental factors to result in a wide spectrum of inter-individual drug response. Potential pharmacogenetic markers of variation may include measurable differences in gene expression or functional deficiencies related to genetic factors, i.e. somatic or germline mutations and chromosomal abnormalities.

Mutations are heritable changes in the base sequence of DNA. These may, or may not, [3] result in a change in the amino acid sequence of the protein for which the gene codes. *Germline* or *hereditary* mutations are those that affect the body's reproductive cells (egg or sperm) and can be passed to the next generation where they are present in all cells. In practice, tests for such germline mutations in individuals are usually made on venous blood samples that contain chromosomal and mitochondrial DNA in white blood cells. Germline genetic variations that contribute to differences in drug response and adverse effects in specific populations can be assessed in large cohort or case-control studies that use microarrays or whole genome/exome sequencing strategies to analyse several million genetic variants. The recent emergence of high-throughput genotyping technology has enabled genome-wide association studies to identify loci that are potentially linked to drug effect.

Somatic or *acquired* mutations are not present at birth but can occur in any of the body cells (except the ova and sperm) during a lifetime and are not passed on to the offspring. Whilst the vast majority of somatic mutations are thought to have no clinical consequence, those that affect key signalling pathways involved in cell growth, division and differentiation can predispose to

carcinogenesis, as well as late-onset mitochondrial and neurogenerative disorders. Somatic cell mutations underlie the pathogenesis of some tumours (see **Ch. 6**), and the presence or absence of such somatic cell mutations guides drug selection. The genomic tests are performed on DNA from samples of the tumour obtained surgically. The tests themselves involve amplification of the relevant sequence(s) and molecular biological methods, often utilising chip technology, to identify the various polymorphisms.

Genetic variation or mutations are not always deleterious and they may confer an advantage under some environmental circumstances. A pharmacogenetically relevant example is the X-linked gene for *glucose 6-phosphate dehydrogenase* (G6PD); deficiency of this enzyme confers partial resistance to malaria (a considerable selective advantage in parts of the world where this disease is common) at the expense of susceptibility to haemolysis in response to oxidative stress in the form of exposure to various dietary constituents, including several drugs (e.g. the antimalarial drug **primaquine**; see **Ch. 55**). This ambiguity gives rise to the abnormal gene being preserved in future generations, at a frequency that depends on the balance of selective pressures in the environment. Thus the distribution of G6PD deficiency is similar to the geographical distribution of malaria. The situation where functionally distinct forms of a gene are common in a population is called a 'balanced' polymorphism (balanced because a disadvantage, for example in a homozygote, is balanced by an advantage, for example in a heterozygote).

Polymorphisms are relatively common variants (alternative sequences at a locus within the DNA strand) that are found in >1%

of individuals within a given population. They arise initially because of a mutation, and are stable if they are non-functional, or die out during subsequent generations if (as is usually the case) they are disadvantageous. However, if the prevailing selective pressures in the environment are favourable, leading to a selective advantage, a polymorphism may increase in frequency over successive generations. Now that genes can be sequenced readily, it has become apparent that *single nucleotide polymorphisms* ([SNPs] – DNA sequence variations that occur when a single nucleotide in the genome sequence is altered) are very common. They may entail substitution of one nucleotide for another (substitution of C for T in two-thirds of SNPs), or deletion or insertion of a nucleotide. Insertions and deletions of one or more nucleotides (other than when the change in number of nucleotides is a multiple of three) result in a 'frame shift' in translation. For example, after an insertion of one nucleotide, the first element of the next triplet in the code becomes the second and all subsequent bases are shifted one 'to the right'. Changes to the coding region of a gene may result in loss of protein synthesis, abnormal protein synthesis or an abnormal rate of protein synthesis.

On average, SNPs occur once in every 300 bases along the 3-billion base human genome, thus resulting in the presence of about 10 million SNPs. They can occur in coding (gene) and non-coding regions of the genome, and they may have a greater role in physiological function if located within a gene or in a regulatory sequence close to the gene. Whilst many SNPs do not have a clear association with health conditions, some SNPs have a demonstrable relationship with susceptibility to harmful chemicals, magnitude of

drug response and likelihood of developing a disease. For example, SNPs affecting the *F5* gene can cause factor V Leiden blood-clotting disorder, which is the commonest form of inherited thrombophilia (see **Ch. 23**). The abnormality in the factor V clotting factor confers an increased risk of venous thrombosis in response to environmental factors such as prolonged immobility, but might perhaps have been an advantage to ancestors more at risk of haemorrhage than of thrombosis.

Single-Gene Pharmacokinetic Disorders

The classical Mendelian model contrasts with the complex disease paradigm because it applies to single-gene or monogenic disorders where a mutation in a gene is the primary or sole cause of profound disruption. These are typically rare disorders where the underlying genetic variants have very high penetrance with inheritance patterns that are readily predicted in a Mendelian fashion. This was recognised for albinism (albinos lack an enzyme that is needed to synthesise the brown pigment melanin) and other 'inborn errors of metabolism' in the early part of the 20th century by Archibald Garrod, a British physician who initiated the study of biochemical genetics. Investigation of this large group of individually rare diseases has contributed to our understanding of this particular aspect of molecular pathology – familial hypercholesterolaemia and the mechanism of action of statins (see **Ch. 22**) is one example; further examples of single-gene disorders are given in the following.

Plasma Cholinesterase Deficiency

In the 1950s Walter Kalow discovered that **suxamethonium** sensitivity is due to genetic variation in the rate of drug metabolism

as a result of a Mendelian autosomal recessive trait. This short-acting neuromuscular-blocking drug is widely used in anaesthesia and is normally rapidly hydrolysed by plasma cholinesterase (see **Ch. 14**). About 1 in 3000 individuals fails to inactivate suxamethonium rapidly and experiences prolonged neuromuscular block if treated with it; this is because a recessive gene gives rise to an abnormal type of plasma cholinesterase. The abnormal enzyme has a modified pattern of substrate and inhibitor specificity. It is detected by a blood test that measures the effect of **dibucaine**, which inhibits the abnormal enzyme less than the normal enzyme. Heterozygotes can hydrolyse suxamethonium at a more or less normal rate, but their plasma cholinesterase has reduced sensitivity to dibucaine, intermediate between normal subjects and homozygotes. Only homozygotes express the disease: they appear completely healthy unless exposed to suxamethonium or **mivacurium** (which is also inactivated by plasma cholinesterase) but experience prolonged paralysis if exposed to a dose that would cause neuromuscular block for only a few minutes in a healthy person. [4] There are other reasons why responses to suxamethonium may be abnormal in an individual patient, notably *malignant hyperpyrexia* (see **Ch. 14**), a genetically determined idiosyncratic adverse drug reaction involving the ryanodine receptor (see **Ch. 4**). It is important to check the family history and test family members who may be affected, but the disorder is so rare that it is currently impractical to screen for it routinely before therapeutic use of suxamethonium.

Acute Intermittent Porphyria

The hepatic *porphyrias* are prototypic pharmacogenetic disorders in which patients may be symptomatic even if they are not exposed to a drug, but where many drugs can provoke very severe worsening of the course of the disease. They are inherited disorders involving the biochemical pathway of porphyrin haem biosynthesis. *Acute intermittent porphyria* is the most common acute and severe form. It is inherited as an autosomal dominant trait and is due to one of many different mutations in the gene coding *porphobilinogen deaminase* (PBGD), a key enzyme in haem biosynthesis in red cell precursors, hepatocytes and other cells. All of these mutations reduce the activity of this enzyme, and clinical features are caused by the resulting build-up of haem precursors, including porphyrins. There is a strong interplay with the environment through exposure to drugs, hormones and other chemicals. The use of sedative, anticonvulsant or other drugs in patients with undiagnosed porphyria can be lethal, although with appropriate supportive management most patients recover completely. [5] Many drugs, especially but not exclusively those that induce CYP enzymes (e.g. barbiturates, **griseofulvin**, **carbamazepine**, oestrogens – see **Ch. 10**), can precipitate acute attacks in susceptible individuals. Porphyrins are synthesised from δ-amino laevulinic acid (ALA), which is formed by ALA synthase in the liver. This enzyme is induced by drugs such as barbiturates, resulting in increased ALA production and, hence, increased porphyrin accumulation. As mentioned previously, the genetic trait is inherited as an autosomal dominant trait, but frank disease is approximately five times more common in women than in men, because hormonal fluctuations precipitate acute attacks. Intriguingly, acute intermittent porphyria

can now be treated with **givosiran**, a small interfering RNA that reduces ALA synthase mRNA (and currently one of the world's most expensive drugs), thus alleviating the build up of neurotoxins that are implicated in porphyria attacks.

Therapeutic Drugs and Clinically Available Pharmacogenomic Tests

Clinical tests to predict drug responsiveness were anticipated to be one of the first applications of sequencing the human genome. Although a profusion of new pharmacogenetic tests are now marketed to healthcare professionals as well as direct to consumer, the adoption and implementation in routine clinical practice have been slowed by various scientific, commercial, political and educational barriers. Reimbursement for expensive tests and drugs, whether provided by the state or by insurance schemes, depends increasingly on evidence of cost-effectiveness. Here, new pharmacogenetic tests are required to have a positive or meaningful influence on prescribing practice, such as the use of a validated alternative drug or different dosing regimen that leads to measurable improvements in patient outcomes (**Khoury and Galea, 2016**; **Manrai et al., 2016**). The need for reliable evidence regarding clinical and cost-effectiveness of any diagnostic or prognostic test has stimulated increasing numbers of randomised controlled trials of pharmacogenomics-informed prescribing strategy versus current best practice.

However, evaluation of drug response in complex multifactorial traits is a major challenge because multiple genes and genetic variants interact with environmental factors, and the genetic

component may only have a modest influence on treatment effect. Much of the earlier research has been focused on striking single pathogenic variants that have readily apparent or clear-cut 'all or none' treatment effect. In reality, however, the probability of drug benefit and harm is often a continuum with a wide range of variation across individuals in a population (**Manrai et al., 2016**), and reliance on a single predictive genetic biomarker may not be sufficiently precise or reliable to guide treatment of serious disease. Equally, we recognise that clinicians already tailor treatment according to a multitude of biomarkers such as age, renal function, body surface area and so on. Here, healthcare providers need greater clarity regarding extent of improvement or added value from implementing new clinical pathways based on genetic information.

The clinical setting is another important factor to consider. At present, many of the largest genetic research studies are carried out in resource-rich areas with a predominantly White population. Hence, we are uncertain about the applicability of the studies to wider locations around the world, particularly with areas that have more diverse non-White populations. Equally much of the focus has been on personalising cancer treatments delivered in specialist oncology centres, where the available genetic information is directly relevant to choosing one particular type of drug or another. However, the situation is much more complex in primary care where the prescriber has to deal with patients who are burdened with polypharmacy. Multiple genetics tests of diverse medications would need to be interpreted together with the full medical history and other biomarkers.

The key steps in evaluating pharmacogenetic markers in clinical care should be confirmation of analytic validity (accuracy and reliability of the test) and determination of a robust, replicable relationship between the marker and drug response in the population (clinical validity). Clinical utility must then be demonstrated through improved efficacy or safety in patients receiving the biomarker-guided therapeutic regimens. There are also health economic considerations as to whether the genetic markers are of sufficiently high frequency in their patient population to justify the costs of screening. Policy makers and funding agencies will then have to look at feasibility of using the biomarker testing strategy in a way that does not delay patient treatment. Here, the historical approach of single-gene as needed, or 'one at a time' testing can seem slow, inefficient and costly when compared with the recent availability of pre-emptive testing for multiple genetic markers. The growing availability of rapid testing using multi-gene panels means that the individual's genetic data from a single sample can be used to inform many different treatment decisions that subsequently arise in their lifetime.

At present, pharmacogenetic evaluation can include tests for (a) variants of different human leukocyte antigens (HLAs) that have been strongly linked to susceptibilities to several severe harmful drug reactions that are likely to have arisen from an immunological interaction between the drug molecule and the major histocompatibility molecules in the patient (**Chan et al., 2015**) (b) genes controlling aspects of drug metabolism; and (c) genes encoding drug targets, where the concept of 'companion diagnostics' (defined by the FDA as: 'a diagnostic test used as a companion to a

therapeutic drug to determine its applicability to a specific person') involves detection of a pharmacogenetic marker so that rational drug selection can be made based on the pathway related to the underlying mutation. For one drug (**warfarin**), a test would need to combine genetic information about metabolism with information about its target (see **Fig 12.3**).

Pharmacogenetics and pharmacogenomics

- Several inherited disorders influence responses to drugs, including single-gene conditions such as:
  - *glucose 6-phosphate dehydrogenase deficiency,* a sex-linked disorder in which affected men (or rare homozygous women) experience haemolysis if exposed to various chemicals including the antimalarial drug **primaquine**;
  - *plasma cholinesterase deficiency,* an autosomal recessive disorder that confers sensitivity to the neuromuscular blocker suxamethonium;
  - *acute intermittent porphyria,* an autosomal dominant disease more severe in women and in which severe attacks are precipitated by drugs or endogenous sex hormones that induce CYP enzymes;
- SNPs and combinations of SNPs (haplotypes) in genes coding for proteins involved in drug disposition or drug action are common and may predict drug response. Pharmacogenomic tests in blood or tissue removed surgically have established

associations between several such variants and individual drug response.

- Such tests are available for:
  - several HLA variants that predict toxicity of **abacavir** and **carbamazepine**;
  - genes for several enzymes in drug metabolism including CYP2D6 and CYP2C9, DPYD and thiopurine-*S*-methyltransferase (TPMT);
  - germline and somatic mutations in growth factor receptors that predict responsiveness to cancer treatments including **imatinib** and **trastuzumab.**

Incorporating Pharmacogenetic Data Into Daily Clinical Workflows

One of the major challenges relates to the multiple hurdles spanning the scientific discovery of an important genetic marker to the actual delivery of a tailored treatment plan guided by this new knowledge. The wide availability of large throughput studies and electronic patient databases means that even modest genetic associations can now be readily detected. However, these discoveries come with uncertain clinical relevance, particularly with regards to strength of evidence and the actual size of the genetic contribution to treatment response, given that there are a multitude of influential physiological and environmental factors in the melee. Moreover, whilst 'clinically actionable' is the present 'buzzword' to describe important genetic information, no one knows exactly what the correct clinical action is, nor if any specific pathway is better or

worse than alternative ones. This has led to discrepant or divergent treatment recommendations amongst learned bodies that assess pharmacogenomic data (**Abdullah-Koolmees et al., 2020**). Inevitably, the busy clinician, when considering a pharmacogenetic test, will be confronted with three key questions – is this the right situation to request a genetic test, how should the data be interpreted, and is there a universally agreed recommended course of action?

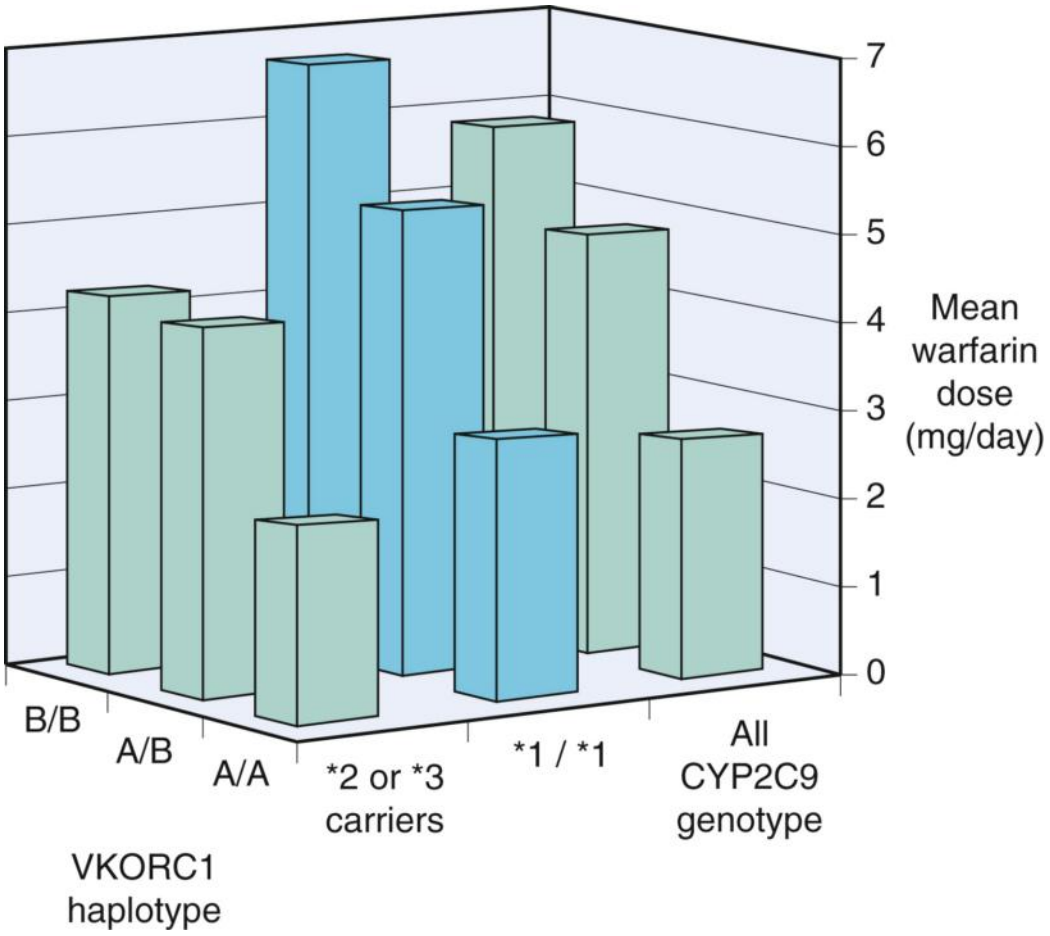

FIG. 12.3 Effect of *VKOR* haplotype and *CYP2C9* genotype on warfarin dose.A series of 186 patients on long-term warfarin treatment who had already been studied for *CYP2C9* were studied retrospectively for genetic variants of *VKOR* (**Rieder et al., 2005**). *VKOR* haplotype as well as *CYP2C9* genotype influenced the mean warfarin dose (which had been adjusted to achieve therapeutic International Normalised Ratio). *A,* Haplotypes 1 and 2; *B,* haplotypes 7, 8 and 9. *A/A, A/B* and *B/B* represent haplotype combinations. **1/*1* represents CYP2C9 wild-

type homozygotes; **2* and **3* represent CYP2C9 variants. Figure redrawn from Beitelshees, A.L., McLeod, H.L., 2006. Applying pharmacogenomics to enhance the use of biomarkers for drug effect and drug safety. TIPS 27, 498–502.

There are a number of examples as how this might pan out in current clinical practice (for further reading, see **Mehta et al., 2020**).

Indications

Here, we describe examples where genetic information helps us decide whether the particular drug is indicated, or not.

Trastuzumab ('Herceptin'; **Ch. 57**) is a monoclonal antibody that antagonises epidermal growth factor (EGF) by binding to one of its receptors (human EGF receptor 2 – HER2) which can occur in tumour tissue as a result of somatic mutation. It is used in patients with breast cancer whose tumour tissue is positive for this receptor.

Dasatinib and imatinib are first-line tyrosine kinase inhibitors used in haematological malignancies characterised by the presence of a Philadelphia chromosome, namely chronic myeloid leukaemia (CML) and in some adults with acute lymphocytic leukaemia (ALL). The Philadelphia chromosome results from a translocation defect when parts of two chromosomes (9 and 22) swap places; part of a 'breakpoint cluster region' (BCR) in chromosome 22 links to the 'Abelson-1' (ABL) region of chromosome 9. A mutation (T315I) in BCR/ABL confers resistance to the inhibitory effect of dasatinib and patients with this variant do not benefit from this drug. Instead,

ponatinib is licensed in the United States for treatment of patients who have this BCR-ABL T315I mutation.

Drug treatment options for cystic fibrosis (an autosomal recessive condition involving the cystic fibrosis transfer receptor) include channel potentiators and channel correctors that are efficacious for patients who carry specific genetic mutations (see **Ch. 28** for further details).

There are now small-molecule-based treatments specifically targeted at patients with certain defined inherited conditions. These include givosiran for acute intermittent porphyria (see earlier) and **eteplersen** (an antisense oligomer that acts on mRNA to restore dystrophin production) for patients with highly specific mutations that cause Duchenne/Becker muscular dystrophy.

Dosage Adjustment Based on Genetic Predictors of Drug Metabolism

Here, we highlight two prominent examples where dosing schedule is can be guided by evaluation of genetic variants.

Thiopurine drugs (**tioguanine**, **mercaptopurine** and its prodrug **azathioprine**; **Ch. 57**) have been used for more than 50 years to treat leukaemias, and more recently to cause immunosuppression, for example, in treating inflammatory disorders involving the bowel, skin, or joints. These drugs are detoxified by thiopurine-*S*-methyltransferase (TPMT), which is present in blood cells, as well as by xanthine oxidase. Reduced starting doses are recommended for patients who have genotypes associated with reduced metabolism. Even with such testing, careful monitoring of the white blood cell count is needed because genetic

testing cannot fully account for toxicity, and there are also environmental susceptibility factors.

5-FU (see **Ch. 57**, **Fig. 57.6**) and related compounds such as capecitabine and tegafur are used extensively to treat solid tumours, but have a narrow therapeutic window and serious toxicity (neutropaenia, vomiting, diarrhoea, mucocutaneous syndromes) in 10%–40% of patients, resulting in a fatality rate of about 1 in 100 overall. Approximately 80% of 5-FU is detoxified by dihydropyrimidine dehydrogenase (DPYD), which has four main clinically important genetic variants that account for 20%–30% of the cases suffering from life-threatening toxicity. Identification of the variants helps to guide dose reductions, more gradual dose increments, and even the choice of moving to a different type of chemotherapy.

Screening Out Patients Who are Highly Susceptibile to Serious Adverse Drug Reactions

Here, we highlight two prominent examples where evaluation of genetic variants can help us avoid prescribing drugs that can cause serious harm to certain susceptible individuals.

▾ **Abacavir** (see **Ch. 53**) is a reverse transcriptase inhibitor that is highly effective in treating HIV infection. Its use has been limited by severe rashes. Susceptibility to this adverse effect is closely linked to the HLA variant *HLAB*5701*, and testing for this variant is now considered a standard of care supported by prospective randomised trials (**Fig. 12.4**; **Martin and Kroetz, 2013**).

Carbamazepine (see **Ch. 46**) can also cause severe (life-threatening) rashes including *Stevens–Johnson syndrome* and *toxic*

epidermal necrolysis (multiform rashes with painful blistering lesions and skin detachment sometimes extending into the gastrointestinal tract) and now considered to be a disease continuum distinguished chiefly by severity, based upon the percentage of body surface involved with skin detachment. These are associated with a particular HLA allele, *HLAB*1502,* which occurs more commonly in ethnic groups in Thailand, Malaysia and Taiwan (**Barbarino et al., 2015**), but with far lower frequencies in Korean, Japanese and White populations. Screening for this allele before starting treatment is potentially worthwhile in populations where the allele frequency is high.

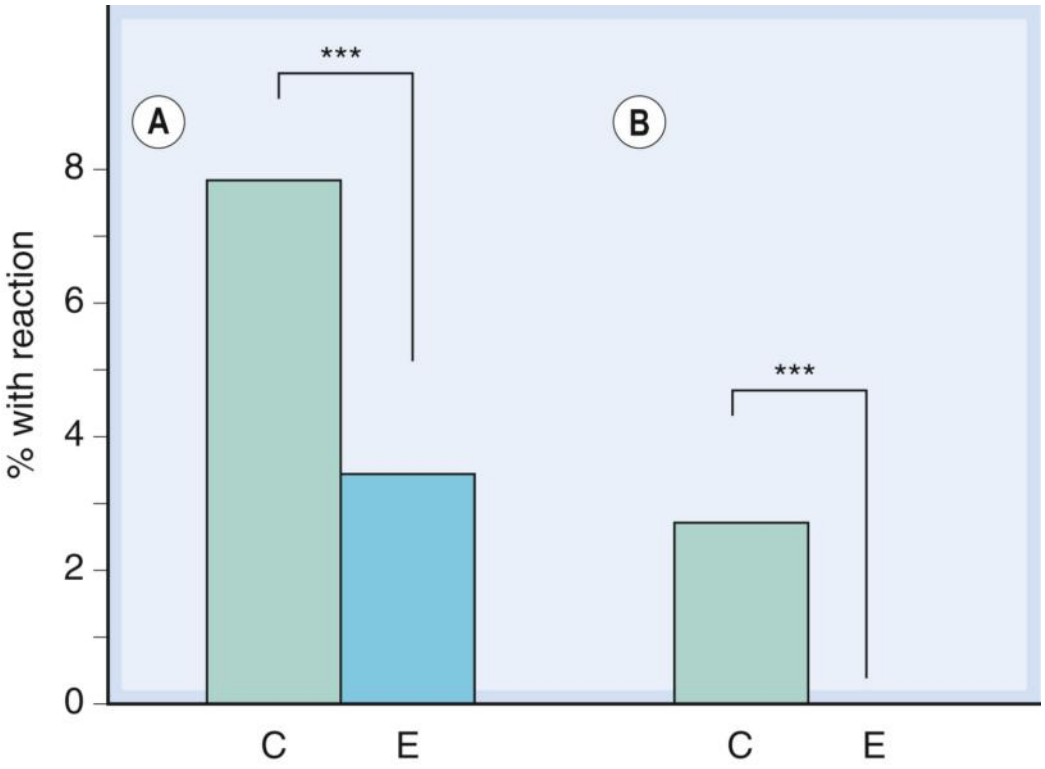

FIG. 12.4 Incidence of abacavir hypersensitivity is reduced by pharmacogenetic screening.In the PREDICT-1 study (**Mallal et al., 2008**), patients were randomised to standard care (*C,* control group) or prospective pharmacogenetic screening (*E,* experimental group). All the control subjects were treated with abacavir, but only those experimental subjects who were *HLA-B*5701* negative were treated with abacavir. There were two prespecified end points: clinically suspected hypersensitivity reactions (A) and clinically suspected reactions that were immunologically confirmed by a positive patch test (B). Both end points favoured the experimental group ($p < 0.0001$). Figure

redrawn from Hughes, A.R., et al., 2008. Pharmacogenet. J. 8, 365–374.

Communicating the Presence or Absence of Risk

Here, a particular drug may have been specifically tested in people with different genetic variants, and there may be information on extent of risk, if any. For instance, the product information for lacosamide (used in the treatment of epilepsy) states that there was no clinically relevant difference in lacosamide exposure when comparing extensive metabolisers against poor metabolisers according to CYP2C19 status.

Conclusions

Twin studies as well as several well-documented single-gene disorders (including Mendelian chromosomal – autosomal recessive, autosomal dominant and X-linked – and maternally inherited mitochondrial disorders) prove the concept that susceptibility to adverse drug effects can be genetically determined. Pharmacogenomic testing offers the possibility of more precise ‘personalised’ therapeutics for several drugs and disorders, but high-quality trial evidence of clinical utility in diverse populations is still being pursued, particularly in instances where drug response is influenced by complex multifactorial traits. This is a field of intense research activity, rapid progress and high expectations, but proving that these tests consistently add to present best practice and improve outcomes remains a key goal.

QUESTIONS

QUESTION 12.1

Pharmacokinetic variation can be caused by different concentrations of the drug at sites of drug action and can occur because of differences in absorption, distribution, metabolism or excretion.

What would be the main contributing factor to pharmacokinetic variation in a 40-year-old Asian gentleman with nephrotic syndrome?

OPTIONS:

A. His age

B. His ethnicity

C. His glomerular filtration rate (GFR)

D. The presence of oedema

E. Variation in his hepatic microsomal enzymes

QUESTION 12.2

The administration of one chemical entity can alter the action of another leading to synergism or antagonism of the pharmacological effect.

Which of the following combinations would lead to a beneficial drug interaction?

OPTIONS:

A. Sulfonamides and trimethoprim

B. Thiopental and suxamethonium

C. Sildenafil and organic nitrates

D. Diuretics and digoxin

E. Warfarin and antibiotics

ANSWERS

ANSWER 12.1

RATIONALE:

A. Body composition varies with age but only impacts significantly on drug pharmacodynamics in the young or elderly.

B. Members of racial groups share some characteristics on the basis of common genetic and cultural heritage, but there is enormous diversity within each group.

C. GFR only impacts significantly on drug pharmacodynamics in the young or elderly.

D.

E. The activity of the enzymes declines slowly with age. Activity can also be affected by polymorphic variation and interacting drugs.

CORRECT AnSWER WITH EXPLANATION:

D. Drug absorption is significantly decreased in patients with ileal oedema which occurs in nephrotic syndrome.

ANSWER 12.2

RATIONALE:

A.

B. Interactions between thiopental and suxamethonium results in the formation of a complex and therefore must not be mixed in the same syringe.

C. Sildenafil inhibits the isoform of phosphodiesterase (type V) that inactivates cGMP; consequently, it potentiates organic nitrates, which activate guanylyl cyclase, and can cause severe hypotension in patients taking these drugs.

D. Many diuretics lower plasma K^+ concentration and thereby predispose to digoxin toxicity.

E. Warfarin competes with vitamin K, preventing hepatic synthesis of various coagulation factors. If vitamin K production in the intestine is inhibited (e.g. by antibiotics), the anticoagulant action of warfarin is increased.

CORRECT ANSWER WITH EXPLANATION:

A. Sulfonamides and trimethoprim

Sulfonamides prevent the synthesis of folic acid by bacteria and other microorganisms; trimethoprim inhibits its reduction to its active tetrahydrofolate form. Given together, the drugs have a synergistic action of value in treating *Pneumocystis* infection.

[1] A third category of pharmaceutical interactions should be mentioned, in which drugs interact in vitro so that one or both are inactivated. No pharmacological principles are involved, just chemistry. An example is the formation of a complex between **thiopental** and **suxamethonium**, which must not be mixed in the same syringe. **Heparin** is highly charged and interacts in this way with many basic drugs; it is sometimes used to keep

intravenous lines or cannulae open and can inactivate basic drugs if they are injected without first clearing the line with saline.

2 The interaction with diuretics may involve a pharmacokinetic interaction in addition to the pharmacodynamic effect described here, because NSAIDs compete with weak acids, including diuretics, for renal tubular secretion; see Chapter 10.

3 The genetic code is said to be 'degenerate' because of presence of redundancy, where more than one set of nucleotide base triplets code for each amino acid. A 'silent' mutation with no change in the protein and consequently no change in function can stem from a base change involving a triplet that codes for the same amino acid as the original. Such mutations are neither advantageous nor disadvantageous, so they will neither be eliminated by natural selection nor accumulate in the population at the expense of the wild-type gene.

4 An apparently healthy middle-aged man saw one of the authors over several months because of hypertension; he also saw a psychiatrist because of depression. This failed to improve with other treatment and he underwent electroconvulsive therapy (ECT). Suxamethonium was used to prevent injury caused by convulsions; this usually results in short-lived paralysis but this poor man recovered consciousness some 2 days later to find himself being weaned from artificial ventilation in an intensive care unit. Subsequent analysis showed him to be homozygous for an ineffective form of plasma cholinesterase.

5 Life expectancy, obtained from parish records, of patients with porphyria diagnosed retrospectively within large kindreds in

Scandinavia was normal until the advent and widespread use of barbiturates and other sedative and anticonvulsant drugs in the 20th century, when it plummeted. There is a long and useful list of drugs to avoid in the *British National Formulary*, together with the warning that drugs not on the list may not necessarily be safe in such patients!

13: Chemical mediators and the autonomic nervous system

OVERVIEW

The network of chemical signals and associated receptors by which cells in the body communicate with one another provides many targets for drug action, and has always been a focus of attention for pharmacologists. Chemical transmission in the peripheral autonomic nervous system, and the various ways in which the process can be pharmacologically subverted, is the main focus of this chapter, but the mechanisms described operate also in the central nervous system (CNS). In addition to neurotransmission, we also consider briefly the less clearly defined processes, collectively termed *neuromodulation*, by which many mediators and drugs exert control over the function of the nervous system. The relative anatomical and physiological simplicity of the peripheral nervous system has made it the proving ground for many important discoveries about chemical transmission, and the same general principles apply to the CNS (see **Ch. 37**). For more detail than is given here, see **Robertson et al. (2012)** and **Kandel et al. (2021)**.

Historical Aspects

Studies initiated on the peripheral nervous system have been central to the understanding and classification of many major types of drug action, so it is worth recounting a little history. Excellent accounts are given by **Bacq (1975)**, **Valenstein (2005)** and **Burnstock (2009)**.

Experimental physiology became established as an approach to the understanding of the function of living organisms in the middle of the 19th century. The peripheral nervous system, and particularly the autonomic nervous system, received a great deal of attention. The fact that electrical stimulation of nerves could elicit a whole variety of physiological effects – from blanching of the skin to arrest of the heart – presented a real challenge to comprehension, particularly of the way in which the signal was passed from the nerve to the effector tissue. In 1877, Du Bois-Reymond was the first to put the alternatives clearly: 'Of known natural processes that might pass on excitation, only two are, in my opinion, worth talking about – either there exists at the boundary of the contractile substance a stimulatory secretion … or the phenomenon is electrical in nature.' The latter view was generally favoured. In 1869, it had been shown that an exogenous substance, **muscarine**, could mimic the effects of stimulating the vagus nerve, and that **atropine** could inhibit the actions both of muscarine and of nerve stimulation. In 1905, Langley showed the same for **nicotine** and **curare** acting at the neuromuscular junction. Most physiologists interpreted these phenomena as stimulation and inhibition of the nerve endings, respectively, rather than as evidence for chemical transmission. Hence the suggestion of T.R. Elliott, in 1904, that **adrenaline**

(**epinephrine**) might act as a chemical transmitter mediating the actions of the sympathetic nervous system was coolly received, until Langley, the Professor of Physiology at Cambridge and a powerful figure at that time, suggested, a year later, that transmission to skeletal muscle involved the secretion by the nerve terminals of a substance related to nicotine.

One of the key observations for Elliott was that degeneration of sympathetic nerve terminals did not abolish the sensitivity of smooth muscle preparations to adrenaline (which the electrical theory predicted) but actually enhanced it. The hypothesis of chemical transmission was put to direct test in 1907 by Dixon, who tried to show that vagus nerve stimulation released from a dog's heart into the blood a substance capable of inhibiting another heart. The experiment failed, and the atmosphere of scepticism prevailed.

It was not until 1921, in Germany, that Loewi showed that stimulation of the vagosympathetic trunk connected to an isolated and cannulated frog's heart could cause the release into the cannula of a substance ('Vagusstoff') that, if the cannula fluid was transferred from the first heart to a second, would inhibit the second heart. This is a classic and much-quoted experiment that proved extremely difficult for even Loewi to perform reproducibly. In an autobiographical sketch, Loewi tells us that the idea of chemical transmission arose in a discussion that he had in 1903, but no way of testing it experimentally occurred to him until he dreamt of the appropriate experiment one night in 1920. He wrote some notes of this very important dream in the middle of the night, but in the morning could not read them. The dream obligingly returned the next night and, taking no chances, he went to the laboratory at 3

a.m. and carried out the experiment successfully. Loewi's experiment may be, and was, criticised on numerous grounds (it could, for example, have been potassium rather than a neurotransmitter that was acting on the recipient heart), but a series of further experiments proved him to be right. His findings can be summarised as follows:

- Stimulation of the vagus caused the appearance in the perfusate of the frog heart of a substance capable of producing, in a second heart, an inhibitory effect resembling vagus stimulation.
- Stimulation of the sympathetic nervous system caused the appearance of a substance capable of accelerating a second heart. By fluorescence measurements, Loewi concluded later that this substance was adrenaline.
- Atropine prevented the inhibitory action of the vagus on the heart but did not prevent release of Vagusstoff. Atropine thus prevented the effects, rather than the release, of the transmitter.
- When Vagusstoff was incubated with ground-up heart muscle, it became inactivated. This effect is now known to be due to enzymatic destruction of acetylcholine (ACh) by cholinesterase.
- **Physostigmine**, which potentiated the effect of vagus stimulation on the heart, prevented destruction of Vagusstoff by heart muscle, providing evidence that the potentiation is due to inhibition of cholinesterase, which normally destroys the transmitter substance ACh.

A few years later, in the early 1930s, Dale showed convincingly that ACh was also the transmitter substance at the neuromuscular junction of striated muscle and at autonomic ganglia. One of the keys to Dale's success lay in the use of highly sensitive bioassays, especially the leech dorsal muscle, for measuring the amount of ACh that had been released. Chemical transmission at sympathetic nerve terminals was demonstrated at about the same time as cholinergic transmission and by very similar methods. Cannon and his colleagues at Harvard first showed unequivocally the phenomenon of chemical transmission at sympathetic nerve endings, by experiments in vivo in which tissues made supersensitive to adrenaline by prior sympathetic denervation were shown to respond, after a delay, to the transmitter released by stimulation of the sympathetic nerves to other parts of the body. The chemical identity of the transmitter, tantalisingly like adrenaline but not identical to it, caused confusion for many years, until, in 1946, von Euler showed it to be the non-methylated derivative **noradrenaline** (**norepinephrine**).

The Autonomic Nervous System

The autonomic nervous system for a long time occupied centre stage in the pharmacology of chemical transmission.

Basic Anatomy and Physiology

The autonomic nervous system (see **Robertson et al., 2012**) consists of three main anatomical divisions: *sympathetic*, *parasympathetic* and *enteric* nervous systems. The sympathetic and parasympathetic systems (**Fig. 13.1**) provide a link between the

CNS and peripheral organs. The enteric nervous system comprises the intrinsic nerve plexuses of the gastrointestinal tract, which are closely interconnected with the sympathetic and parasympathetic systems.

The autonomic nervous system conveys all the outputs from the CNS to the rest of the body, except for the motor innervation of skeletal muscle. The enteric nervous system has sufficient integrative capabilities to allow it to function independently of the CNS, but the sympathetic and parasympathetic systems are agents of the CNS and cannot function without it. The autonomic nervous system is largely outside the influence of voluntary control. The main processes that it regulates, to a greater or lesser extent, are:

- contraction and relaxation of vascular and visceral smooth muscle
- all exocrine and certain endocrine secretions
- the heartbeat

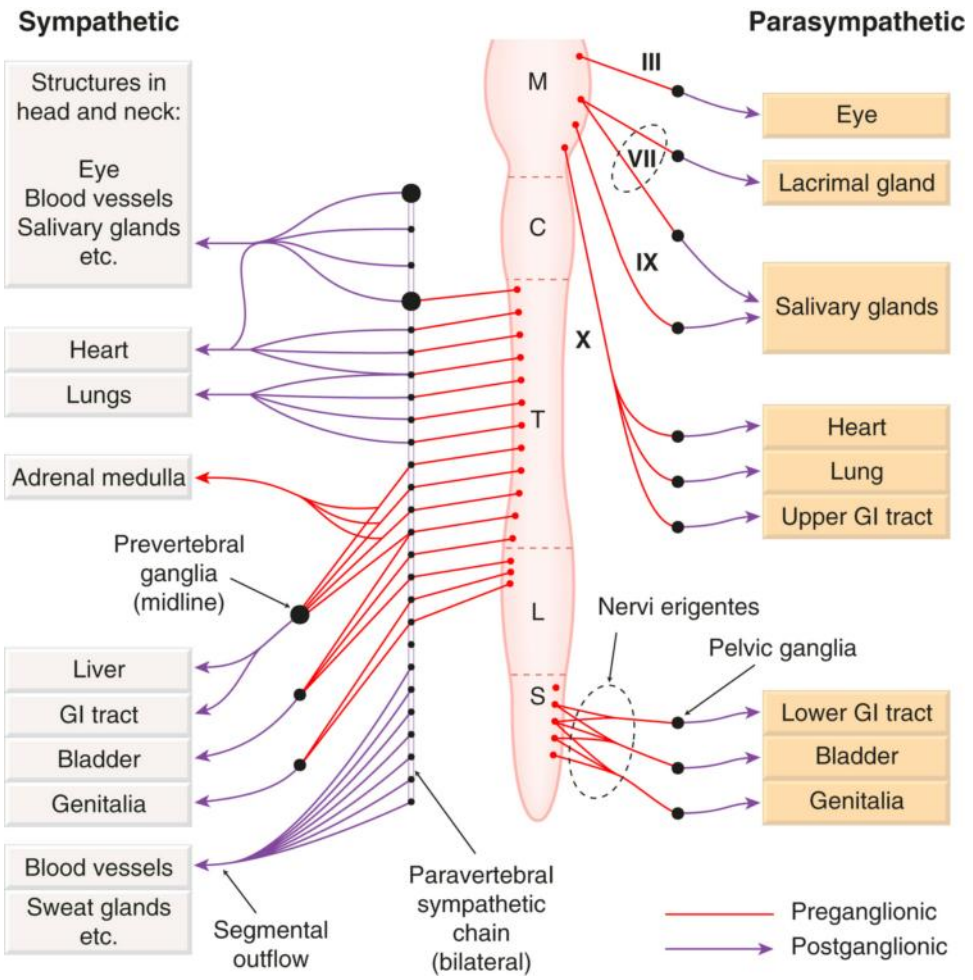

FIG. 13.1 Basic plan of the mammalian autonomic nervous system. *C*, Cervical; *GI*, gastrointestinal; *L*, lumbar; *M*, medullary; *S*, sacral; *T*, thoracic.

- energy metabolism, particularly in liver and skeletal muscle

A degree of autonomic control also affects many other systems, including the kidney, immune system and somatosensory system. The autonomic efferent pathway consists of two neurons arranged in series, whereas in the somatic motor system a single motor neuron connects the CNS to the skeletal muscle fibre (**Fig. 13.2**).

The two neurons in the autonomic pathway are known, respectively, as *preganglionic* and *postganglionic*. In the sympathetic nervous system, the intervening synapses lie in *autonomic* ganglia, which are outside the CNS, and contain the nerve endings of preganglionic fibres and the cell bodies of postganglionic neurons. In parasympathetic pathways, the postganglionic cells are mainly found in the target organs, discrete parasympathetic ganglia (e.g. the ciliary ganglion) being found only in the head and neck.

The cell bodies of the sympathetic preganglionic neurons lie in the *lateral horn* of the grey matter of the thoracic and lumbar segments of the spinal cord, and the fibres leave the spinal cord in the spinal nerves as the *thoracolumbar sympathetic outflow*. The preganglionic fibres synapse in the *paravertebral chains* of sympathetic ganglia, lying on either side of the spinal column. These ganglia contain the cell bodies of the postganglionic sympathetic neurons, the axons of which rejoin the spinal nerve. Many of the postganglionic sympathetic fibres reach their peripheral destinations via the branches of the spinal nerves. Others, destined for abdominal and pelvic viscera, have their cell bodies in a group of unpaired *prevertebral ganglia* in the abdominal cavity. The only exception to the two-neuron arrangement is the innervation of the adrenal medulla. The catecholamine-secreting cells of the adrenal medulla are, in effect, modified postganglionic sympathetic neurons, and the nerves supplying the gland are equivalent to preganglionic fibres.

The parasympathetic nerves emerge from two separate regions of the CNS. The *cranial outflow* consists of preganglionic fibres in certain cranial nerves, namely the *oculomotor nerve* (carrying

parasympathetic fibres destined for the eye), the *facial* and *glossopharyngeal nerves* (carrying fibres to the salivary glands and the nasopharynx) and the *vagus nerve* (carrying fibres to the thoracic and abdominal viscera). The ganglia lie scattered in close relation to the target organs; the postganglionic axons are very short compared with those of the sympathetic system. Parasympathetic fibres destined for the pelvic and abdominal viscera emerge as the *sacral outflow* from the spinal cord in a bundle of nerves known as the *nervi erigentes* (because stimulation of these nerves evokes genital erection – a fact of some importance to those responsible for artificial insemination of livestock). These fibres synapse in a group of scattered *pelvic ganglia*, whence the short postganglionic fibres run to target tissues such as the bladder, rectum and genitalia. The pelvic ganglia carry both sympathetic and parasympathetic fibres, and the two divisions are not anatomically distinct in this region.

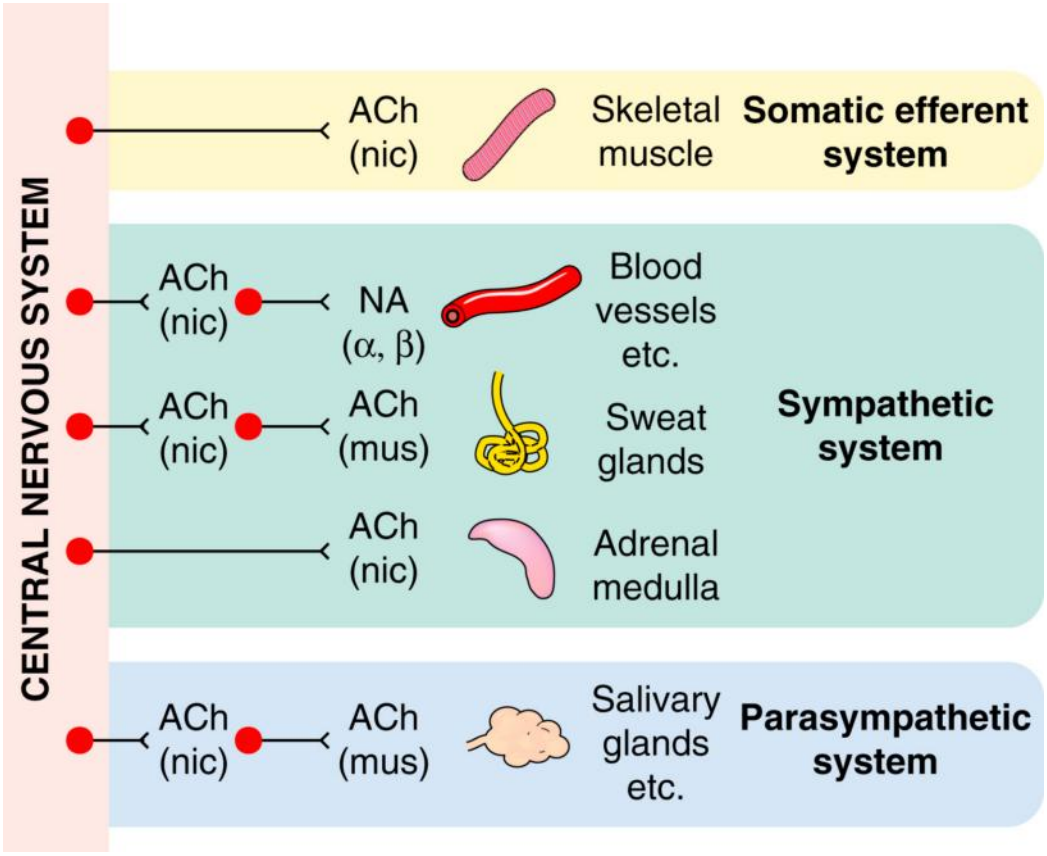

FIG. 13.2 Acetylcholine and noradrenaline as transmitters in the peripheral nervous system.The two main types of acetylcholine (ACh) receptor, nicotinic (nic) and muscarinic (mus) (see **Ch. 14**) and two types of adrenoceptor, α and β (see **Ch. 15**), are indicated. *NA*, Noradrenaline (norepinephrine).

The enteric nervous system (reviewed by **Furness et al., 2014**) consists of the neurons whose cell bodies lie in the intramural plexuses in the wall of the intestine. It is estimated that there are more cells in this system than in the spinal cord, and functionally they do not fit simply into the sympathetic/parasympathetic classification. Incoming nerves from both the sympathetic and the

parasympathetic systems terminate on enteric neurons, as well as running directly to smooth muscle, glands and blood vessels. Some enteric neurons function as mechanoreceptors or chemoreceptors, providing local reflex pathways that can control gastrointestinal function without external inputs. The enteric nervous system is pharmacologically more complex than the sympathetic or parasympathetic systems, involving many neuropeptide and other transmitters (such as 5-hydroxytryptamine, nitric oxide and ATP; see **Ch. 30**).

In some places (e.g. in the visceral smooth muscle of the gut and bladder, and in the heart), the sympathetic and the parasympathetic systems produce opposite effects, but there are others where only one division of the autonomic system operates. The *sweat glands* and most *blood vessels*, for example, have only a sympathetic innervation, whereas the *ciliary muscle* of the eye has only a parasympathetic innervation. *Bronchial smooth muscle* has only a parasympathetic (constrictor) innervation (although its tone is highly sensitive to circulating adrenaline). *Resistance arteries* (see **Ch. 21**) have a sympathetic vasoconstrictor innervation but no parasympathetic innervation; instead, the constrictor tone is opposed by a background release of nitric oxide from the endothelial cells (see **Ch. 19**). There are other examples, such as the *salivary glands*, where the two systems produce similar, rather than opposing, effects.

It is therefore a mistake to think of the sympathetic and parasympathetic systems simply as physiological opponents. Each serves its own physiological function and can be more or less active in a particular organ or tissue according to the need of the moment.

Cannon rightly emphasised the general role of the sympathetic system in evoking ‘fight or flight’ reactions in an emergency, but emergencies are rare for most animals. In everyday life, the autonomic nervous system functions continuously to control specific local functions, such as adjustments to postural changes, exercise or ambient temperature. The popular concept of a continuum from the extreme ‘rest and digest’ state (parasympathetic active, sympathetic quiescent) to the extreme emergency fight or flight state (sympathetic active, parasympathetic quiescent) is an oversimplification, albeit one that provides the student with a generally reliable *aide memoire*.

Table 13.1 lists some of the more important autonomic responses in humans.

Table 13.1

[a] The adrenoceptor and cholinoceptor types shown are described more fully in **Chapters 14** and **15**. Transmitters other than acetylcholine and noradrenaline contribute to many of these responses (see **Table 13.2**).

[b] Vasodilator effects of M_3 receptors are due to nitric oxide release from endothelial cells (see **Ch. 19**).

[c] No direct innervation. Effect mediated by circulating adrenaline released from the adrenal medulla.

Basic anatomy and physiology of the autonomic nervous system

Anatomy

- The autonomic nervous system comprises three divisions: *sympathetic*, *parasympathetic* and *enteric*.
- The basic (two-neuron) pattern of the sympathetic and parasympathetic systems consists of a *preganglionic* neuron with a cell body in the CNS and a *postganglionic* neuron with a cell body in an autonomic ganglion.
- The parasympathetic system is connected to the CNS via:
  - cranial nerve outflow (III, VII, IX, X)
  - sacral outflow.
- Parasympathetic ganglia usually lie close to or within the target organ.
- Sympathetic outflow leaves the CNS in thoracic and lumbar spinal roots. Sympathetic ganglia form two paravertebral chains, plus some midline ganglia.
- The enteric nervous system consists of neurons lying in the intramural plexuses of the gastrointestinal tract. It receives inputs from sympathetic and parasympathetic systems, but can act on its own to control the motor and secretory functions of the intestine.

Physiology

- The autonomic system controls smooth muscle (visceral and vascular), exocrine (and some endocrine) secretions, rate and force of contraction of the heart and certain metabolic processes (e.g. glucose utilisation).

- Sympathetic and parasympathetic systems have opposing actions in some situations (e.g. control of heart rate, gastrointestinal smooth muscle), but not in others (e.g. salivary glands, ciliary muscle).
- Sympathetic activity increases in stress ('fight or flight' response), whereas parasympathetic activity predominates during satiation and repose. Both systems exert a continuous physiological control of specific organs under normal conditions, when the body is at neither extreme.

Transmitters in the Autonomic Nervous System

The two main neurotransmitters that operate in the autonomic system are **acetylcholine** and **noradrenaline**, whose sites of action are shown diagrammatically in **Fig. 13.2**. This diagram also shows the type of postsynaptic receptor with which the transmitters interact at the different sites (discussed more fully in Chs **14** and **15**). Some general rules apply:

- All autonomic nerve fibres leaving the CNS release ACh, which acts on *nicotinic receptors* (although in autonomic ganglia a minor component of excitation is due to activation of *muscarinic receptors*; see **Ch. 14**).
- All postganglionic parasympathetic fibres release ACh, which acts on *muscarinic receptors*.
- All postganglionic sympathetic fibres (with one important exception) release noradrenaline, which may act on either *α* or *β adrenoceptors* (see **Ch. 15**). The exception is the sympathetic innervation of sweat glands, where

transmission is due to ACh acting on muscarinic receptors. In some species, but not humans, vasodilatation in skeletal muscle is produced by cholinergic sympathetic nerve fibres.

ACh and noradrenaline are the grandees among autonomic transmitters and are central to understanding autonomic pharmacology. However, many other chemical mediators are also released by autonomic neurons (see later in this chapter), and their functional significance is gradually becoming clearer.

Transmitters of the autonomic nervous system

- The principal transmitters are **acetylcholine** (ACh) and **noradrenaline.**
- Preganglionic neurons are cholinergic, and ganglionic transmission occurs via nicotinic ACh receptors (nAChRs) (although excitatory muscarinic ACh receptors are also present on postganglionic cells).
- Postganglionic parasympathetic neurons are cholinergic, acting on muscarinic receptors in target organs.
- Postganglionic sympathetic neurons are mainly noradrenergic, although a few are cholinergic (e.g. sweat glands).
- Transmitters other than noradrenaline and ACh (NANC transmitters) are also abundant in the autonomic nervous system. The main ones are nitric oxide and vasoactive intestinal peptide (VIP) (parasympathetic), ATP and

neuropeptide Y (NPY) (sympathetic). Others, such as 5-hydroxytryptamine, γ-aminobutyric acid (GABA) and dopamine, also play a role.

- Co-transmission, release of more than one transmitter from a nerve ending, is a general phenomenon.

Some General Principles of Chemical Transmission

The essential processes in chemical transmission – the release of mediators, and their interaction with receptors on target cells – are described in **Chapters 4** and 3, respectively. Here we consider some general characteristics of chemical transmission of particular relevance to pharmacology. Many of these principles apply also to the CNS and are taken up again in **Chapter 37**.

Presynaptic Modulation

The presynaptic terminals that synthesise and release transmitter in response to electrical activity in the nerve fibre are often themselves sensitive to transmitter substances and to other substances that may be produced locally in tissues (for review see **Boehm and Kubista, 2002**). Such presynaptic effects most commonly act to inhibit transmitter release, but may enhance it. **Fig. 13.3A** shows the inhibitory effect of adrenaline on the release of ACh (evoked by electrical stimulation) from the postganglionic parasympathetic nerve terminals of the intestine. The release of noradrenaline from nearby sympathetic nerve terminals can also inhibit release of ACh. Noradrenergic and cholinergic nerve terminals often lie close

together in the myenteric plexus, so the opposing effects of the sympathetic and parasympathetic systems result not only from the opposite effects of the two transmitters on the smooth muscle cells, but also from the inhibition of ACh release by noradrenaline acting on the parasympathetic nerve terminals. A similar situation of mutual presynaptic inhibition exists in the heart, where noradrenaline inhibits ACh release and ACh also inhibits noradrenaline release. These are examples of *heterotropic interactions*, where one neurotransmitter affects the release of another. *Homotropic interactions* also occur, where the transmitter, by binding to presynaptic autoreceptors, affects the nerve terminals from which it is being released. This type of *autoinhibitory feedback* acts powerfully at noradrenergic nerve terminals (see **Starke et al., 1989**). **Fig. 13.3B** shows that in normal mice, noradrenaline release increases only slightly as the number of stimuli increases from 1 to 64. In transgenic mice lacking a specific type of presynaptic α_2 adrenoceptor (see **Ch. 15**), the amount released by the longer stimulus train is greatly increased, although the amount released by a single stimulus is unaffected. This is because with one or a few stimuli, there is no opportunity for autoinhibitory feedback to develop, whereas with longer trains the inhibition operates powerfully. A similar autoinhibitory feedback occurs with many transmitters, including ACh and 5-hydroxytryptamine.

In both the noradrenergic and cholinergic systems, the presynaptic autoreceptors are pharmacologically distinct from the postsynaptic receptors (see **Fig. 13.4** and Chs **14** and **15**), and there are drugs that act selectively, as agonists or antagonists, on the pre- or postsynaptic receptors.

Cholinergic and noradrenergic nerve terminals respond not only to ACh and noradrenaline, as described earlier, but also to other substances that are released as co-transmitters, such as ATP and NPY, or derived from other sources, including nitric oxide, prostaglandins, adenosine, dopamine, 5-hydroxytryptamine, GABA, opioid peptides, endocannabinoids and many other substances. The description of the autonomic nervous system represented in **Fig. 13.2** is undoubtedly oversimplified. **Fig. 13.4** shows some of the main presynaptic interactions between autonomic neurons and summarises the many chemical influences that regulate transmitter release from noradrenergic neurons.

Presynaptic receptors regulate transmitter release mainly by affecting Ca^{2+} entry into the nerve terminal (see **Ch. 4**), but also by other mechanisms (see **Kubista and Boehm, 2006**). Most presynaptic receptors are of the G protein–coupled type (see **Ch. 3**), which control the function of calcium channels and potassium channels either through a direct interaction of G proteins with the channels or by second messengers that regulate the state of phosphorylation of the channel proteins. Transmitter release is inhibited when calcium channel opening is inhibited, or when potassium channel opening is increased (see **Ch. 4**); in many cases, both mechanisms operate simultaneously. Presynaptic regulation by receptors linked directly to ion channels (ionotropic receptors; see **Ch. 3**) rather than to G proteins also occurs (see **Dorostkar and Boehm, 2008**). nAChRs are particularly important in this respect. They can either facilitate or inhibit the release of other transmitters, such as glutamate (see **Ch. 38**), and most of the nAChRs expressed in the CNS are located presynaptically. Another

example is the $GABA_A$ receptor, whose action is to inhibit transmitter release (see Chs **4** and **37**). Other ionotropic receptors, such as those activated by ATP and 5-hydroxytryptamine (see Chs **16** and **39**), have similar effects on transmitter release.

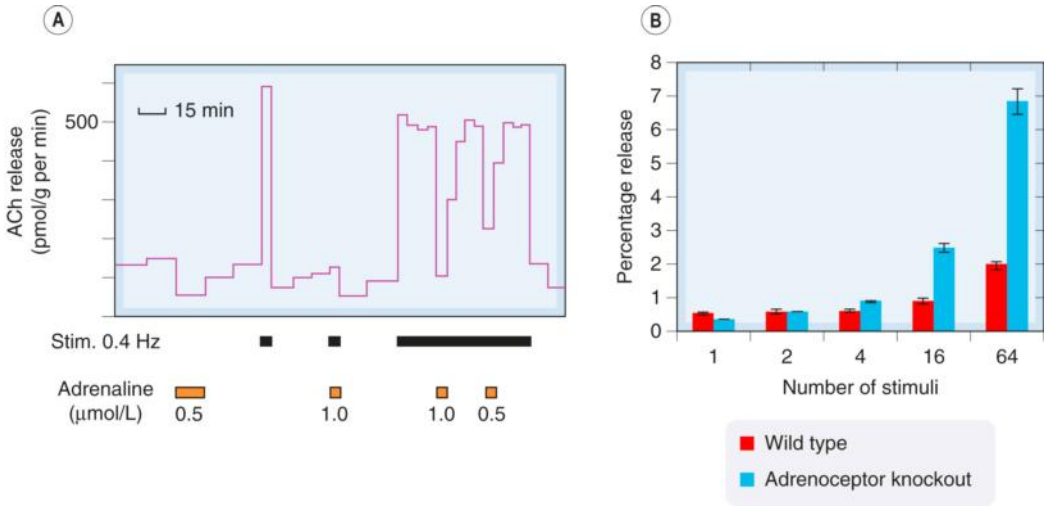

FIG. 13.3 Examples of presynaptic inhibition. (A) Inhibitory effect of adrenaline on acetylcholine (ACh) release from postganglionic parasympathetic nerves in the guinea pig ileum. The intramural nerves were stimulated electrically where indicated, and the ACh released into the bathing fluid determined by bioassay. Adrenaline strongly inhibits ACh release. (B) Noradrenaline (NA) release from mouse hippocampal slices in response to trains of electrical stimuli. *Red bars* show normal (wild-type) mice. *Blue bars* show α_2-adrenoceptor knockout mice. The lack of presynaptic autoinhibition in the knockout mice results in a large increase in release with a long stimulus train but does not affect release by fewer than four stimuli, because the autoinhibition takes a few seconds to develop. This example is taken from a study of brain noradrenergic nerves, but similar findings have

been made on sympathetic nerves. Panel [A] from Vizi, E.S., 1979. Prog. Neurobiol. 12, 181; panel [B] redrawn from Trendelenburg, et al., 2001. Naunyn Schmiedeberg's Arch. Pharmacol. 364, 117–130.

Neuromodulation and presynaptic interactions

- As well as functioning directly as neurotransmitters, chemical mediators may regulate:
  - presynaptic transmitter release
  - neuronal excitability.
- Both are examples of *neuromodulation* and generally involve second messenger regulation of membrane ion channels.
- Presynaptic receptors may inhibit or increase transmitter release, the former being more important.
- Inhibitory *presynaptic autoreceptors* occur on noradrenergic and cholinergic neurons, causing each transmitter to inhibit its own release (*autoinhibitory feedback*).
- Many endogenous mediators (e.g. GABA, prostaglandins, opioid and other peptides), as well as the transmitters themselves, exert presynaptic control (mainly inhibitory) over autonomic transmitter release.

Postsynaptic Modulation

Chemical mediators often act on postsynaptic structures, including neurons, smooth muscle cells, cardiac muscle cells, and so on, in such a way that their excitability or spontaneous firing pattern is altered. In many cases, as with presynaptic modulation, this is caused by changes in calcium and/or potassium channel function. We give only a few examples here.

- The slow excitatory effect produced by various mediators, including ACh and peptides such as **substance P**, results mainly from a decrease in K^+ permeability. Conversely, the inhibitory effect of various opioid peptides in the gut is mainly due to increased K^+ permeability.

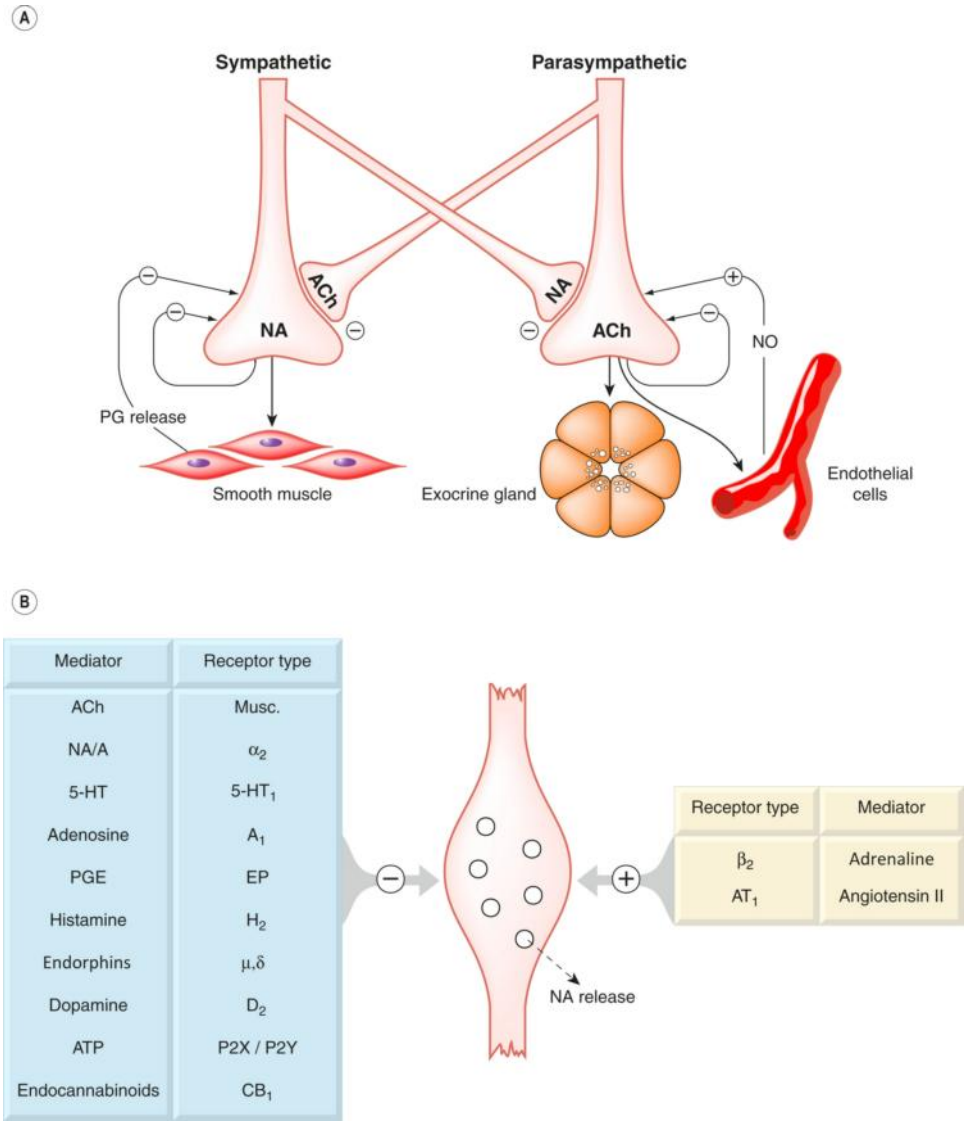

FIG. 13.4 Presynaptic regulation of transmitter release from noradrenergic and cholinergic nerve terminals.(A) Postulated homotropic and heterotropic interactions between sympathetic and parasympathetic nerves. (B) Some of the known inhibitory and facilitatory influences on noradrenaline release from sympathetic nerve endings. *ATP*, Adenosine triphosphate; *5-HT*, 5-

hydroxytryptamine; *ACh,* acetylcholine; *NA,* noradrenaline; *NO,* nitric oxide; *PG,* prostaglandin; *PGE*, prostaglandin E.

- **NPY**, is released as a co-transmitter with noradrenaline at many sympathetic nerve endings and acts on smooth muscle cells to enhance the vasoconstrictor effect of noradrenaline, thus greatly facilitating transmission.

The pre- and postsynaptic effects described previously are often described as *neuromodulation*, because the mediator acts to increase or decrease the efficacy of synaptic transmission without participating directly as a transmitter. Many neuropeptides, for example, affect membrane ion channels in such a way as to increase or decrease excitability and thus control the firing pattern of the cell. Neuromodulation is loosely defined but, in general, involves slower processes (taking seconds to days) than neurotransmission (which occurs in milliseconds), and operates through cascades of intracellular messengers (see **Ch. 3**) rather than directly on ligand-gated ion channels.

Transmitters Other than Acetylcholine and Noradrenaline

As mentioned earlier, ACh and noradrenaline are not the only autonomic transmitters. The rather grudging realisation that this was so dawned many years ago when it was noticed that autonomic transmission in many organs could not be completely blocked by drugs that abolish responses to these transmitters. The dismal but tenacious term *non-adrenergic non-cholinergic* (NANC)

transmission was coined. Later, fluorescence and immunocytochemical methods showed that neurons, including autonomic neurons, contain many potential transmitters, often several in the same cell. Compounds now known to function as NANC transmitters include ATP, VIP, NPY and nitric oxide (**Fig. 13.5** and **Table 13.2**), which function at postganglionic nerve terminals, as well as substance P, 5-hydroxytryptamine, GABA and dopamine, which play a role in ganglionic transmission (see **Lundberg, 1996**, for a comprehensive review).

Co-Transmission

It is the rule rather than the exception that neurons release more than one transmitter or modulator (see **Lundberg, 1996**), each of which interacts with specific receptors and produces effects, often both pre- and postsynaptically. The example of noradrenaline/ATP co-transmission at sympathetic nerve endings is shown in **Fig. 13.5**, and the best-studied examples and mechanisms are summarised in **Table 13.2** and Figs **13.6** and **13.7**.

What, one might well ask, could be the functional advantage of co-transmission, compared with a single transmitter acting on various different receptors? The possible advantages include the following:

- One constituent of the cocktail (e.g. a peptide) may be removed or inactivated more slowly than the other (e.g. a monoamine), and therefore reach targets further from the site of release and produce longer-lasting effects. This appears to be the case, for example, with ACh and gonadotrophin-releasing hormone in sympathetic ganglia.

- The balance of the transmitters released may vary under different conditions. At sympathetic nerve terminals, for example, where noradrenaline and NPY are stored in separate vesicles, NPY is preferentially released at high stimulation frequencies, so that differential release of one or other mediator may result from varying impulse patterns. Differential effects of presynaptic modulators are also possible; for example, activation of β adrenoceptors inhibits ATP release while enhancing noradrenaline release from sympathetic nerve terminals.

Termination of Transmitter Action

Chemically transmitting synapses other than the peptidergic variety invariably incorporate a mechanism for disposing rapidly of the released transmitter, so that its action remains brief and localised. At cholinergic synapses (see **Ch. 14**), the released ACh is inactivated very rapidly in the synaptic cleft by *acetylcholinesterase*. In most other cases (see **Fig. 13.8**), transmitter action is terminated by active reuptake into the presynaptic nerve, or into smooth muscle. Such reuptake depends on transporter proteins (see **Ch. 4**), each being specific for a particular transmitter. The major class (Na^+/Cl^- co-transporters), whose molecular structure and function are well understood (see **Torres et al., 2003**; **Gether et al., 2006**), consists of a family of membrane proteins, each possessing 12 transmembrane helices. Different members of the family show selectivity for each of the main monoamine transmitters (e.g. the noradrenaline [norepinephrine] transporter [NET]; the serotonin transporter [SERT], which transports 5-

hydroxytryptamine; and the dopamine transporter [DAT]) (see **Manepalli et al., 2012**). These transporters are important targets for psychoactive drugs, particularly antidepressants (see **Ch. 48**), anxiolytic drugs (see **Ch. 45**) and stimulants (see **Ch. 49**). Transporters for glycine and GABA belong to the same family.

Vesicular transporters (see **Ch. 4**), which load synaptic vesicles with transmitter molecules, are closely related to plasma membrane transporters. Membrane transporters usually act as co-transporters of Na^+, Cl^- and transmitter molecules, and it is the inwardly directed 'downhill' gradient for Na^+ that provides the energy for the inward 'uphill' movement of the transmitter. The simultaneous transport of ions along with the transmitter means that the process generates a net current across the membrane, which can be measured directly and used to monitor the transport process. Very similar mechanisms are responsible for other physiological transport processes, such as glucose uptake (see **Ch. 31**) and renal tubular transport of amino acids. Because it is the electrochemical gradient for sodium that drives the inward transport of transmitter molecules, a reduction of this gradient can reduce or even reverse the flow of transmitter. This is probably not important under physiological conditions, but when the nerve terminals are depolarised or abnormally loaded with sodium (e.g. in ischaemic conditions), the resulting non-vesicular release of transmitter (and inhibition of the normal synaptic reuptake mechanism) may play a significant role in the effects of ischaemia on tissues such as heart and brain (see Chs **20** and **40**). Studies with transgenic 'knockout' mice (see **Torres et al., 2003**) show that the store of releasable transmitter is substantially depleted in animals lacking the

membrane transporter, showing that synthesis is unable to maintain the store if the recapture mechanism is disabled. As with receptors (see **Ch. 3**), many genetic polymorphisms of transporter genes occur in humans, finding associations with various neurological, cardiovascular and psychiatric disorders has provided insight into their aetiology and may explain altered responsiveness to drugs (see **Reynolds et al., 2014**).

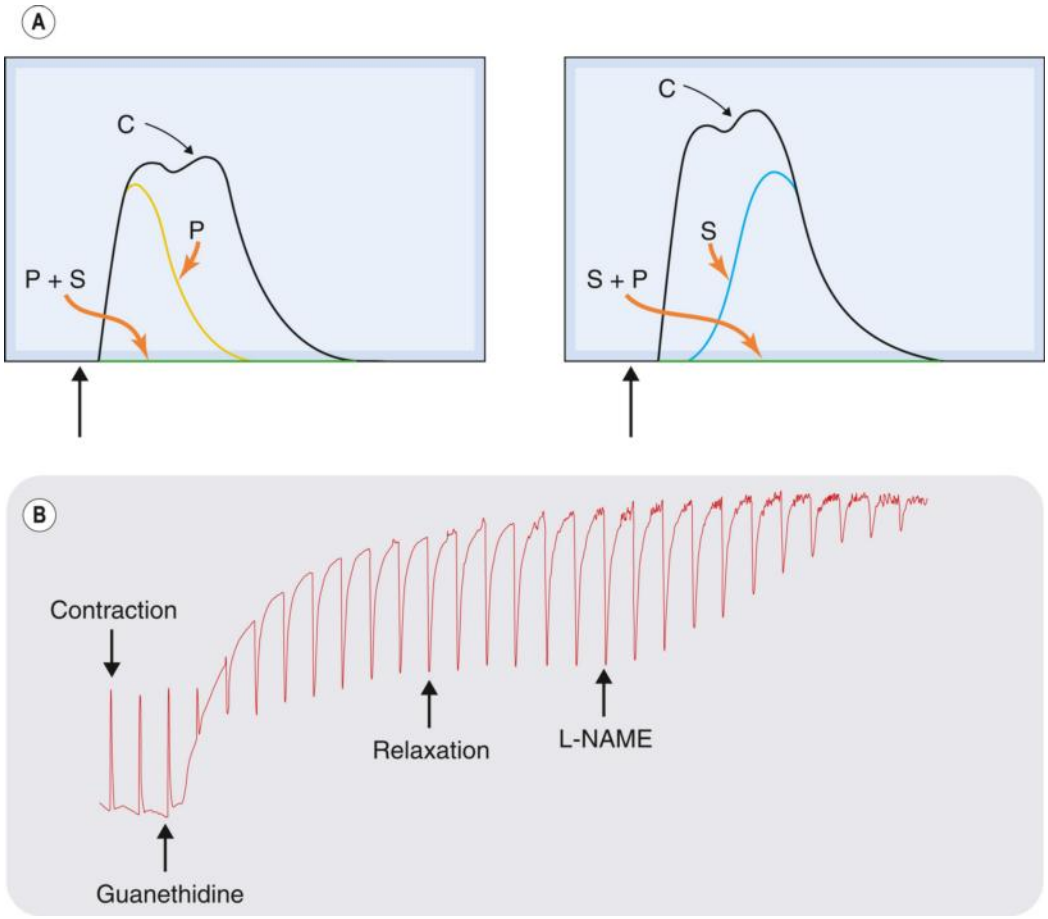

FIG. 13.5 ATP and nitric oxide as neurotransmitters.(A) Noradrenaline and ATP are co-transmitters released from the same nerves in the guinea pig vas deferens. Contractions of the tissue are shown in response to a single electrical stimulus causing excitation of sympathetic nerve endings. With no blocking drugs present, a twin-peaked response is produced *(C)*. The early peak is selectively abolished by the ATP antagonist suramin *(S)*, while the late peak is blocked by the α_1-adrenoceptor antagonist prazosin *(P)*. The response is completely eliminated when both

drugs are present. (B) Noradrenaline and nitric oxide are neurotransmitters in the rat anococcygeus muscle but are probably released from different nerves. The nerves innervating the muscle were stimulated with brief trains of pulses. Initially, nerve stimulation evoked rapid contractions by releasing noradrenaline. Application of guanethidine blocked stimulus-evoked noradrenaline release and raised the tone of the preparation revealing nerve-evoked relaxations that were blocked by L-NAME, an inhibitor of nitric oxide synthesis. Panel [A] reproduced with permission from von Kugelglen, I., Starke, K., 1991. Trends Pharmacol. Sci. 12, 319–324; data in panel [B] are from a student practical class at Glasgow Caledonian University, courtesy of A. Corbett.

As we shall see in subsequent chapters, both plasma membrane and vesicular transporters are targets for various drugs, and defining the physiological role and pharmacological properties of these molecules has been the focus of much research.

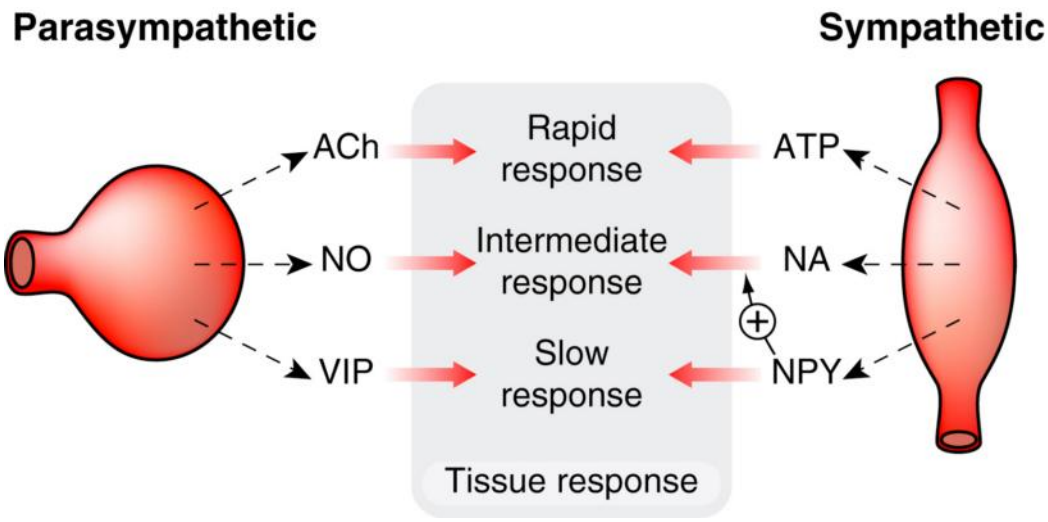

FIG. 13.6 The main co-transmitters at postganglionic parasympathetic and sympathetic neurons.The different mediators generally give rise to fast, intermediate and slow responses of the target organ. *ACh,* Acetylcholine; *ATP,* adenosine triphosphate; *NA,* noradrenaline; *NO,* nitric oxide; *NPY,* neuropeptide Y; *VIP,* vasoactive intestinal peptide.

Table 13.2

ATP, Adenosine triphosphate; *GABA,* gamma-aminobutyric acid; *5-HT,* 5-hydroxytryptamine; *NANC,* non-adrenergic non-cholinergic; *VIP,* vasoactive intestinal peptide.

Denervation Supersensitivity

It is known, mainly from the work of Cannon on the sympathetic system, that if a nerve is cut and its terminals are allowed to degenerate, the structure supplied by it becomes supersensitive to

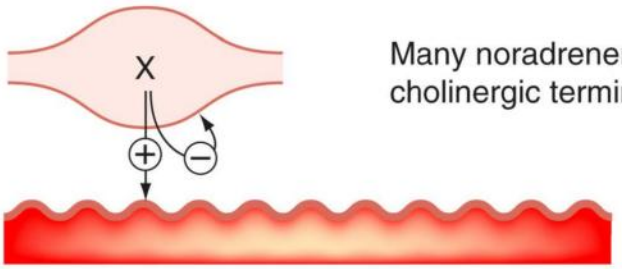
the transmitter substance released by the terminals. Thus skeletal muscle, which normally responds to injected ACh only if a large dose is given directly into the arterial blood supply, will, after denervation, respond by contracture to much smaller amounts. Other organs, such as salivary glands and blood vessels, show similar supersensitivity to ACh and noradrenaline when the postganglionic nerves degenerate, and there is evidence that pathways in the CNS show the same phenomenon.

Several mechanisms contribute to denervation supersensitivity, and the extent and mechanism of the phenomenon varies from organ to organ. Reported mechanisms include the following (see **Luis and Noel, 2009**).

- Proliferation of receptors. This is particularly marked in skeletal muscle, in which the number of ACh receptors increases 20-fold or more after denervation; the receptors, normally localised to the endplate region of the fibres (see **Ch. 14**), spread over the whole surface. Elsewhere, increases in receptor number are much smaller, or absent altogether.
- Loss of mechanisms for transmitter removal. At noradrenergic synapses, the loss of neuronal uptake of noradrenaline (see **Ch. 15**) contributes substantially to denervation supersensitivity. At cholinergic synapses, a partial loss of cholinesterase occurs (see **Ch. 14**).
- Increased postjunctional responsiveness. Smooth muscle cells become partly depolarised and hyperexcitable after denervation (due in part to reduced Na^+-K^+-ATPase activity; see **Ch. 4**) and this phenomenon contributes appreciably to

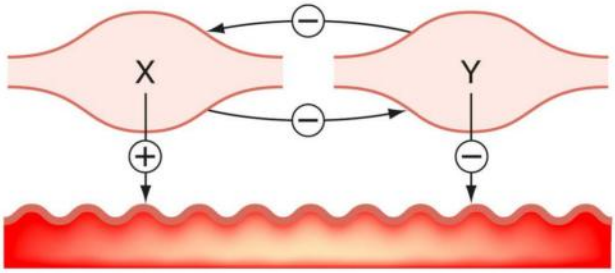
their supersensitivity. Increased Ca^{2+} signalling, resulting in enhanced excitation–contraction coupling, may also occur.

A Presynaptic inhibition



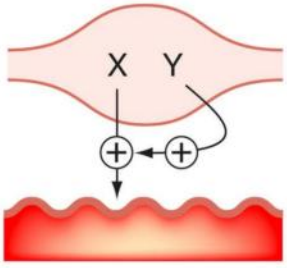
Many noradrenergic and cholinergic terminals

B Heterotropic presynaptic inhibition

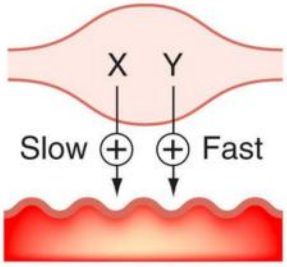


Noradrenergic /cholinergic nerve terminals in the heart

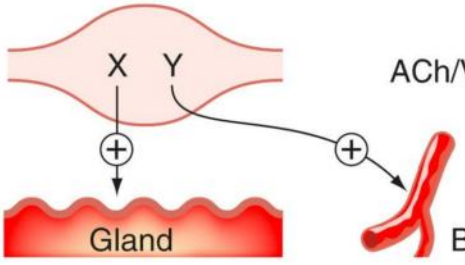
C Postsynaptic synergism



Noradrenaline/NPY in blood vessels



Noradrenaline/ATP in blood vessels, vas deferens
ACh/GnRH in sympathetic ganglia
ACh/SP in enteric ganglia



ACh/VIP in salivary gland

FIG. 13.7 Co-transmission and neuromodulation – some examples.(A) Presynaptic inhibition. (B) Heterotropic presynaptic inhibition. (C) Postsynaptic synergism. *ACh,* Acetylcholine; *ATP,* adenosine triphosphate; *GnRH,* gonadotrophin-releasing hormone (luteinising hormone-releasing hormone); *NPY,* neuropeptide Y; *SP,* substance P; *VIP,* vasoactive intestinal peptide.

Supersensitivity can occur, but is less marked, when transmission is interrupted by processes other than nerve section. Pharmacological block of ganglionic transmission, for example, if sustained for a few days, causes some degree of supersensitivity of the target organs, and long-term blockade of postsynaptic receptors also causes receptors to proliferate, leaving the cell supersensitive when the blocking agent is removed. Phenomena such as this are of importance in the CNS, where such supersensitivity can cause 'rebound' effects when drugs that impair synaptic transmission are given for some time and then discontinued.

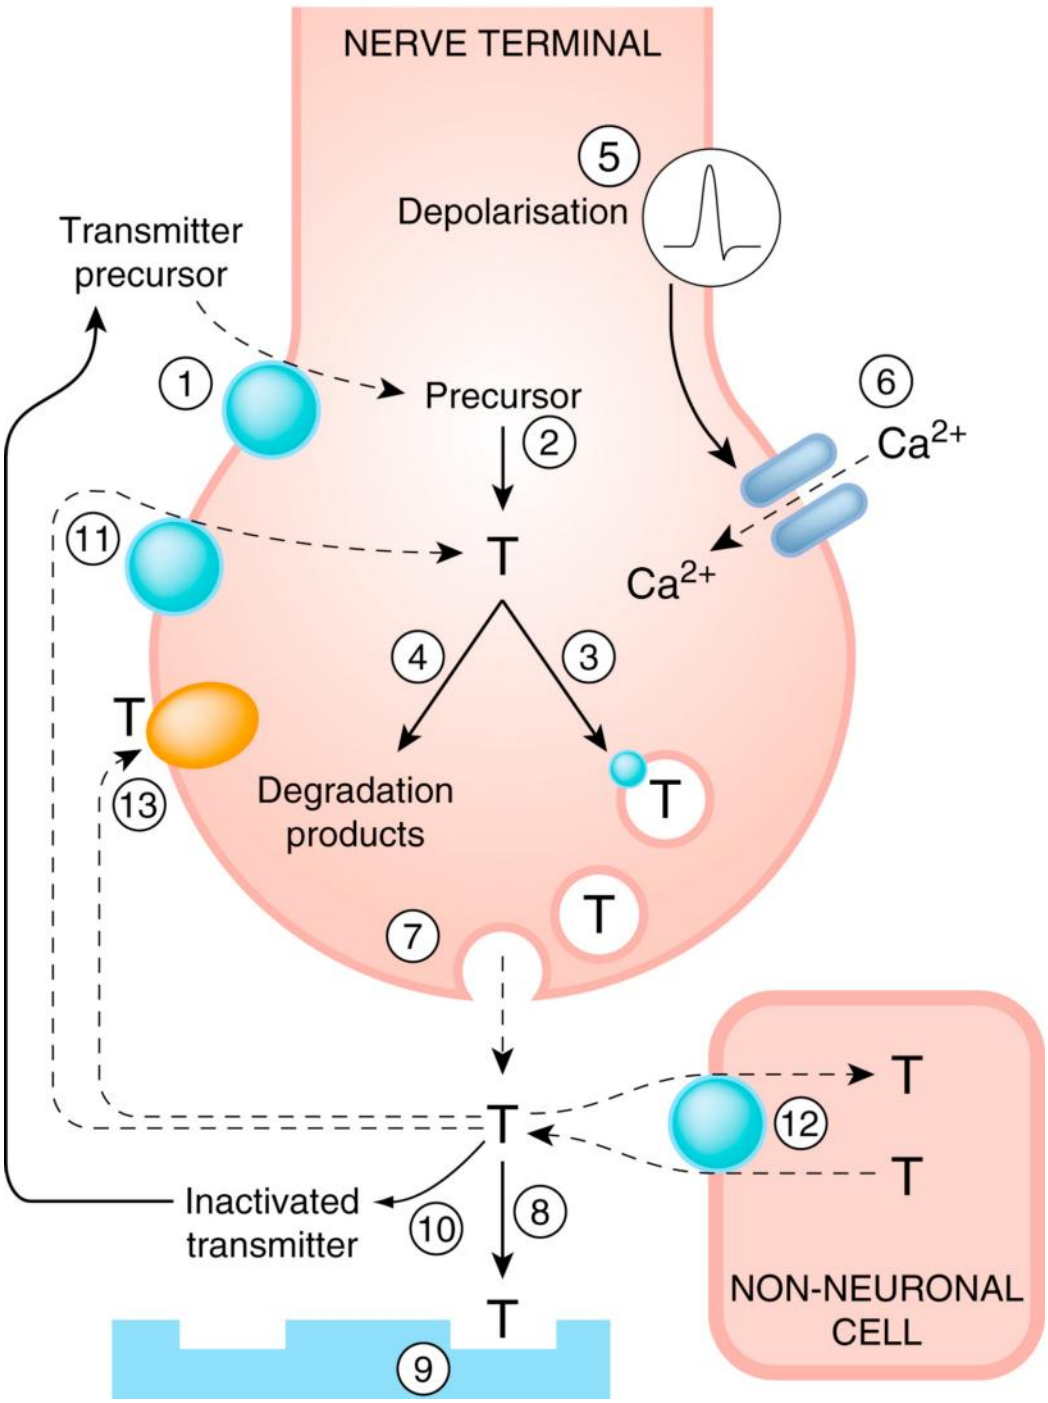


FIG. 13.8 The main processes involved in synthesis, storage and release of amine and amino acid transmitters. *1,* Uptake of precursors; *2,* synthesis of transmitter; *3,* uptake/transport

of transmitter into vesicles; *4,* degradation of surplus transmitter; *5,* depolarisation by propagated action potential; *6,* influx of Ca^{2+} in response to depolarisation; *7,* release of transmitter by exocytosis; *8,* diffusion to postsynaptic membrane; *9,* interaction with postsynaptic receptors; *10,* inactivation of transmitter; *11,* reuptake of transmitter or degradation products by nerve terminals; *12,* uptake and release of transmitter by non-neuronal cells; and *13,* interaction with presynaptic receptors. The transporters *(11 and 12)* can release transmitter under certain conditions by working in reverse. These processes are well characterised for many transmitters (e.g. acetylcholine, monoamines, amino acids, ATP). Peptide mediators differ in that they may be synthesised and packaged in the cell body rather than the terminals.

Basic Steps in Neurochemical Transmission: Sites of Drug Action

Fig. 13.8 summarises the main processes that occur in a classical chemically transmitting synapse, and provides a useful basis for understanding the actions of the many different classes of drug, discussed in later chapters, that act by facilitating or blocking neurochemical transmission.

All the steps shown in **Fig. 13.8** (except for transmitter diffusion, step 8) can be influenced by drugs. For example, the enzymes involved in synthesis or inactivation of the transmitter can be inhibited, as can the transport systems responsible for the neuronal and vesicular uptake of the transmitter or its precursor. The actions of the great majority of drugs that act on the peripheral nervous system (see Chs **14** and **15**) and the CNS fit into this general scheme.

QUESTIONS

QUESTION 13.1

The peripheral nervous system comprises three main divisions which regulate organ function.

Which of the following statements about autonomic control is incorrect?

OPTIONS:

A. Bronchial smooth muscle is under sympathetic control.

B. The postganglionic cells of parasympathetic neurons are found mainly in the target organs.

C. The heartbeat is regulated by sympathetic control.

D. The enteric nervous system involves mechanoreceptors which provide local reflex pathways that can control gastrointestinal function.

E. Blood vessels are innervated by sympathetic neurons.

QUESTION 13.2

Many tissues and organs are innervated by both cholinergic and adrenergic neurons.

Which of the following is an example of a heterotropic interaction?

OPTIONS:

A. ACh and NA exerting opposing effects on the same postsynaptic tissue.

B. NA mediating both presynaptic inhibition and postsynaptic stimulation.

C. NA and ACh affect the release of the other.

D. Release of more than one neurotransmitter from a nerve ending.

E. ACh, by binding to presynaptic autoreceptors, affects the nerve terminals from which it is being released.

QUESTION 13.3

Nerve function is dependent upon levels of available transmitter.

What is the main alteration in transmitter function observed during ischaemia?

OPTIONS:

A. Alterations in transmitter synthesis

B. Alterations in vesicular loading of transmitter

C. Alterations in balance of release of co-transmitters

D. Alterations in degradation of transmitter

E. Alterations in reuptake mechanisms

ANSWERS

ANSWER 13.1

RATIONALE:

A.

B. In the sympathetic nervous system, the synapses lie in *autonomic* ganglia, which are outside the central nervous system (CNS), and contain the nerve endings of preganglionic fibres and the cell bodies of postganglionic neurons. In parasympathetic pathways, the postganglionic cells are mainly found in the target organs.

C. The heartbeat is regulated by sympathetic control.

D. Some enteric neurons function as mechanoreceptors or chemoreceptors, providing local reflex pathways that can control gastrointestinal function.

E. Most blood vessels have only a sympathetic innervation.

CORRECT ANSWER WITH EXPLANATION:

A. Bronchial smooth muscle is under sympathetic control.

Bronchial smooth muscle has only a parasympathetic (constrictor) innervation (although its tone is highly sensitive to circulating adrenaline).

ANSWER 13.2

RATIONALE:

A. ACh and NA exerting opposing effects on the same postsynaptic tissue is an example of mutual competition.

B. NA mediating both presynaptic inhibition and postsynaptic stimulation is an autoregulatory mechanism to control transmitter levels in the synapse.

C.

D. Release of more than one neurotransmitter from a nerve ending is an example of co-transmission.

E. ACh, by binding to presynaptic autoreceptors, affecting the nerve terminals from which it is being released is an example of a homotropic interaction.

CORRECT ANSWER WITH EXPLANATION:

C. NA and ACh affect the release of the other.

NA and ACh mutually inhibit the release of the other which is an example of a heterotropic interaction.

ANSWER 13.3

RATIONALE:

A. Alterations in transmitter synthesis

B. Alterations in vesicular loading of transmitter

C. Alterations in balance of release of co-transmitters

D. Alterations in degradation of transmitter

E.

CORRECT ANSWER WITH EXPLANATION:

E. Alterations in reuptake mechanisms

When the nerve terminals are depolarised or abnormally loaded with sodium (e.g. in ischaemic conditions), the resulting non-vesicular release of transmitter (and inhibition of the normal synaptic reuptake mechanism) may play a significant role in the effects of ischaemia on tissues such as heart and brain.

14: Cholinergic transmission

OVERVIEW

This chapter is concerned mainly with cholinergic transmission in the periphery, and the ways in which drugs affect it. We describe the different types of acetylcholine (ACh) receptors and their functions, as well as the synthesis, release and degradation of ACh. Drugs that act on ACh receptors, many of which have clinical uses, are described, as are drugs that inhibit cholinesterase enzymes. Cholinergic mechanisms in the central nervous system (CNS) and their relevance to dementia are discussed in **Chapters 39** and **40**.

Muscarinic and Nicotinic Actions of Acetylcholine

The discovery of the pharmacological action of ACh came, paradoxically, from work on adrenal glands, extracts of which were known to produce a rise in blood pressure owing to their content of adrenaline (epinephrine). In 1900, Reid Hunt found that after adrenaline had been removed from such extracts, they produced a fall in blood pressure instead of a rise. He established that this was likely due to the presence of ACh, the physiological role of which became apparent when Loewi, Dale and their colleagues demonstrated its transmitter role in the 1930s.

Analysing the pharmacological actions of ACh in 1914, Dale distinguished two types of activity, which he designated as *muscarinic* and *nicotinic* because they mimicked, respectively, the effects of **muscarine**, the active principle of the poisonous mushroom *Amanita muscaria*, and of **nicotine**. Muscarinic actions closely resemble the effects of parasympathetic stimulation (see **Table 13.1**). After the muscarinic effects have been blocked by **atropine**, larger doses of ACh produce nicotine-like effects, which include:

- stimulation of all autonomic ganglia
- stimulation of voluntary muscle
- secretion of adrenaline from the adrenal medulla.

The muscarinic and nicotinic actions of ACh are demonstrated in **Fig. 14.1**. Bolus intravenous doses of ACh produce a transient fall in blood pressure due to arteriolar vasodilatation and slowing of the heart – muscarinic effects that are abolished by atropine. A large dose of ACh given after atropine produces nicotinic effects: an initial rise in blood pressure due to a stimulation of sympathetic ganglia and consequent vasoconstriction, and a secondary rise resulting from secretion of adrenaline.

Dale's pharmacological classification corresponds closely to the main physiological functions of ACh in the body. The muscarinic actions correspond to those of ACh released at postganglionic parasympathetic nerve endings, with two significant exceptions:

1. ACh causes generalised vasodilatation, even though most blood vessels have no parasympathetic innervation. This is

an indirect effect: ACh (like many other mediators) acts on vascular endothelial cells to release **nitric oxide** (see Chs **19** and **21**), which relaxes smooth muscle. The physiological function of this is uncertain, because ACh is not normally present in circulating blood.

2. ACh evokes secretion from sweat glands, which are innervated by cholinergic fibres of the sympathetic nervous system (see **Table 13.1**).

The nicotinic actions correspond to those of ACh acting on autonomic ganglia of the sympathetic and parasympathetic systems, the motor endplate of voluntary muscle and the secretory cells of the adrenal medulla.

Acetylcholine Receptors

Although Dale himself dismissed the concept of receptors as sophistry rather than science, his functional classification provided the basis for distinguishing muscarinic and nicotinic receptors, the two major classes of ACh receptor (see **Ch. 3** and **Southan et al., 2016**). Many important therapeutic drugs target these receptors, and despite their long and distinguished history, recent advances continue to open new opportunities for drug development in both muscarinic (**Kruse et al., 2014**; **He et al., 2015**) and nicotinic (**Dinely et al., 2015**) fields, especially for CNS indications (see Chs **39** and **40**).

Nicotinic Receptors

All nicotinic ACh receptors (nAChRs) are pentameric structures that function as ligand-gated ion channels (see **Fig. 3.4**). nAChRs fall into three main classes – the muscle, ganglionic and CNS types – whose subunit compositions are summarised in **Table 14.1**. Muscle receptors are confined to the skeletal neuromuscular junction; ganglionic receptors are responsible for fast transmission at sympathetic and parasympathetic ganglia; and CNS-type receptors are widespread in the brain, and are heterogeneous with respect to their molecular composition and location (see **Ch. 39**). Most of the CNS-type nAChRs are located presynaptically and serve to facilitate or inhibit the release of other mediators, such as glutamate and dopamine.

The five subunits that form the receptor–channel complex are similar in structure, and so far 17 different members of the family have been identified and cloned, designated α (10 types), β (4 types) and γ, δ and ε (1 of each). The five subunits each possess four membrane-spanning helical domains, and one of these helices (M_2) from each subunit defines the central pore (see **Ch. 3**). nAChR subtypes generally contain both α and β subunits, the exception being the homomeric α_7 subtype found mainly in the brain (see **Ch. 39**). The adult muscle receptor has the composition α2β1ε1δ1, while the main ganglionic subtype is α2β3 (for more detail on which subunits are present in the different subtypes see **Southan et al., 2016**). The two binding sites for ACh (both of which need to be occupied to cause the channel to open) reside at the interface between the extracellular domain of each of the α subunits and its neighbour.

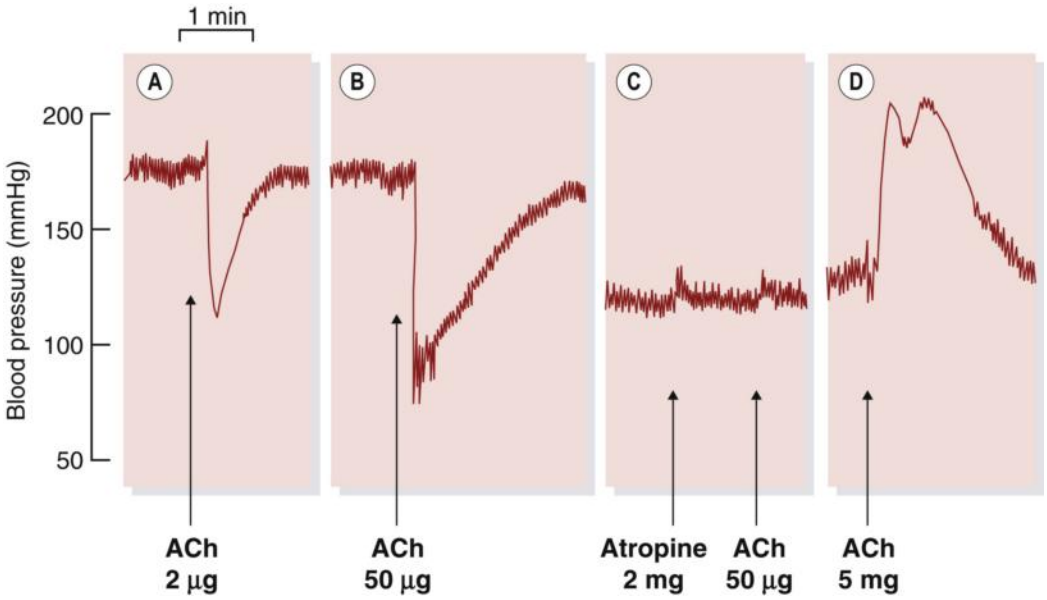

FIG. 14.1 Dale's experiment showing that acetylcholine (ACh) produces two kinds of effect on blood pressure.Arterial pressure was recorded with a mercury manometer in a cat with spinal cord intact but brainstem control centres surgically disconnected. (A) ACh causes a fall in blood pressure due to vasodilatation. (B) A larger dose also produces bradycardia. Both (A) and (B) are muscarinic effects. (C) After atropine (muscarinic antagonist), the same dose of ACh has no effect. (D) Still under the influence of atropine, a much larger dose of ACh causes a rise in blood pressure due to stimulation of sympathetic ganglia, accompanied by tachycardia, followed by a secondary rise due to release of adrenaline from the adrenal gland, resulting from its action on nicotinic

receptors. From Burn, J.H., 1963. Autonomic Pharmacology. Blackwell, Oxford.

The patch clamp technique has enabled the function of the nAChR-channel complex to be studied in their physiological environment at the molecular level (see **Bouzat and Sine, 2018**, for a review). As explained in **Chapter 3** nicotinic agonists open a pore, approximately 0.7 nm diameter, that penetrates the central core of the pentameric complex and, when the receptor complex is activated, permits cation flux across the cell membrane (see **Fig. 3.4**). The channel conductance produced by different agonists is the same, whereas the mean channel lifetime varies according to the efficacy of the agonist. The mean open time is determined mainly by the closing rate constant α for the reaction $AR \rightleftarrows AR*$, where A is the agonist and R* is the activated conformation of the receptor (see **Fig. 2.1**). This rate constant varies from drug to drug.

The diversity of the nAChR family (for details see **Kalamida et al., 2007**), which emerged from cloning studies in the 1980s, took pharmacologists somewhat by surprise. Although they knew that the neuromuscular and ganglionic synapses differed pharmacologically and suspected that cholinergic synapses in the CNS might be different again, the molecular diversity goes far beyond this, and its functional significance is only slowly emerging.

The different action of agonists and antagonists on neuromuscular, ganglionic and brain synapses is of practical importance and mainly reflects the differences between the muscle and neuronal nAChRs (**Table 14.1**).

Muscarinic Receptors

Muscarinic receptors (mAChRs) are typical G protein–coupled receptors (see **Ch. 3**), and five molecular subtypes (M_1–M_5) are known. The odd-numbered members of the group (M_1, M_3, M_5) couple with G_q to activate the inositol phosphate pathway (see **Ch. 3**), while the even-numbered receptors (M_2, M_4) act through G_i to open potassium (K_{ir}) channels, causing membrane hyperpolarisation which inhibits voltage-dependent Ca^{2+}-channels, and to inhibit adenylyl cyclase. G_q- and G_i-coupled muscarinic receptors also activate the mitogen-activated protein kinase pathway. The location and pharmacology of the various receptor subtypes are summarised in **Table 14.2**.

M_1 receptors (‘*neural*’) are found mainly on CNS and peripheral neurons and on gastric parietal cells. They mediate excitatory effects, for example, the slow muscarinic excitation mediated by ACh in sympathetic ganglia (see **Ch. 13**) and central neurons. This excitation is produced by a decrease in K^+ conductance, which causes membrane depolarisation. Deficiency of this kind of ACh-mediated effect in the brain is possibly associated with dementia (see **Ch. 40**), although transgenic M_1-receptor knockout mice show only slight cognitive impairment. M_1 receptors are also implicated in the increase of gastric acid secretion following vagal stimulation (see **Ch. 30**).

M_2 receptors (‘*cardiac*’) occur in the heart, and on the presynaptic terminals of peripheral and central neurons. They exert inhibitory effects, mainly by increasing K^+ conductance and by inhibiting calcium channels (see **Ch. 4**). M_2-receptor activation is responsible for cholinergic inhibition of the heart, as well as presynaptic inhibition in the CNS and periphery (see **Ch. 13**). They

are also co-expressed with M_3 receptors in visceral smooth muscle and contribute to the smooth-muscle-stimulating effect of muscarinic agonists in several organs.

Table 14.1

[a] This table shows only the main subtypes expressed in mammalian tissues. Several other subtypes are expressed in selected brain regions, and also in the peripheral nervous system and in non-neuronal tissues. For further details, see **Chapter 39** and review by Kalamida et al. (2007).

[b] Varenicline is used as an aid to smoking cessation. It acts as a partial agonist on $(\alpha4)_2(\beta2)_3$ receptors and a full agonist on $(\alpha7)_5$ receptors (see **Ch. 50**).

M_3 receptors (*glandular/smooth muscle*) produce mainly excitatory effects, i.e. stimulation of glandular secretions (salivary, bronchial, sweat, etc.) and contraction of visceral smooth muscle. M_3 receptor activation also causes relaxation of some smooth muscles (mainly vascular) via the release of nitric oxide from neighbouring endothelial cells (see **Ch. 19**). M_3 receptors occur also in specific locations in the CNS (see **Ch. 39**).

M_4 and *M_5 receptors* are largely confined to the CNS, and their functional role is not well understood, although mice lacking these receptors do show behavioural changes.

Cytokine secretion from lymphocytes and other cells is regulated by M_1 and M_3 receptors, while M_2 and M_4 receptors affect cell proliferation in various situations, opening up the possibility of new

therapeutic roles for mAChR ligands (see **Wessler and Kirkpatrick, 2020**).

The agonist binding region is highly conserved between the different subtypes, so attempts to develop selective agonists and antagonists have had limited success. Most known agonists are non-selective, although an experimental compound, **McNA343**, is selective for M_1 receptors. **Cevimeline**, a relatively selective M_3-receptor agonist, is used clinically (see further in the chapter). It is possible that new mAChR ligands (see **Jakubik and El-Fakahany, 2020**) known as positive allosteric modulators (PAMs, see **Ch. 3**, **Fig. 3.7**) will allow better subtype selectivity for drugs acting on this important class of receptors, for example, by targeting CNS muscarinic receptors without producing unwanted cardiovascular effects (see **Ch. 40**).

There is more subtype selectivity among antagonists. Although most of the classic muscarinic antagonists (e.g. **atropine**, **hyoscine**) are non-selective, **pirenzepine** (previously used for peptic ulcer disease) is selective for M_1 receptors, and **darifenacin** (used for urinary incontinence in adults with detrusor muscle instability, known as 'overactive bladder') is selective for M_3 receptors. **Gallamine**, once used as a neuromuscular-blocking drug, is also a selective, although weak, allosteric M_2 receptor antagonist. [1] Toxins from the venom of the green mamba have been discovered to be highly selective mAChR antagonists (see **Table 14.2**).

Acetylcholine receptors

- Main subdivision is into nicotinic (nAChR) and muscarinic (mAChR) subtypes.
- nAChRs are directly coupled to cation channels, and mediate fast excitatory synaptic transmission at the neuromuscular junction, autonomic ganglia and various sites in the CNS. Muscle and neuronal nAChRs differ in their molecular structure and pharmacology.
- mAChRs and nAChRs occur presynaptically as well as postsynaptically, and function to regulate transmitter release.
- mAChRs are G protein–coupled receptors causing:
  - Gq: activation of phospholipase C (hence formation of diacylglycerol and inositol trisphosphate as second messengers, releasing Ca^{2+} from the endoplasmic reticulum).
  - Gi: activation of potassium channels and/or inhibition of calcium channels; inhibition of adenylyl cyclase.
- All mAChRs are activated by ACh and blocked by **atropine.** They mediate ACh effects at postganglionic parasympathetic synapses (mainly heart, smooth muscle and glands), and contribute to ganglionic excitation. They occur in many parts of the CNS.
- There are three main types of mAChR:
  - M_1 receptors ('neural') producing slow excitation of ganglia. They are selectively blocked by **pirenzepine.**
  - M_2 receptors ('cardiac') causing decrease in cardiac rate. They are selectively blocked by **gallamine.** M_2 receptors also mediate presynaptic inhibition.

  - M_3 receptors ('glandular') causing secretion, contraction of visceral smooth muscle, vascular relaxation. **Cevimeline** is a selective M_3 agonist.
- Two further mAChR subtypes, M_4 and M_5, occur mainly in the CNS.

Physiology of Cholinergic Transmission

The physiology of cholinergic neurotransmission is described in detail by **Nicholls et al. (2012)**. The main ways in which drugs can affect cholinergic transmission are shown in **Fig. 14.2**.

Acetylcholine Synthesis and Release

ACh is synthesised within the nerve terminal from choline, which is taken up into the nerve terminal by a specific transporter (see **Ch. 13**), similar to those that operate for many transmitters but which transports the precursor, choline, not ACh, so it is not important in terminating the action of the transmitter. The concentration of choline in the blood and body fluids is normally about 10 µmol/L, but in the immediate vicinity of cholinergic nerve terminals it increases, probably to about 1 mmol/L, when the released ACh is hydrolysed, and more than 50% of this choline is normally recaptured by the nerve terminals. Free choline within the nerve terminal is acetylated by a cytosolic enzyme, *choline acetyltransferase* (CAT), which transfers the acetyl group from acetyl coenzyme A. The rate-limiting process in ACh synthesis appears to be choline transport, which is determined by the extracellular choline concentration and hence is linked to the rate at

which ACh is being released (see **Fig. 14.2**). *Cholinesterase* is present in the presynaptic nerve terminals, and ACh is continually being hydrolysed and resynthesised. Inhibition of the nerve terminal cholinesterase causes the accumulation of surplus ACh in the cytosol, which is not available for release by nerve impulses (although it is able to leak out via the choline carrier). Most of the ACh synthesised, however, is packaged into synaptic vesicles, in which its concentration is extraordinarily high (about 100 mmol/L), and from which release occurs by exocytosis triggered by Ca^{2+} entry into the nerve terminal (see **Ch. 4**).

Cholinergic vesicles accumulate ACh actively, by means of a specific transporter belonging to the family of amine transporters described in **Chapter 13**. Accumulation of ACh is coupled to the large electrochemical gradient for protons that exists between acidic intracellular organelles and the cytosol; it is blocked selectively by the experimental drug **vesamicol**. Following its release, ACh diffuses across the synaptic cleft to combine with receptors on the postsynaptic cell. Some of it succumbs on the way to hydrolysis by *acetylcholinesterase* (AChE), an enzyme that is bound to the basement membrane that lies between the pre- and postsynaptic membranes. At fast cholinergic synapses (e.g. the neuromuscular and ganglionic synapses), but not at slow ones (smooth muscle, gland cells, heart, etc.), the released ACh is hydrolysed very rapidly (within 1 ms), so that it acts only very briefly.

At the neuromuscular junction, which is a highly specialised synapse, a single nerve impulse releases about 300 synaptic vesicles (altogether about 3 million ACh molecules) from the nerve terminals supplying a single muscle fibre. Each nerve terminal

contains a total of approximately 3 million synaptic vesicles. The synaptic vesicles are the structural basis for the release of ACh from the nerve terminal in packets ('quanta'). Approximately 2 million of the ACh molecules released by a single impulse combine with receptors, of which there are about 30 million on each muscle fibre, the rest of the released ACh being hydrolysed without reaching a receptor. The ACh molecules remain bound to receptors for, on average, about 2 ms, and are quickly hydrolysed after dissociating. The result is that transmitter action is very rapid in onset and very brief in duration, which is important for a synapse that initiates speedy muscular responses and transmits signals faithfully at high frequency. Muscle cells are much larger than neurons and require much more synaptic current to generate an action potential. Thus all the chemical events happen on a larger scale than at a neuronal synapse; the number of transmitter molecules in a quantum, the number of quanta released, and the number of receptors activated by each quantum are all 10–100 times greater. Our brains would be huge, but not very clever, if their synapses were built on the industrial scale of the neuromuscular junction.

Presynaptic Modulation

ACh release is regulated by mediators, including ACh itself, acting on presynaptic receptors, as discussed in **Chapter 13**. At postganglionic parasympathetic nerve endings, inhibitory M_2 receptors participate in autoinhibition of ACh release; other mediators, such as noradrenaline, also inhibit the release of ACh (see **Ch. 13**). At the neuromuscular junction, however, presynaptic nAChRs facilitate ACh release, a mechanism that may allow the

synapse to function reliably during prolonged high-frequency activity. In the brain, as mentioned previously, presynaptic nAChRs either facilitate or inhibit the release of other mediators.

Table 14.2

DAG, Diacylglycerol; *epsp,* excitatory postsynaptic potential; IP_3, inositol trisphosphate.

[a] This table shows only the predominant subtypes expressed in mammalian tissues. For further details, see **Chapter 39** and review by Kalamida et al. (2007).

Electrical Events in Transmission at Fast Cholinergic Synapses

ACh, acting on the postsynaptic membrane of a nicotinic (neuromuscular or ganglionic) synapse, causes a large increase in its permeability to cations, particularly to Na^+ and K^+, and to a lesser extent Ca^{2+}. The resulting inflow of Na^+ depolarises the postsynaptic membrane. This transmitter-mediated depolarisation is called an *endplate potential* (*epp*) in a skeletal muscle fibre, or a *fast excitatory postsynaptic potential* (*fast epsp*) at the ganglionic synapse. In a muscle fibre, the localised epp spreads to adjacent, electrically excitable parts of the muscle fibre; if its amplitude reaches the threshold for excitation, an action potential is initiated, which propagates to the rest of the fibre and evokes a contraction (see **Ch. 4**).

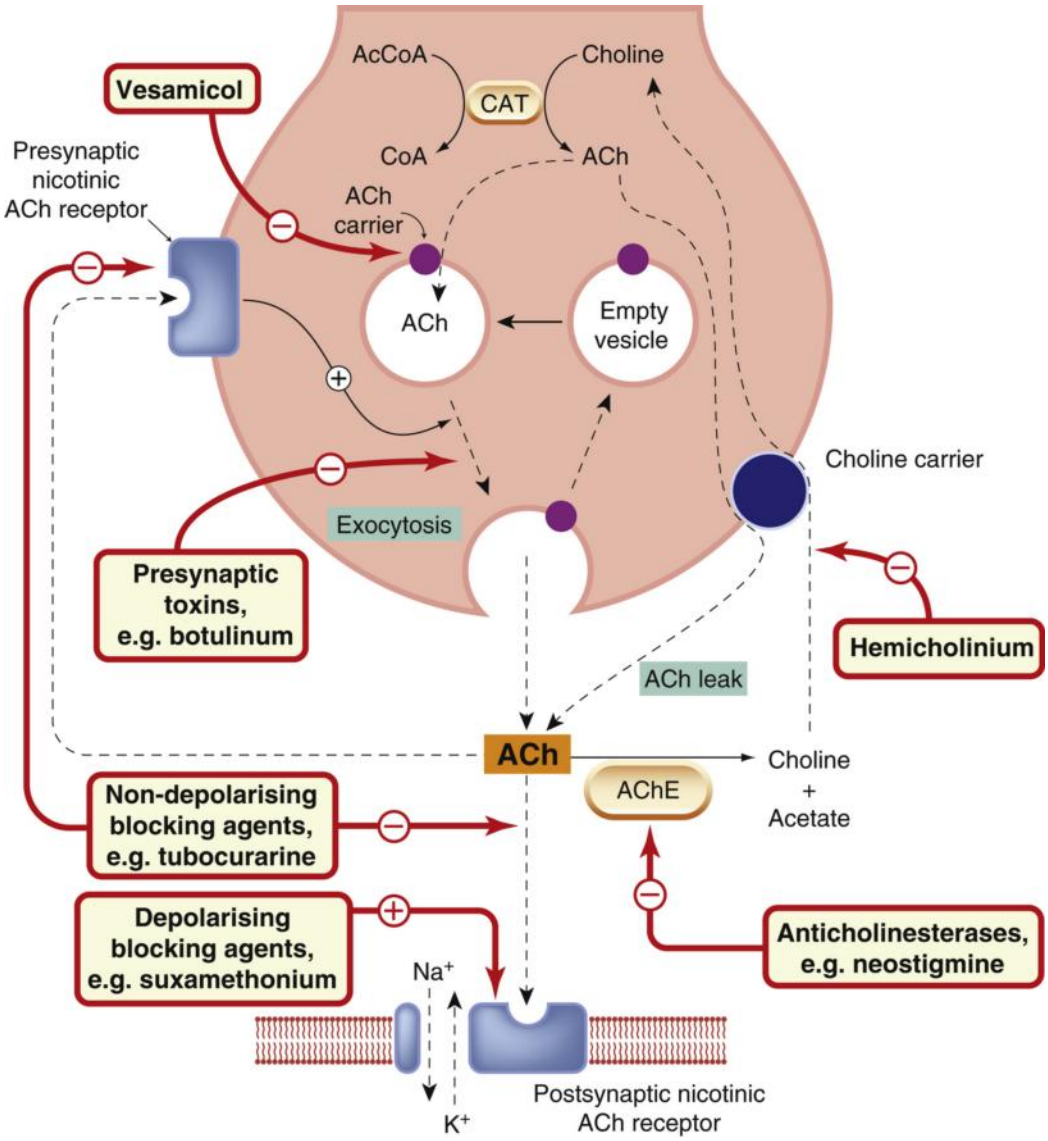

FIG. 14.2 Events and sites of drug action at a nicotinic cholinergic synapse.Acetylcholine (ACh) is shown acting postsynaptically on a nicotinic receptor controlling a cation channel (e.g. at the neuromuscular or ganglionic synapse), and also on a presynaptic nicotinic receptor that acts to facilitate ACh release during sustained synaptic activity. The nerve terminal also contains acetylcholinesterase (not shown);

when this is inhibited, the amount of free ACh, and the rate of leakage of ACh via the choline carrier, is increased. Under normal conditions, this leakage of ACh is insignificant. At muscarinic cholinergic junctions (e.g. heart, smooth muscle and exocrine glands), both postsynaptic and presynaptic (inhibitory) receptors are of the muscarinic type. *AcCoA,* Acetyl coenzyme A; *AChE,* acetylcholinesterase; *CAT,* choline acetyltransferase; *CoA,* coenzyme A.

In a nerve cell, depolarisation of the soma or a dendrite by the fast epsp causes a local current to flow. This depolarises the axon hillock region of the cell, where, if the epsp is large enough, an action potential is initiated. **Fig. 14.3** shows that **tubocurarine**, a drug that blocks postsynaptic nACh receptors, reduces the amplitude of the fast epsp until it no longer initiates an action potential, although the cell is still capable of responding when it is stimulated electrically. Most ganglion cells are supplied by several presynaptic axons, and it requires simultaneous activity in more than one to make the postganglionic cell fire (integrative action). At the neuromuscular junction, only one nerve fibre supplies each muscle fibre – like a relay station in a telegraph line the synapse ensures faithful 1:1 transmission despite the impedance mismatch between the fine nerve fibre and the much larger muscle fibre. The amplitude of the epp is normally more than enough to initiate an action potential – indeed, transmission still occurs when the epp is reduced by 70%–80%, showing a large margin of safety so that

fluctuations in transmitter release (e.g. during repetitive stimulation) do not affect transmission.

Transmission at the ganglionic synapse is more complex than at the neuromuscular junction. Although the primary event at both is the depolarisation (fast epsp or epp, respectively) produced by ACh acting on nAChRs, this is followed in the ganglion by a succession of much slower postsynaptic responses:

- A *slow inhibitory (hyperpolarising) postsynaptic potential (slow ipsp),* lasting 2–5 s. This mainly reflects a muscarinic (M_2)-receptor-mediated increase in K^+ conductance, but other transmitters, such as dopamine and adenosine, also contribute.
- A *slow epsp,* which lasts for about 10 s. This is produced by ACh acting on M_1 receptors, which close K^+ channels.
- A *late slow epsp,* lasting for 1–2 min. This is thought to be mediated by a peptide co-transmitter, substance P in some ganglia, and a gonadotrophin-releasing hormone-like peptide in others (see **Ch. 13**). Like the slow epsp, it is produced by a decrease in K^+ conductance.

Cholinergic transmission

- Acetylcholine (ACh) synthesis:
  - requires choline, which enters the neuron via carrier-mediated transport
  - choline is acetylated to form ACh by choline acetyl transferase, a cytosolic enzyme found only in cholinergic

neurons. Acetyl coenzyme A provides the acetyl groups.

- ACh is packaged into synaptic vesicles at high concentration by carrier-mediated transport.
- ACh release occurs by Ca^{2+}-mediated exocytosis. At the neuromuscular junction, one presynaptic nerve impulse releases 100–500 vesicles.
- At the neuromuscular junction, ACh acts on nicotinic receptors to open cation channels, producing a rapid depolarisation (endplate potential), which normally initiates an action potential in the muscle fibre. Transmission at other 'fast' cholinergic synapses (e.g. ganglionic) is qualitatively similar.
- At 'fast' cholinergic synapses, ACh is hydrolysed within about 1 ms by acetylcholinesterase, so a presynaptic action potential produces only one postsynaptic action potential.
- Transmission mediated by muscarinic receptors is much slower in its time course, and synaptic structures are less clearly defined. In many such situations, ACh functions as a *modulator* (i.e. where the mediator acts indirectly to alter the efficiency of transmission rather than as a direct transmitter – see **Ch. 13**).
- Main mechanisms of pharmacological block: inhibition of choline uptake, inhibition of ACh release, block of postsynaptic receptors or ion channels, persistent postsynaptic depolarisation.

Depolarisation Block

Depolarisation block occurs at cholinergic synapses when the excitatory nAChRs are persistently activated, and it results from a decrease in the electrical excitability of the postsynaptic cell. This is shown in **Fig. 14.4**. Application of nicotine to a sympathetic ganglion activates nAChRs, causing a depolarisation of the cell, which at first initiates action potential discharge. After a few seconds, this discharge ceases and transmission is blocked. The loss of electrical excitability is shown by the fact that electrical stimuli also fail to produce an action potential. The main reason for the loss of electrical excitability during a period of maintained depolarisation is that the voltage-sensitive sodium channels (see **Ch. 4**) become inactivated (i.e. refractory) and no longer able to open in response to a brief depolarising stimulus.

A second type of effect is also seen in the experiment shown in **Fig. 14.4**. After nicotine has acted for several minutes, the cell partially repolarises and its electrical excitability returns but, despite this, transmission remains blocked. This type of secondary, *non-depolarising block* occurs also at the neuromuscular junction if repeated doses of the depolarising drug **suxamethonium** [2] (see later) are used. The main factor responsible for the secondary block (known clinically as *phase II block*) appears to be receptor desensitisation (see **Ch. 2**). This causes the depolarising action of the blocking drug to subside, but transmission remains blocked because the receptors are desensitised to ACh.

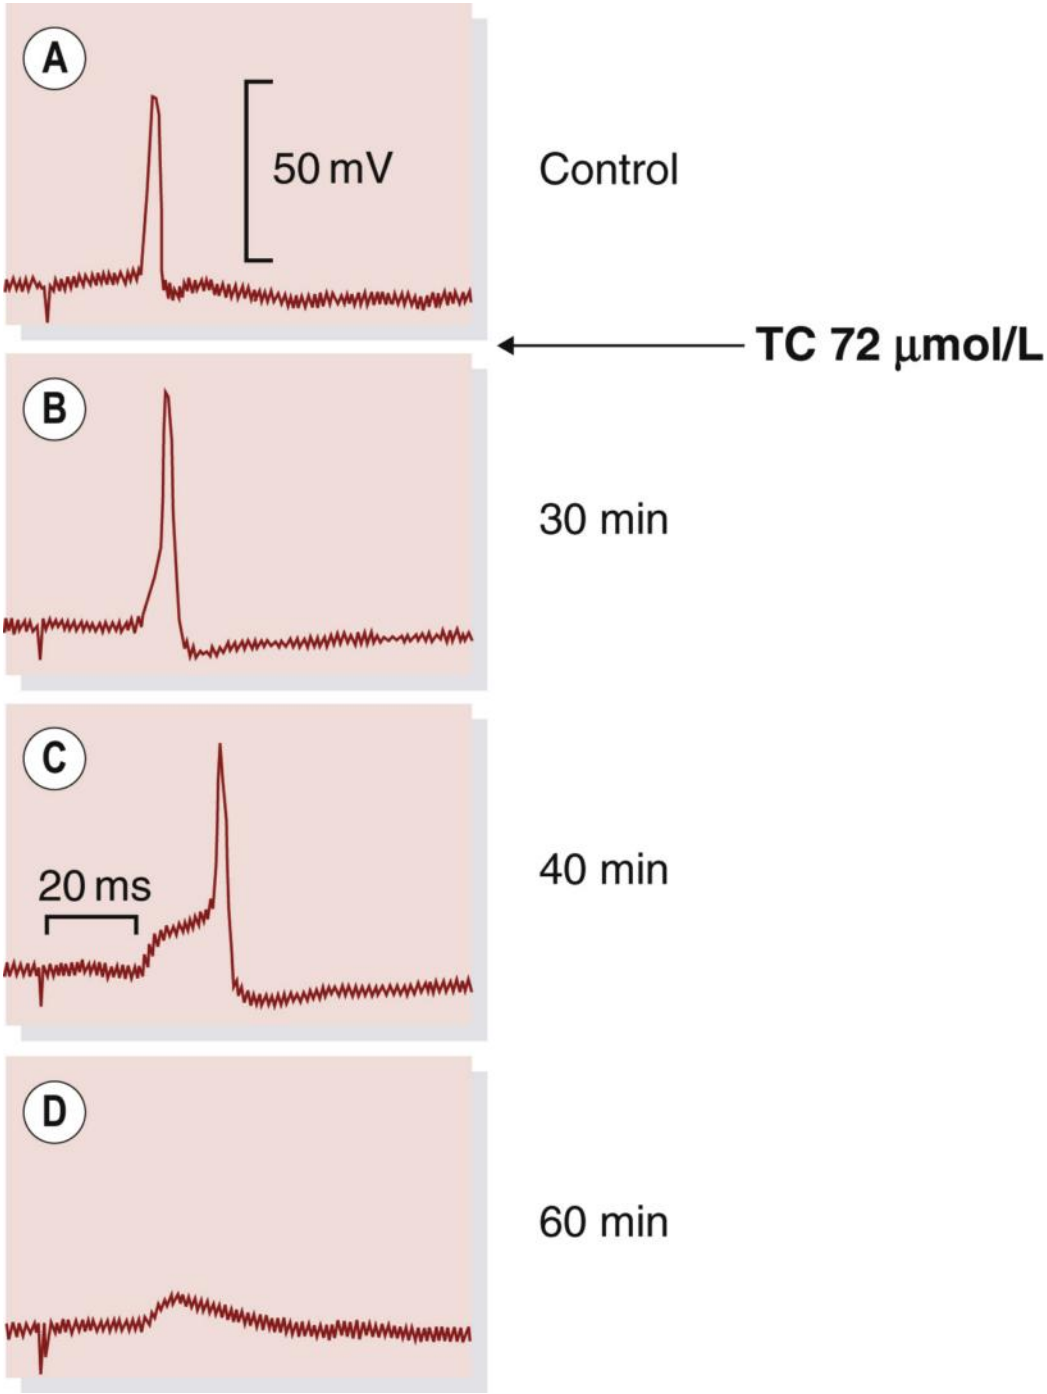

FIG. 14.3 Cholinergic transmission in an autonomic ganglion cell.Records were obtained with an intracellular microelectrode from a guinea pig parasympathetic ganglion cell. The artefact at the beginning of each trace shows the

moment of stimulation of the preganglionic nerve. Tubocurarine (TC), an acetylcholine antagonist, causes the excitatory postsynaptic potential to become smaller. In record (C), it only just succeeds in triggering the action potential, and in (D) it has fallen below the threshold. Following complete block, antidromic stimulation (not shown) will still produce an action potential (cf. depolarisation block, **Fig. 14.4**). From Blackman, J.G., et al., 1969. J. Physiol. 201, 723.

Effects of Drugs on Cholinergic Transmission

As shown in **Fig. 14.2**, drugs can influence cholinergic transmission either by acting on postsynaptic ACh receptors as agonists or antagonists (see Tables **14.1** and **14.2**), or by affecting the release or destruction of endogenous ACh.

In the rest of this chapter, we describe the following groups of drugs, subdivided according to their site of action:

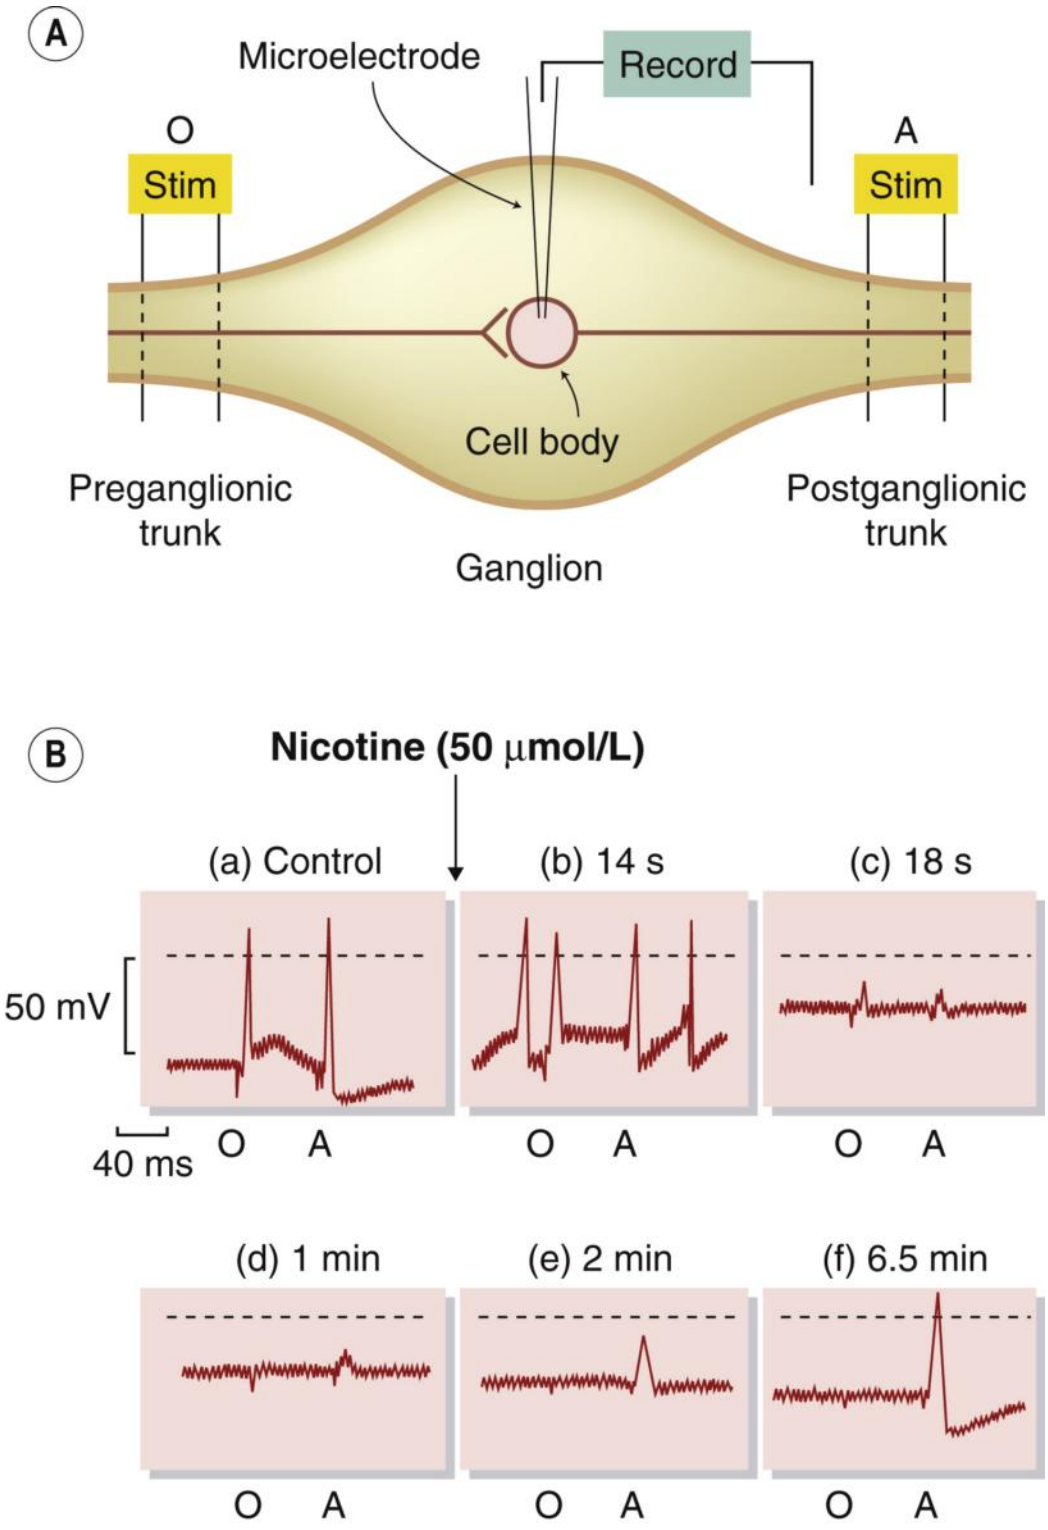

FIG. 14.4 Depolarisation block of ganglionic transmission by nicotine.(A) System used for intracellular recording from sympathetic

ganglion cells of the frog, showing the location of orthodromic *(O)* and antidromic *(A)* stimulating (stim) electrodes. Stimulation at *O* excites the cell via the cholinergic synapse, whereas stimulation at *A* excites it by electrical propagation of the action potential. (B) The effect of nicotine. *(a)* Control records. The membrane potential is −55 mV (dotted line = 0 mV), and the cell responds to both *O* and *A*. *(b)* Shortly after adding nicotine, the cell is slightly depolarised and spontaneously active, but still responsive to *O* and *A*. *(c and d)* The cell is further depolarised, to −25 mV, and produces only a vestigial action potential. The fact that it does not respond to *A* shows that it is electrically inexcitable. *(e and f)* In the continued presence of nicotine, the cell repolarises and regains its responsiveness to *A*, but it is still unresponsive to *O* because the ACh receptors are desensitised by nicotine. From Ginsborg, B.L., Guerrero, S., 1964. J. Physiol. 172, 189.

- ganglion-blocking drugs
- neuromuscular-blocking drugs

- anticholinesterases and other drugs that enhance cholinergic transmission

Drugs Affecting Muscarinic Receptors

Muscarinic Agonists

Structure–activity relationships

Muscarinic agonists, as a group, are often referred to as *parasympathomimetic*, because the main effects that they produce in the whole animal resemble those of parasympathetic stimulation. The structures of ACh and related choline esters are given in **Table 14.3**. They are agonists at both mAChRs and nAChRs, but act more potently on mAChRs (see **Fig. 14.1**). **Bethanechol**, **pilocarpine** and **cevimeline** are the main ones used clinically.

The key features of the ACh molecule are the quaternary ammonium group, which bears a positive charge, and the ester group, which bears a partial negative charge and is susceptible to rapid hydrolysis by cholinesterase. Variants of the choline ester structure (see **Table 14.3**) have the effect of reducing the susceptibility of the compound to hydrolysis by cholinesterase and altering the relative activity on mAChRs and nAChRs.

Carbachol and **methacholine** are less rapidly hydrolysed by cholinesterase enzymes than is ACh. They are used as experimental tools. Bethanechol, which is a hybrid of these two molecules, is stable to hydrolysis and selective for mAChRs, and has been used clinically (see clinical box, later). Pilocarpine is a partial agonist and shows some selectivity in stimulating secretion from sweat, salivary, lacrimal and bronchial glands, and contracting iris smooth

muscle, with weak effects on gastrointestinal smooth muscle and the heart.

Effects of muscarinic agonists

The main actions of muscarinic agonists are readily understood in terms of the parasympathetic nervous system.

Cardiovascular effects

These include cardiac slowing and a decrease in cardiac output due mainly to the reduced heart rate. There is also a decreased force of contraction of the atria (the ventricles have only a sparse parasympathetic innervation and a low sensitivity to muscarinic agonists). Generalised vasodilatation also occurs (mediated by nitric oxide, NO; see **Ch. 19**) and, combined with the reduced cardiac output, produces a fall in arterial pressure (see **Fig. 14.1**). Parasympathetic regulation of the heart is discussed in **Chapter 20** (see **Fig. 20.7**).

Smooth muscle

Smooth muscle generally *contracts* in direct response to muscarinic agonists, in contrast to their indirect effect via NO on vascular smooth muscle. Peristaltic activity of the gastrointestinal tract is increased, which can cause colicky pain, and the bladder and bronchial smooth muscle also contract.

Sweating, lacrimation, salivation and bronchial secretion

Muscarinic agonists stimulate exocrine glands. The combined effect of bronchial secretion and constriction can interfere with breathing.

Methacholine is used as an inhaled challenge agent in the investigation of airways responsiveness.

Effects on the eye

The ocular effects of muscarinic agents are clinically important. The parasympathetic nerves to the eye supply the constrictor pupillae muscle and the ciliary muscle. The constrictor pupillae is important not only for adjusting the pupil in response to changes in light intensity, but also in regulating the intraocular pressure. The effects of drugs that influence cholinergic transmission on the eye are described in more detail in **Chapter 27**.

Table 14.3

[a] Essential to check that bladder neck is not obstructed.

[b] Cause of one type of mushroom poisoning.

[c] Selective for M_3 receptors.

Clinical use

Currently there are few important clinical uses of muscarinic agonists, although hopes remain that new more selective agents may prove useful in various CNS disorders. **Pilocarpine** can be used as eye drops (see **Ch. 27**) and it or the M_3-selective agonist **cevimeline** are used to increase salivary and lacrimal secretion in patients with dry eyes and dry mouth, e.g. following irradiation or in patients with Sjögren's syndrome, an autoimmune disorder characterised by dryness of mouth and eyes. Cholinesterase inhibitors (see later) were used in the past to potentiate endogenous

parasympathetic muscarinic effects on bowel and bladder, as stimulant laxatives or to stimulate bladder emptying.

Muscarinic Antagonists

mAChR antagonists (*parasympatholytic drugs*; **Table 14.4**) are competitive antagonists whose chemical structures usually contain ester and basic groups in the same relationship as ACh, but with a bulky aromatic group in place of the acetyl group. The two naturally occurring compounds, **atropine** and **hyoscine** (also known as **scopolamine**), are alkaloids found in solanaceous plants. The deadly nightshade (*Atropa belladonna*) contains mainly atropine, whereas the thorn apple (*Datura stramonium*) contains mainly hyoscine. These are tertiary ammonium compounds that are sufficiently lipid-soluble to be readily absorbed from the gut or conjunctival sac and, importantly, to penetrate the blood–brain barrier. Analogues containing quaternary rather than tertiary ammonium groups have peripheral actions very similar to those of atropine but, because of their exclusion from the brain, lack central actions. Clinically important examples include **hyoscine butylbromide** and **propantheline**. Other muscarinic antagonists in clinical use are described later.

Effects of muscarinic antagonists

All muscarinic antagonists produce similar peripheral effects, although some show a degree of selectivity, for example, for the heart or bladder, reflecting heterogeneity among mAChRs.

The main effects of atropine are:

Inhibition of secretions

Salivary, lacrimal, bronchial and sweat glands are inhibited by very low doses of atropine, producing uncomfortably dry eyes, mouth and skin. Gastric secretion is only slightly reduced. Mucociliary clearance in the bronchi is inhibited, so that residual secretions tend to accumulate in the lungs. **Ipratropium** (see later) lacks this latter undesired effect.

Effects on heart rate

Atropine causes tachycardia through block of cardiac mAChRs. The tachycardia is modest, up to 80–90 beats/min in humans, since it has no effect on the sympathetic system, working by inhibition of tonic parasympathetic activity. Tachycardia is most pronounced in young people, in whom vagal tone at rest is highest; it is often absent in the elderly. At very low doses, atropine causes a paradoxical bradycardia, possibly due to a central action. Arterial blood pressure and the response of the heart to exercise are unaffected.

Table 14.4

Muscarinic antagonists [a]

Compound	Pharmacological properties	Notes
Atropine	Non-selective antagonist Well absorbed orally CNS stimulant	Belladonna alkaloid Main side effects: urinary retention, dry mouth, blurred vision Dicycloverine (dicyclomine) is similar and used mainly as an antispasmodic agent

Compound	Pharmacological properties	Notes
Glycopyrronium	Similar to atropine	Quaternary ammoniun compound Reduces secretions and salivation in palliative care, perioperative patients, and children with chronic neurological conditions. Also available as inhaler for chronic obstructive pulmonary disease

Compound	Pharmacological properties	Notes
Hyoscine	Similar to atropine CNS depressant	Belladonna alkaloid (also known as scopolamine) Causes sedation; other side effects as atropine
Hyoscine butylbromide	Similar to atropine but poorly absorbed and lacks many CNS effects Significant ganglion-blocking activity	Quaternary ammonium derivative Similar drugs include atropine methonitrate, propantheline

Compound	Pharmacological properties	Notes
Tiotropium	Similar to atropine methonitrate Does not inhibit mucociliary clearance from bronchi	Quaternary ammonium compound Ipratropium similar
Tropicamide	Similar to atropine May raise intraocular pressure	Used topically (eye drops) as a mydriatic
Cyclopentolate	Similar to tropicamide	—
Darifenacin	Selective for M_3 receptors	Used to treat unstable bladder and associated urge incontinence. Causes fewer adverse effects than unselective muscarinic antagonists

Compound	Pharmacological properties	Notes
Solifenacin	Selective for M_3 receptors	Similar to darifenacin
Tolterodine	Selective for M_3 and M_2 receptors	Similar to darifenacin and solifenacin

CNS, Central nervous system.

[a] For chemical structures, see Southan, C., Sharman, J.L., Benson, H.E., et al., 2016. The IUPHAR/BPS Guide to Pharmacology in 2016: towards curated quantitative interactions between 1300 protein targets and 6000 ligands. Nucl. Acids Res. 44 (Database Issue), D1054–D1068.

Effects on the eye

These are described in **Chapter 27**.

Effects on the gastrointestinal tract

Gastrointestinal motility is inhibited by atropine, although this requires larger doses than the other effects listed and is not complete since excitatory transmitters other than ACh are important in normal function of the myenteric plexus (see **Ch. 13**). Atropine-like drugs such as **hyoscine butylbromide** relax intestinal spasm and are used for symptomatic relief in pathological conditions in which there is gastrointestinal spasm, as well as in gastrointestinal imaging to improve resolution. **Pirenzepine**, owing to its selectivity for M_1 receptors, inhibits gastric acid secretion in doses that do not affect other systems.

Effects on other smooth muscle

Atropine relaxes bronchial, biliary and urinary tract smooth muscle. Reflex bronchoconstriction (e.g. during anaesthesia) is prevented, whereas bronchoconstriction caused by mediators such as histamine and leukotrienes (see **Ch. 28**) is unaffected. **Ipratropium** and **tiotropium**, quaternary ammonium antimuscarinic drugs, are administered by inhalation as bronchodilators (see **Ch. 28**). Biliary and urinary tract smooth muscle are only slightly affected in normal individuals, probably because transmitters other than ACh (see **Ch. 13**) are important in these organs; nevertheless, atropine and similar drugs commonly worsen urinary hesitancy and can precipitate urinary retention in elderly men with prostatic enlargement. **Oxybutynin**, **tolterodine** and **darifenacin** (M_3-selective) act on the bladder to inhibit micturition and are used for treating overactive bladder. They produce unwanted effects typical of muscarinic antagonists, such as dry mouth, constipation and blurred vision, but these are less severe than with less selective drugs.

Effects on the CNS

Atropine produces mainly excitatory effects on the CNS. At low doses, this causes mild restlessness; higher doses cause agitation and disorientation. In atropine poisoning, which occurs in young children who eat deadly nightshade berries, marked excitement and irritability result in hyperactivity and a considerable rise in body temperature, which is accentuated by the loss of sweating. The central effects are the result of blocking mAChRs in the brain and are less marked or absent with quaternary ammonium drugs such

as hyoscine butylbromide, propantheline, ipratropium and tiotropium that have limited access beyond the blood–brain barrier. The central effects of muscarinic antagonists are opposed by anticholinesterase drugs (see later) such as **physostigmine**, which have been used to treat atropine poisoning. Hyoscine in low doses causes marked sedation but has similar effects to atropine in high dosage. Hyoscine has a central antiemetic effect and is used to prevent motion sickness; hyoscine hydrobromide is also effective for this indication, presumably because the blood–brain barrier is deficient in the location of the chemoreceptor trigger zone (see **Ch. 30** on antiemetic drugs). Muscarinic antagonists also affect the extrapyramidal system, reducing the involuntary movement and rigidity of patients with Parkinson's disease (see **Ch. 40**) and counteracting the unwanted extrapyramidal effects caused by many antipsychotic drugs (see **Ch. 47**).

Drugs acting on muscarinic receptors

Muscarinic agonists

- Important compounds include **acetylcholine**, **carbachol**, **methacholine**, **muscarine** and **pilocarpine.** They vary in muscarinic/nicotinic selectivity, and in susceptibility to cholinesterase.
- Main effects are bradycardia and vasodilatation (endothelium-dependent), leading to fall in blood pressure; contraction of visceral smooth muscle (gut, bladder, bronchi, etc.); exocrine secretions (e.g. salivation); pupillary constriction and ciliary

muscle contraction, leading to constriction of the pupil and reduced intraocular pressure.

- Main use is in treatment of glaucoma (especially **pilocarpine**) see **Chapter 27**.
- Most agonists currently in therapeutic use show little receptor subtype selectivity; **cevimeline**, a selective M_3 agonist, is an exception.
- PAMs offer prospects for more selective clinical agents.

Muscarinic antagonists

- The main drugs are **atropine, hyoscine butylbromide, ipratropium, tiotropium** and the M_3-selective drugs **oxybutynin, tolterodine** and **darifenacin.**
- Main effects are inhibition of secretions; tachycardia, pupillary dilatation and paralysis of accommodation; relaxation of smooth muscle (gut, bronchi, biliary tract, bladder); CNS effects (mainly excitatory with **atropine**; depressant, including amnesia, with **hyoscine**), including antiemetic effect and antiparkinsonian effect.

Clinical use

The main uses of muscarinic antagonists are summarised in the clinical box.

Clinical uses of muscarinic antagonists

Cardiovascular

- Treatment of sinus bradycardia (e.g. after myocardial infarction; see **Ch. 20**): for example, **atropine.**

Ophthalmic

- To dilate the pupil: for example **tropicamide** or **cyclopentolate** eye drops (see **Ch. 27**).

Neurological

- Prevention of motion sickness: for example, **hyoscine hydrobromide.**
- Parkinsonism (see **Ch. 40**), especially to counteract movement disorders caused by antipsychotic drugs (see **Ch. 47**): for example, **orphenadrine.**

Respiratory

- Asthma and chronic obstructive pulmonary disease (see **Ch. 28**): **ipratropium** or **tiotropium** by inhalation.

Palliative care

- Bowel colic and excessive salivation/respiratory secretion: hyoscine or glycopyrronium.

Anaesthetic premedication

- To dry secretions: for example, **atropine**, **hyoscine.** (Current anaesthetics are relatively non-irritant, see **Ch. 41**, so this is less important than in the past.)

Gastrointestinal

- To facilitate endoscopy and gastrointestinal radiology by relaxing gastrointestinal smooth muscle (antispasmodic action; see **Ch. 30**): for example, **hyoscine butylbromide.**
- As an antispasmodic in irritable bowel syndrome or colonic diverticular disease: for example, **dicycloverine** (**dicyclomine**).

Urinary tract

- To relieve symptoms of overactive bladder: for example, **oxybutynin**, **tolterodine**, **darifenacin.**

Drugs Affecting Autonomic Ganglia

Ganglion Stimulants

Most nAChR agonists act on either neuronal (ganglionic and CNS) nAChRs or on striated muscle (motor endplate) receptors but not, apart from nicotine and ACh, on both (**Table 14.5**).

Nicotine and **lobeline** are tertiary amines found in the leaves of tobacco and lobelia plants, respectively. Nicotine belongs in pharmacological folklore, as it was the substance on the tip of Langley's paintbrush causing stimulation of muscle fibres when applied to the endplate region, leading him to postulate in 1905 the existence of a 'receptive substance' on the surface of the fibres (see **Ch. 13**). **Epibatidine**, found in the skin of poisonous frogs, is a highly potent nicotinic agonist selective for ganglionic and CNS receptors. It was found, unexpectedly, to be a powerful analgesic

(see **Ch. 43**), although its autonomic side effects ruled out its clinical use. **Varenicline**, a synthetic agonist relatively selective for CNS receptors, is used (as is nicotine itself) to treat nicotine addiction (see **Ch. 50**). Otherwise, these drugs are used only as experimental tools.

Table 14.5

CNS, Central nervous system.

Nicotinic agonists cause complex peripheral responses associated with generalised stimulation of autonomic ganglia. The effects of nicotine on the gastrointestinal tract and sweat glands are familiar to neophyte smokers (see **Ch. 50**), although usually insufficient to act as an effective deterrent.

Ganglion-Blocking Drugs

Ganglion-blocking drugs are used experimentally to study autonomic function. In the middle of the last century, Paton and Zaimis investigated a series of linear bisquaternary compounds and found that compounds with five or six carbon atoms in the methylene chain linking the two quaternary groups produced ganglionic block.[3] **Hexamethonium** is obsolete clinically but famous as the first effective antihypertensive drug.

Ganglion block can occur by several mechanisms:

- By interference with ACh release, as at the neuromuscular junction (see **Ch. 13**).
- By prolonged depolarisation. Nicotine (see **Fig. 14.4**) blocks ganglia after initial stimulation, as does ACh itself if

cholinesterase is inhibited.
- Interfering with the postsynaptic action of ACh, by blocking neuronal nAChRs or the associated ion channels.

Effects of ganglion-blocking drugs

The effects of ganglion-blocking drugs are diverse, because both divisions of the autonomic nervous system are blocked indiscriminately. The description by Paton of ‘hexamethonium man’ cannot be bettered:He is a pink-complexioned person, except when he has stood in a queue for a long time, when he may get pale and faint. His handshake is warm and dry. He is a placid and relaxed companion; for instance he may laugh but he can’t cry because the tears cannot come. Your rudest story will not make him blush, and the most unpleasant circumstances will fail to make him turn pale. His collars and socks stay very clean and sweet. He wears corsets and may, if you meet him out, be rather fidgety (corsets to compress his splanchnic vascular pool, fidgety to keep the venous return going from his legs). He dislikes speaking much unless helped with something to moisten his dry mouth and throat. He is long-sighted and easily blinded by bright light. The redness of his eyeballs may suggest irregular habits and in fact his head is rather weak. But he always behaves like a gentleman and never belches or hiccups. He tends to get cold and keeps well wrapped up. But his health is good; he does not have chilblains and those diseases of modern civilisation, hypertension and peptic ulcer, pass him by. He gets thin because his appetite is modest; he never feels hunger pains and his stomach never rumbles. He gets rather constipated so that his intake of liquid paraffin is high. As old age comes on, he will suffer

from retention of urine and impotence, but frequency, precipitancy and strangury (i.e. an intensely painful sensation of needing to pass urine coupled with an inability to do so) will not worry him. One is uncertain how he will end, but perhaps if he is not careful, by eating less and less and getting colder and colder, he will sink into a symptomless, hypoglycaemic coma and die, as was proposed for the universe, a sort of entropy death.(From Paton, W.D.M., 1954. The principles of ganglion block. Lectures on the Scientific Basis of Medicine, Vol. 2.)

In practice, the main effect is a marked fall in arterial blood pressure on standing upright ('postural hypotension') resulting mainly from block of sympathetic ganglia. This causes vasodilatation and loss of cardiovascular reflexes so that the heart rate fails to increase in compensation for the fall in blood pressure. Venoconstriction, which occurs normally when a subject stands up and prevents a fall in central venous pressure and cardiac output, is reduced leading to faintness or syncope.

Drugs acting on autonomic ganglia

Ganglion-stimulating drugs

- Compounds include nicotine, dimethylphenyl-piperazinium (DMPP).
- Both sympathetic and parasympathetic ganglia are stimulated, so effects are complex, including tachycardia and increase of blood pressure; variable effects on gastrointestinal motility and secretions; increased bronchial, salivary and sweat secretions. Additional effects result from stimulation of other

neuronal structures, including sensory and noradrenergic nerve terminals.

- Ganglion stimulation is followed by depolarisation block.
- Nicotine also has important CNS effects (see **Ch. 50**).
- Therapeutic uses are limited to assisting smoking cessation (nicotine, varenicline).

Ganglion-blocking drugs

- Compounds include hexamethonium, tubocurarine (also nicotine).
- Block all autonomic ganglia and enteric ganglia. Main effects: postural hypotension and loss of cardiovascular reflexes, inhibition of secretions, gastrointestinal paralysis, impaired micturition.
- Clinically obsolete (historically: the first therapeutic drugs for treating hypertension).

Neuromuscular-Blocking Drugs

Drugs can block neuromuscular transmission either by acting presynaptically to inhibit ACh synthesis or release or by acting postsynaptically.

Neuromuscular block is an important adjunct to general anaesthesia (see **Ch. 41**). The drugs used for this purpose all work postsynaptically, either (a) by blocking ACh receptors (or in some cases the ion channel) or (b) by activating ACh receptors and thus causing persistent depolarisation of the motor endplate.

Suxamethonium is the only depolarising blocker in clinical use, while all of the other drugs used clinically are *non-depolarising agents*.

Non-Depolarising Blocking Agents

In 1856, Claude Bernard, in a famous experiment, showed that 'curare' causes paralysis by blocking neuromuscular transmission, rather than by abolishing nerve conduction or muscle contractility. Curare is a mixture of naturally occurring alkaloids found in various South American plants and used as arrow poisons by South American Indians. The most important component is **tubocurarine**, itself now rarely used in clinical medicine, being superseded by synthetic drugs with improved properties. The most important are **pancuronium**, **vecuronium**, **cisatracurium** and **mivacurium** (**Table 14.6**), which differ mainly in their duration of action. These substances are all quaternary ammonium compounds, so are poorly absorbed [4] (they are administered intravenously) and generally are efficiently excreted by the kidneys. They do not cross the placenta, which is important in relation to their use in obstetric anaesthesia.

Mechanism of action

Non-depolarising blocking agents act as competitive antagonists (see **Ch. 2**) at the nACh receptors of the endplate.

The amount of ACh released by a nerve impulse normally exceeds by several-fold what is needed to elicit an action potential in the muscle fibre (see **Ch. 3**). It is therefore necessary to block 70%–80% of the receptor sites before transmission actually fails. In any individual muscle fibre, transmission is all-or-nothing, so graded

degrees of block represent a varying proportion of muscle fibres failing to respond. In this situation, where the amplitude of the epp in all the fibres is close to threshold (just above in some, just below in others), small variations in the amount of transmitter released, or in the rate at which it is destroyed, will have a large effect on the proportion of fibres contracting, so the degree of block is liable to vary according to various physiological circumstances (e.g. stimulation frequency, temperature and cholinesterase activity), which otherwise have little effect on the efficiency of transmission.

Non-depolarising blocking agents also block facilitatory presynaptic autoreceptors, and thus inhibit the release of ACh during repetitive stimulation of the motor nerve, contributing to the phenomenon of 'tetanic fade', used by anaesthetists to monitor postoperative recovery of neuromuscular transmission.

Effects of non-depolarising blocking drugs

The effects of non-depolarising neuromuscular-blocking agents are mainly due to motor paralysis, although some of the drugs also produce clinically significant autonomic effects by blocking ganglionic transmission.

Table 14.6

[a] For chemical structures, see Hardman, J.G., Limbird, L.E., Gilman, A.G., Goodman-Gilman A. et al., 2001. Goodman and Gilman's Pharmacological Basis of Therapeutics, 10th ed. McGraw-Hill, New York.

The first muscles to be affected are the extrinsic eye muscles (causing double vision), reminiscent of the disease myasthenia

gravis, which is caused by autoantibodies directed against nAChR (see later), and the small muscles of the face, limbs and pharynx (causing difficulty in swallowing). Respiratory muscles are the last to be affected and the first to recover. An experiment in 1947 in which a heroic volunteer was fully curarised while conscious under artificial ventilation established this orderly paralytic march and showed that consciousness and awareness of pain were quite normal even when paralysis was complete. [5]

Unwanted effects

An important unwanted effect of tubocurarine is a fall in arterial pressure, due to (a) sympathetic ganglion block and (b) histamine release from mast cells (see **Ch. 17**), which can also give rise to bronchospasm in sensitive individuals. This is unrelated to nAChRs but also occurs with **atracurium** and **mivacurium** as well as with some pharmacologically unrelated drugs such as morphine (see **Ch. 42**). Other non-depolarising blocking drugs lack these adverse effects. **Pancuronium** also blocks mAChRs, particularly in the heart, causing tachycardia.

Pharmacokinetic aspects

Neuromuscular-blocking drugs are given intravenously. They differ in their rates of onset and recovery (**Fig. 14.5** and **Table 14.6**).

Most non-depolarising blocking agents are metabolised by the liver or excreted unchanged in the urine, exceptions being **atracurium**, which hydrolyses spontaneously in plasma, and **mivacurium**, which, like **suxamethonium** (see later), is hydrolysed by plasma cholinesterase. Their duration of action varies between about 15 min and 1–2 h (see **Table 14.6**), by which time

the patient regains enough strength to cough and breathe properly. The route of elimination is important, because many patients undergoing anaesthesia have impaired renal or hepatic function, which can enhance or prolong paralysis to an important degree.

Atracurium, although stable when stored at an acid pH, was designed to be chemically unstable at physiological pH, splitting into two inactive fragments by cleavage at one of the quaternary nitrogen atoms. It has a short duration of action, which is unaffected by renal or hepatic function. Because of the marked pH dependence of its degradation, however, its action is shortened during respiratory alkalosis caused by hyperventilation.

Rapid postoperative recovery of muscle strength after surgery is important to minimise respiratory complications. The cholinesterase inhibitor **neostigmine** (**Table 14.7**) is often used to reverse the action of non-depolarising drugs postoperatively. Co-administration of atropine is necessary to prevent unwanted parasympathomimetic effects.

Anticholinesterase drugs *overcome* the blocking action of non-depolarising agents because released ACh, protected from hydrolysis, can diffuse further within the synaptic cleft and so access a wider area of postsynaptic membrane. The chances of an ACh molecule finding an unoccupied receptor before being hydrolysed are thus increased. This diffusional effect seems to be more important than a truly competitive interaction, for it is unlikely that appreciable dissociation of the antagonist can occur in the short time for which the ACh is present. In contrast, depolarisation block is either unaffected by anticholinesterase drugs

or even increased via potentiation of the depolarising action of endogenous ACh.

An alternative approach for reversal of neuromuscular blockade induced by **rocuronium** or **vecuronium** is the use of a synthetic cyclodextrin, **sugammadex**, a macromolecule that selectively binds steroidal neuromuscular-blocking drugs as an inactive complex in the plasma (**Nicholson et al., 2007**). The complex is excreted unchanged in the urine. Sugammadex rapidly reverses block with few unwanted effects.

Depolarising Blocking Agents

Suxamethonium is the only depolarising agent used clinically. There are several differences in the pattern of neuromuscular block produced by depolarising and non-depolarising mechanisms:

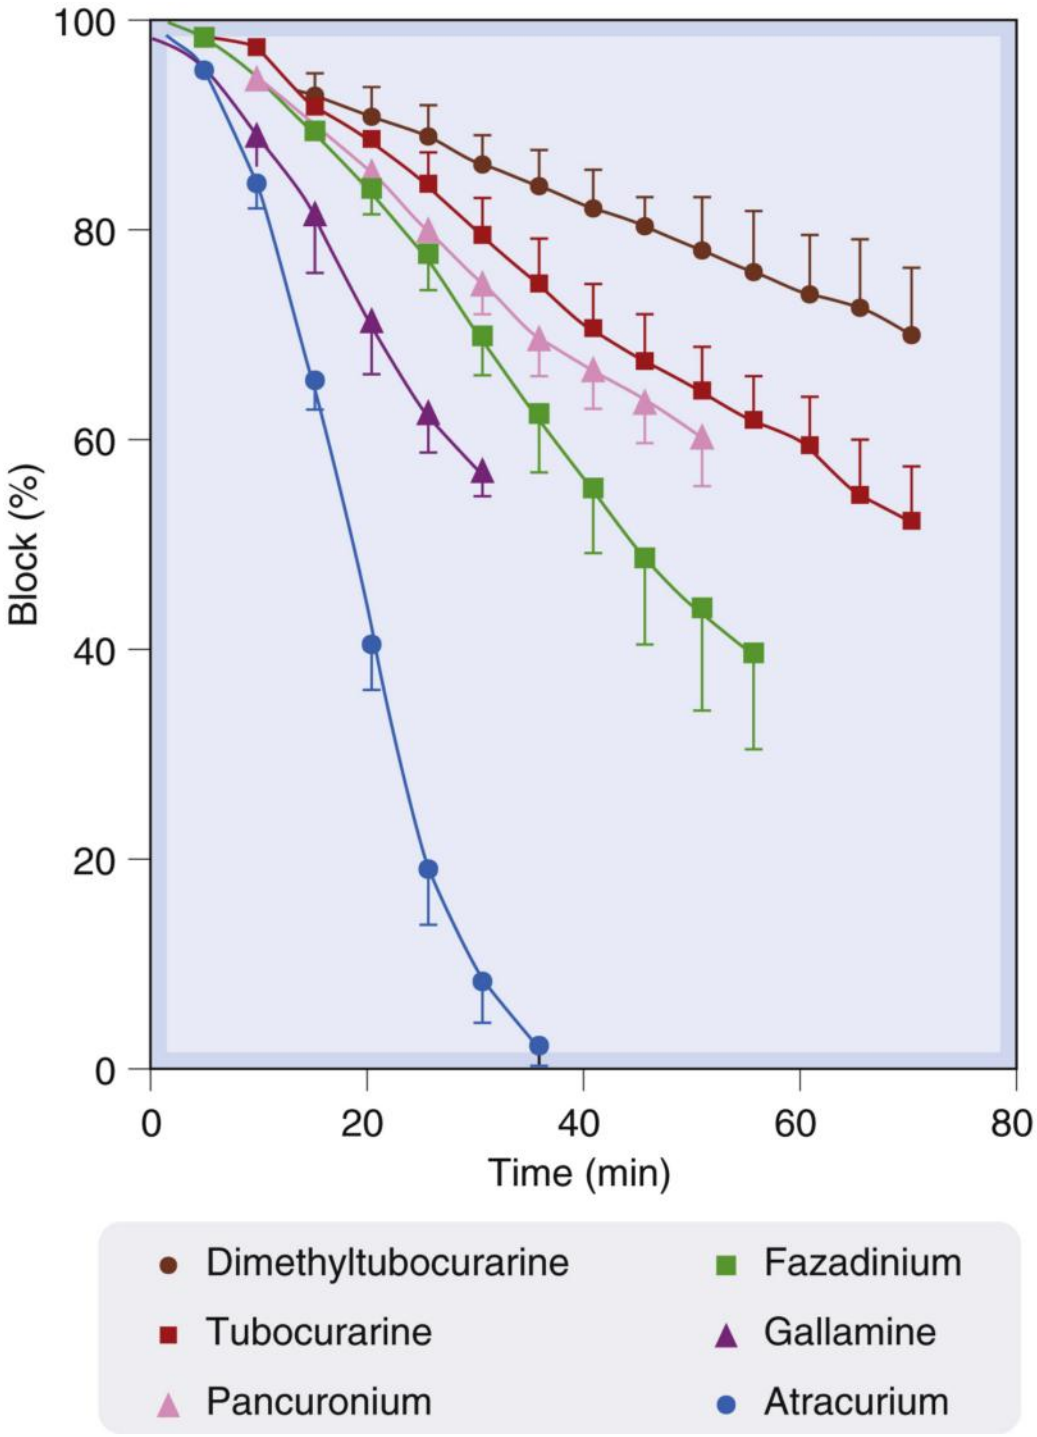

FIG. 14.5 Rate of recovery from various non-depolarising neuromuscular-blocking drugs in humans.Drugs were given intravenously to patients undergoing surgery, in doses just

sufficient to cause 100% block of the tetanic tension of the indirectly stimulated adductor pollicis muscle. Recovery of tension was then followed as a function of time. From Payne, J.P., Hughes, R., 1981. Br. J. Anaesth. 53, 45.

- Fasciculation, seen with suxamethonium (see **Table 14.6**) as a prelude to paralysis, does not occur with non-depolarising drugs. Its severity is linked to postoperative muscle pain experienced after suxamethonium.
- *Tetanic fade* (see earlier in the chapter) occurs with non-depolarising blocking drugs, but not with suxamethonium, which does not block presynaptic nAChRs.

Unwanted effects and dangers of suxamethonium

Suxamethonium has several adverse effects (see **Table 14.6**), but remains in use for short-lasting procedures because of the rapid recovery that follows its intravenous administration.

Bradycardia

This is preventable by atropine and is due to a direct muscarinic action.

Potassium release

The increase in cation permeability of the motor endplates causes a net loss of K^+ from muscle, and thus a small rise in plasma K^+ concentration. This is not usually important, but may be an issue following trauma, burns or injuries causing muscle denervation

(**Fig. 14.6**). Denervation increases the rise in plasma K^+ caused by suxamethonium because it causes ACh receptors to spread to regions of the muscle fibre away from the endplates (see **Ch. 13**), so that a much larger area of membrane is sensitive to suxamethonium. The resulting hyperkalaemia can be enough to cause ventricular dysrhythmia or cardiac arrest.

Increased intraocular pressure

Extraocular muscles are unusual in containing a population of fibres with nAChRs distributed along their length, rather than localised at motor endplates; these respond to suxamethonium with a sustained contracture, applying pressure to the eyeball. It is particularly important to avoid this if the eyeball has been injured.

Prolonged paralysis

The action of suxamethonium, given as an intravenous bolus to achieve relaxation during tracheal intubation, normally lasts for only 2–6 min, because the drug is hydrolysed by plasma cholinesterase. Its action is prolonged by various factors that reduce the activity of this enzyme:

- Genetic variants of plasma cholinesterase with reduced activity (see **Ch. 12**). Severe deficiency, enough to increase the duration of action to 2 h or more, occurs in approximately 1 in 3500 individuals. Rarely, the enzyme is completely absent, and paralysis lasts for many hours. Biochemical testing of enzyme activity in the plasma and its sensitivity to inhibitors is used clinically to diagnose this

problem; genotyping is possible but as yet not practicable for routine screening to prevent the problem.

- Anticholinesterase drugs. The topical use of organophosphates to treat glaucoma (see **Ch. 27**) can inhibit plasma cholinesterase and prolong the action of suxamethonium. Competing substrates for plasma cholinesterase (e.g. **procaine**, **propanidid**) can also have this effect.

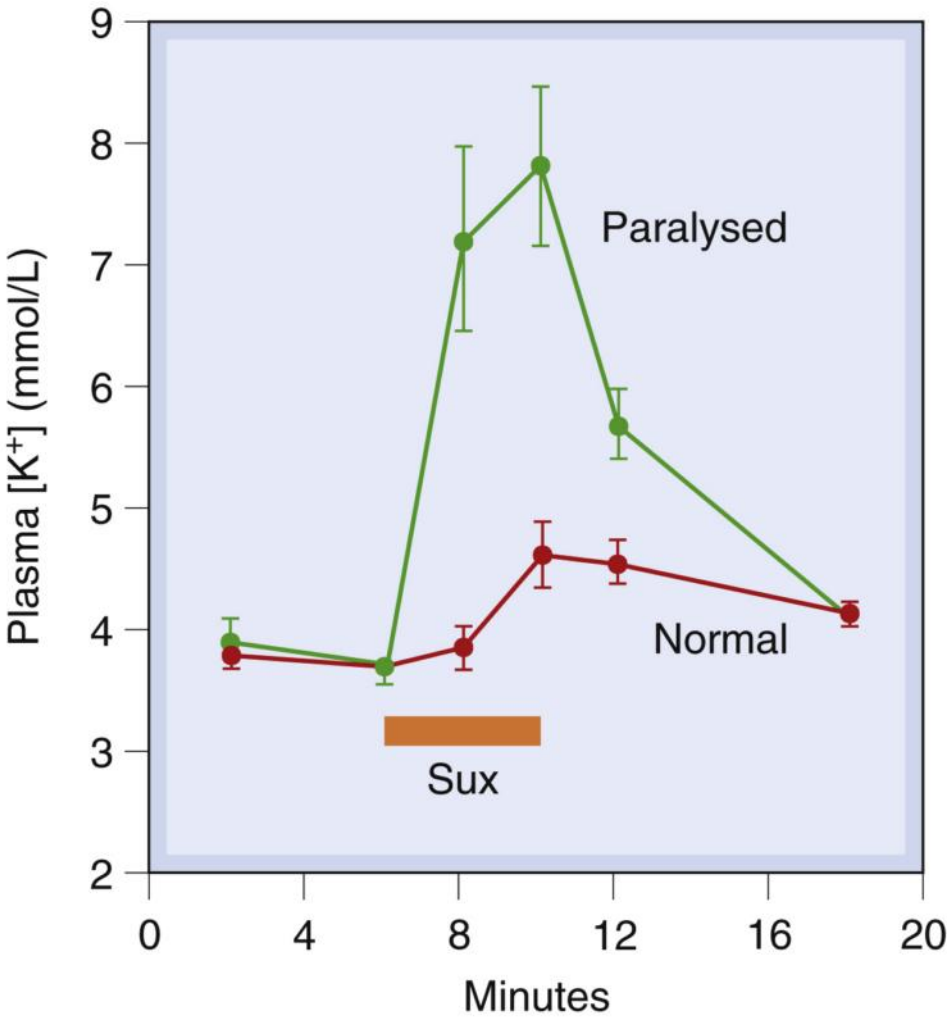

FIG. 14.6 Effect of suxamethonium (Sux) on plasma potassium concentration in humans.Blood was collected from veins draining paralysed and non-paralysed limbs of seven injured patients undergoing surgery. The injuries had resulted in motor nerve degeneration, and hence denervation supersensitivity of the affected muscles. From Tobey, R.E., et al., 1972. Anaesthesiology 37, 322.

- Neonates may have low plasma cholinesterase activity and experience prolonged paralysis if treated with suxamethonium.

Malignant hyperpyrexia

This is a rare inherited condition, due to a mutation of the Ca^{2+} release channel of the sarcoplasmic reticulum (the ryanodine receptor, see **Ch. 4**), which results in intense muscle spasm and a dramatic rise in body temperature in response to certain drugs (see **Ch. 12**). Suxamethonium is now the commonest culprit. The condition carries a high mortality (about 65%) and is treated by administration of **dantrolene**, a drug that inhibits muscle contraction by preventing Ca^{2+} release from the sarcoplasmic reticulum.

Neuromuscular-blocking drugs

- Substances that block neuronal choline uptake: for example, **hemicholinium** (not used clinically).
- Substances that block acetylcholine release: **aminoglycoside antibiotics**, **botulinum toxin.**
- Drugs used to cause paralysis during anaesthesia comprise:
  - Depolarising neuromuscular-blocking agents: **suxamethonium**, short-acting and used during induction of anaesthesia and intubation of the airway.
  - Non-depolarising neuromuscular-blocking agents: **tubocurarine**, **pancuronium**, **atracurium**, **vecuronium**, **mivacurium.** These block nicotinic

acetylcholine receptors and differ mainly in duration of action; they are used to maintain neuromuscular relaxation throughout a surgical operation, or in patients in an intensive care unit who may otherwise experience muscular spasm or involuntary movement.

- Important characteristics of non-depolarising and depolarising blocking drugs:
  - Non-depolarising block is reversible by anticholinesterase drugs, depolarising block is not.
  - Steroidal ('curonium') drugs (**rocuronium**, **vecuronium**) are reversed by **sugammadex.**
  - Depolarising block produces initial fasciculations and often postoperative muscle pain.
  - **Suxamethonium** is hydrolysed by plasma cholinesterase and is normally very short-acting but may cause long-lasting paralysis in subjects with genetic cholinesterase-deficiency.
- Main side effects: early curare derivatives caused ganglion block, histamine release and hence hypotension and bronchoconstriction; newer non-depolarising blocking drugs have fewer side effects; **suxamethonium** may cause bradycardia, cardiac dysrhythmias due to K^+ release (especially in burned or injured patients), increased intraocular pressure or (in rare genetically susceptible individuals) malignant hyperthermia.

Drugs that Act Presynaptically

Drugs that Inhibit Acetylcholine Synthesis

The steps in the synthesis of ACh in the presynaptic nerve terminals are shown in **Fig. 14.2**. The rate-limiting process appears to be the transport of choline into the nerve terminal. **Hemicholinium** blocks this transport and thereby inhibits ACh synthesis. It is useful as an experimental tool but has no clinical applications. Its blocking effect on transmission develops slowly, as the existing stores of ACh become depleted. **Vesamicol**, which acts by blocking ACh transport into synaptic vesicles, has a similar effect.

Drugs that Inhibit Acetylcholine Release

ACh release by a nerve impulse involves the entry of Ca^{2+} into the nerve terminal; the increase in $[Ca^{2+}]_i$ stimulates exocytosis and increases the rate of quantal release (see **Fig. 14.2**). Agents that inhibit Ca^{2+} entry include Mg^{2+} and various aminoglycoside antibiotics (e.g. **streptomycin** and **gentamicin**; see **Ch. 52**), which can unpredictably prolong muscle paralysis when used clinically in patients treated with neuromuscular-blocking agents as an adjunct to general anaesthesia.

Two potent neurotoxins, **botulinum toxin** and **β-bungarotoxin**, act specifically to inhibit ACh release. Botulinum toxins are of particular scientific and medical interest (see review by **Pirazzini et al., 2017**). They are a family of proteins produced by the anaerobic bacillus *Clostridium botulinum*, an organism that can multiply in preserved food and can cause botulism, an extremely serious type of food poisoning. [6] Novel botulinum neurotoxins are being discovered by next generation sequencing and their pharmacology is a current focus of interest. The potency of

botulinum toxin is extraordinary, the minimum lethal dose in a mouse being less than 10^{-12} g – only a few million molecules. It belongs to the group of potent bacterial exotoxins that includes tetanus and diphtheria toxins. These possess two subunits, one of which binds to a membrane receptor and is responsible for cellular specificity. By this means, the toxin enters the cell, where the other subunit produces the toxic effect. Botulinum toxins are peptidases that cleave specific proteins involved in exocytosis (*synaptobrevins*, *syntaxins*, etc.; see **Ch. 4**), thereby producing a long-lasting block of synaptic function. Each toxin component inactivates a different functional protein – a remarkably coordinated attack by a humble bacterium on a vital component of mammalian physiology.

Botulinum poisoning causes progressive parasympathetic and motor paralysis, with dry mouth, blurred vision and difficulty in swallowing, followed by progressive respiratory paralysis. Treatment with antitoxin is effective only if given before symptoms appear, for once the toxin is bound its action cannot be reversed. Mortality is high, and recovery takes several weeks. Anticholinesterases and drugs that increase transmitter release are ineffective in restoring transmission. **Botulinum toxin**, given by local injection, has a number of clinical and cosmetic uses (a testament to Paracelsus' dictum that all drugs are poisons, the distinction lying in the dose), including:

- *blepharospasm* (persistent and disabling eyelid spasm) and other forms of unwanted movement disorder including *torsion dystonia* and *spasmodic torticollis* (twisting movements of, respectively, limbs or neck);

- *spasticity* (excessive extensor muscle tone, associated with developmental brain abnormalities or birth injury);
- *urinary incontinence* associated with bladder overactivity (given by intravesical injection);
- *squint* (given by injection into extraocular muscles);
- *hyperhidrosis* (injected intradermally into axillary skin), for excessive sweating resistant to other treatment;
- *sialorrhoea* (excessive salivary secretion);
- *headache prophylaxis* (in adults with chronic migraine and frequent headaches);
- *forehead wrinkles* (injected intradermally it removes frown lines by paralysing the superficial muscles that pucker the skin).

Injections need to be repeated every few months. Botulinum toxin is antigenic, and may lose its effectiveness due to its immunogenicity. There is a risk of more general muscle paralysis if the toxin spreads beyond the injected region.

β-Bungarotoxin is a protein contained in the venom of various snakes of the cobra family, and has a similar action to botulinum toxin, although its active component is a phospholipase rather than a peptidase. The same venoms also contain α-bungarotoxin (see **Ch. 3**), which blocks postsynaptic ACh receptors. These snakes evidently cover all eventualities as far as causing paralysis of their victims is concerned.

Drugs that Enhance Cholinergic Transmission

Drugs that enhance cholinergic transmission act either by inhibiting cholinesterase (the main group) or by increasing ACh release. In

this chapter, we focus on the peripheral actions of such drugs; drugs affecting cholinergic transmission in the CNS, used to treat dementia, are discussed in **Chapter 40**, which also mentions *spinal muscular atrophy* – a rare genetic disorder characterised by degeneration of the anterior horn cells in the spinal cord and motor nuclei in the lower brainstem resulting in clinical features reminiscent of infant botulism and caused by loss of a survival protein in the motoneurones. Such patients may be treated with **nusinersen**, an antisense oligonucleotide designed to increase expression of the survival protein and administered intrathecally (see Chs **5**, **39** and **40**).

Distribution and Function of Cholinesterase

There are two distinct types of cholinesterase, namely *AChE* and *butyrylcholinesterase* (BuChE, sometimes called pseudocholinesterase), closely related in molecular structure but differing in their distribution, substrate specificity and functions. Both consist of globular catalytic subunits, which constitute the soluble forms found in plasma (BuChE) and cerebrospinal fluid (AChE). Elsewhere, the catalytic units are linked to accessory proteins, which tether them like a bunch of balloons to the basement membrane (at the neuromuscular junction) or to the neuronal membrane at neuronal synapses (and also, oddly, to erythrocyte membranes, where the function of the enzyme is unknown).

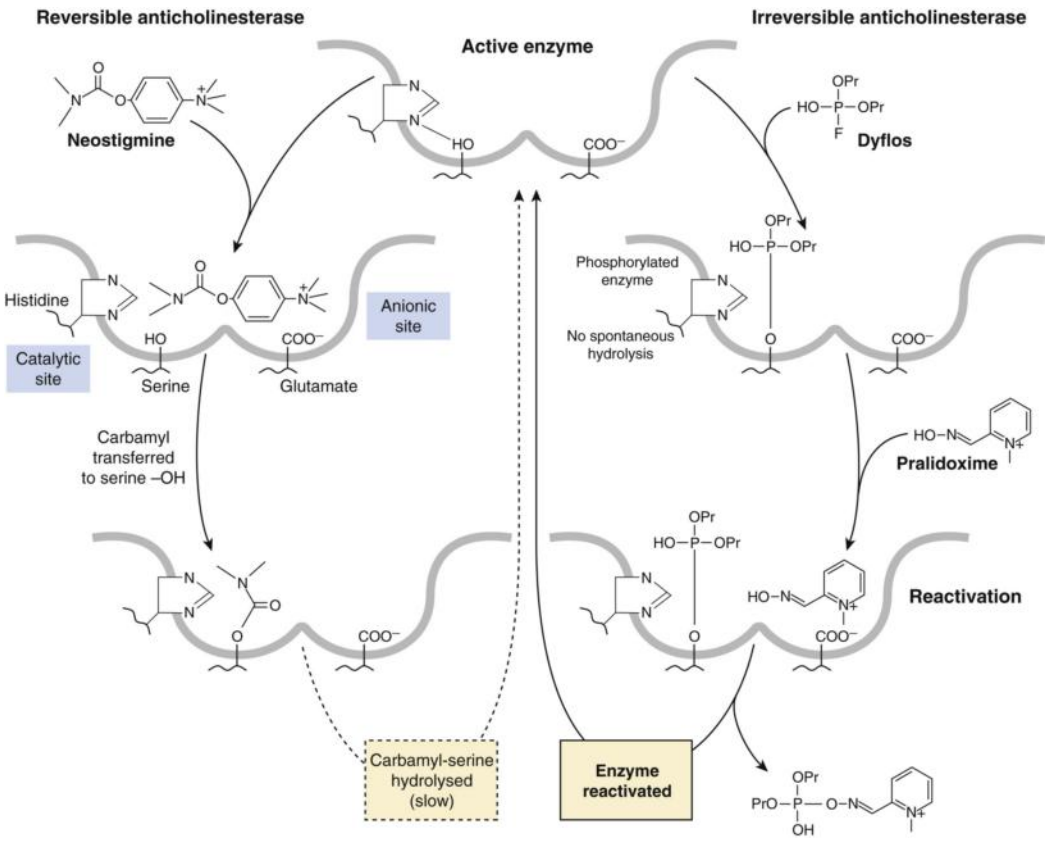

FIG. 14.7 Action of anticholinesterase drugs.Reversible anticholinesterase *(neostigmine)*: recovery of activity by hydrolysis of the carbamylated enzyme takes many minutes. Irreversible anticholinesterase *(Dyflos)*: reactivation of phosphorylated enzyme by pralidoxime. The representation of the active site is purely diagrammatic and not representative of the actual molecular structure.

The bound AChE at cholinergic synapses serves to hydrolyse the released transmitter and terminate its action rapidly. Soluble AChE is present in cholinergic nerve terminals, where it has a role in regulating the free ACh concentration, and from which it may be

secreted; the function of the secreted enzyme is so far unclear. AChE is quite specific for ACh and closely related esters such as methacholine. Certain neuropeptides, such as substance P (see **Ch. 19**), are inactivated by AChE, but it is not known whether this is of physiological significance. Overall, there is poor correspondence between the distribution of cholinergic synapses and that of AChE, both in the brain and in the periphery, and AChE most probably has synaptic functions additional to disposal of ACh, although the details remain unclear (see review by **Zimmerman and Soreq, 2006**).

BuChE has a widespread distribution, being found in tissues such as liver, skin, brain and gastrointestinal smooth muscle, as well as in soluble form in the plasma. It is not particularly associated with cholinergic synapses, and its physiological function is unclear. It has a broader substrate specificity than AChE. It hydrolyses the synthetic substrate butyrylcholine and other esters, such as **procaine**, **suxamethonium** and **propanidid** (a short-acting anaesthetic agent; see **Ch. 41**), more rapidly than ACh. The plasma enzyme is important in inactivating these esters. Genetic variants of BuChE causing significantly reduced enzymic activity occur rarely, and these partly account for the variability in the duration of action of such drugs. The short duration of action of ACh given intravenously (see **Fig. 14.1**) results from its rapid hydrolysis in the plasma. Normally, AChE (on red cells) and BuChE (in plasma) between them keep the plasma ACh at an undetectably low level, so ACh is strictly a neurotransmitter and not a hormone.

Both AChE and BuChE belong to the class of serine hydrolases, which includes many proteases such as trypsin. The active site of

AChE comprises two distinct regions (**Fig. 14.7**): an *anionic site* (glutamate residue), which binds the positively charged (choline) moiety of ACh, and an *esteratic (catalytic) site* (histidine + serine). As with other serine hydrolases, the acidic (acetyl) group of the substrate is transferred to the serine hydroxyl group, leaving (transiently) an acetylated enzyme molecule and a molecule of free choline. Spontaneous hydrolysis of the serine acetyl group occurs rapidly, and the overall turnover number of AChE is extremely high (over 10,000 molecules of ACh hydrolysed per second by a single active site).

Drugs that Inhibit Cholinesterase

Peripherally acting anticholinesterase drugs, summarised in **Table 14.7**, fall into three main groups according to the nature of their interaction with the active site, which determines their duration of action. Most of them inhibit AChE and BuChE approximately equally. Centrally acting anticholinesterases such as **donepezil**, developed for the treatment of dementia, are discussed in **Chapter 40**.

Short-acting anticholinesterases

The only important drug of this type is **edrophonium**, a quaternary ammonium compound that binds to the anionic site of the enzyme only. The ionic bond formed is readily reversible, and the action of the drug is very brief. It has previously been used for diagnostic purposes, because improvement of muscle strength by an anticholinesterase is characteristic of myasthenia gravis (see below) but not when muscle weakness is due to other causes. However, this test has been largely superseded by measures such as repetitive

nerve stimulation, and serological testing for ACh receptor antibodies.

Table 14.7

Other anticholinesterase drugs developed for the treatment of dementia are described in **Chapter 41**.

NMJ, Neuromuscular junction; *P,* postganglionic parasympathetic junction.

Medium-duration anticholinesterases

These include **neostigmine** and **pyridostigmine**, which are quaternary ammonium compounds of clinical importance, and **physostigmine** (eserine), a tertiary amine, which occurs naturally in the Calabar bean. [7]

These drugs are all carbamyl, as opposed to acetyl, esters and all possess basic groups that bind to the anionic site in the enzyme. Transfer of the carbamyl group to the serine hydroxyl group of the esteratic site occurs as with ACh, but the carbamylated enzyme is very much slower to hydrolyse (see **Fig. 14.7**), taking minutes rather than microseconds. The anticholinesterase drug is therefore hydrolysed, but at a negligible rate compared with ACh, and the slow recovery of the carbamylated enzyme means that the action of these drugs is quite long-lasting.

Irreversible anticholinesterases

Irreversible anticholinesterases (see **Table 14.7**) are pentavalent phosphorus compounds containing a labile group such as fluoride (in **dyflos**) or an organic group (in **parathion** and

echothiophate). This group is released, leaving the serine hydroxyl group of the enzyme phosphorylated (see **Fig. 14.7**). Most of these organophosphate compounds, of which there are many, were developed as weapons. **Sarin** and the more potent **VX** (10 mg of which through skin contact is said to be fatal), which acquired notoriety as an agent of state-sponsored assassination [8] , are examples. Some are used as pesticides as well as for clinical use; they interact only with the esteratic site of the enzyme and have no cationic group. **Echothiophate** is an exception in having a quaternary nitrogen group designed to bind also to the anionic site on the enzyme.

The inactive phosphorylated enzyme is usually very stable. With drugs such as dyflos, no appreciable hydrolysis occurs, and recovery of enzymic activity depends on the synthesis of new enzyme molecules, a process that may take weeks. With other drugs, such as echothiophate, hydrolysis occurs over the course of a few days, so that their action is not strictly irreversible. Dyflos and parathion are volatile non-polar substances of very high lipid solubility and are rapidly absorbed through mucous membranes and even through unbroken skin and insect cuticles; the use of these agents as war gases or insecticides relies on this property. The lack of a specificity-conferring quaternary group means that most of these drugs also block other serine hydrolases (e.g. trypsin, thrombin), although their pharmacological effects result mainly from cholinesterase inhibition.

Effects of anticholinesterase drugs

Some organophosphate compounds can produce, in addition, a severe form of neurotoxicity.

Cholinesterase inhibitors affect peripheral (autonomic ganglia, neuromuscular junction and post-ganglionic parasympathetic nerves) as well as central cholinergic synapses.

Effects on autonomic cholinergic synapses

These mainly reflect enhancement of ACh activity at parasympathetic postganglionic synapses – namely increased secretions from salivary, lacrimal, bronchial and gastrointestinal glands; increased peristaltic activity; bronchoconstriction; bradycardia and hypotension; pupillary constriction; fixation of accommodation for near vision; and a fall in intraocular pressure – referred to as 'parasympathomimetic' effects. Large doses can additionally stimulate, and later block, autonomic ganglia, producing complex autonomic effects. The block, if it occurs, is a depolarisation block and is associated with a build-up of ACh in the plasma and body fluids. Neostigmine and pyridostigmine tend to affect neuromuscular transmission more than the autonomic system, whereas physostigmine and organophosphates show the reverse pattern. The reason is not clear, but therapeutic usage takes advantage of this partial selectivity.

Acute anticholinesterase poisoning (e.g. from contact with insecticides or war gases) causes severe bradycardia, hypotension and difficulty in breathing. Combined with a depolarising neuromuscular block and central effects (see later), the result may be fatal.

Effects on the neuromuscular junction

The twitch tension of a muscle stimulated via its motor nerve is increased by anticholinesterases, owing to repetitive firing in muscle fibres caused by prolongation of the epp. Normally, ACh is hydrolysed so quickly that each stimulus initiates only one action potential in the muscle fibre, but when AChE is inhibited this is converted to a short train of action potentials in the muscle fibre, and hence greater tension. Much more important is the effect produced when transmission has been blocked by a non-depolarising blocking agent such as pancuronium. In this case, addition of an anticholinesterase can dramatically restore transmission. If a large proportion of the receptors is blocked, the majority of ACh molecules will normally encounter, and be destroyed by, an AChE molecule before reaching a vacant receptor; inhibiting AChE gives the ACh molecules a greater chance of finding a vacant receptor before being destroyed, and thus increase the epp so that it reaches threshold. In myasthenia gravis (see later), transmission fails because there are too few functional ACh receptors, and cholinesterase inhibition improves transmission just as it does in the presence of a competitive antagonist.

In large doses, such as can occur in poisoning, anticholinesterases initially cause twitching of muscles. This is because spontaneous ACh release can give rise to epps that reach the firing threshold. Later, paralysis may occur due to depolarisation block, which is associated with the build-up of ACh.

Effects on the CNS

Tertiary compounds, such as physostigmine, and the non-polar organophosphates penetrate the blood–brain barrier freely and

affect the brain. The result is an initial excitation, which can result in convulsions, followed by depression, which can cause unconsciousness and respiratory failure. These central effects result mainly from the activation of mAChRs and are antagonised by atropine. The use of anticholinesterases to treat dementia is discussed in **Chapter 40**.

Cholinesterase and anticholinesterase drugs

- There are two main forms of cholinesterase: *acetylcholinesterase (AChE)*, which is mainly membrane bound, relatively specific for acetylcholine, and responsible for rapid acetylcholine hydrolysis at cholinergic synapses; and *butyrylcholinesterase* (BuChE) or pseudocholinesterase, which is relatively non-selective and occurs in plasma and many tissues. Both enzymes belong to the family of serine hydrolases.
- Anticholinesterase drugs are of three main types: short-acting (**edrophonium**), medium-acting (**neostigmine**, **physostigmine**) and irreversible (organophosphates, **dyflos**, **echothiophate**). They differ in the nature of their chemical interaction with the active site of cholinesterase.
- The effects of anticholinesterase drugs are due mainly to enhancement of cholinergic transmission at cholinergic autonomic synapses and at the neuromuscular junction. Anticholinesterases that cross the blood–brain barrier (e.g. **physostigmine**, organophosphates) also have marked CNS

effects. Autonomic effects include bradycardia, hypotension, excessive secretions, bronchoconstriction, gastrointestinal hypermotility and decrease of intraocular pressure. Neuromuscular action causes muscle fasciculation and increased twitch tension and can produce depolarisation block.

- Anticholinesterase poisoning may occur from exposure to insecticides or nerve gases or to non-deliberate overdosing of patients taking it to relieve symptoms of myasthenia gravis.

Delayed neurotoxicity of organophosphates

Many organophosphates can cause a severe type of delayed peripheral nerve degeneration, leading to progressive weakness and sensory loss. This is not a problem with clinically used anticholinesterases but occasionally results from poisoning with insecticides or nerve gases. In 1931, an estimated 20,000 Americans were affected, some fatally, by contamination of fruit juice with an organophosphate insecticide, and other similar outbreaks have been recorded. The mechanism of this reaction is only partly understood, but it seems to result from inhibition of a *neuropathy target esterase* distinct from cholinesterase. Chronic low-level exposure of agricultural and other workers to organophosphorous pesticides has been associated with neurobehavioural disorders (**Blanc-Lapierre et al., 2013**). Other serine hydrolases apart from AChE can be secondary organophosphate targets including neuropathy target esterase, lipases and endocannabinoid hydrolases (**Casida, 2017**).

The main uses of anticholinesterases are summarised in the next clinical box.

Clinical uses of anticholinesterase drugs

- To reverse the action of non-depolarising neuromuscular-blocking drugs after surgery (**neostigmine**). A muscarinic antagonist (e.g. **atropine**) must be given to limit parasympathomimetic effects.
- To treat myasthenia gravis (**neostigmine** or **pyridostigmine**).
- **Edrophonium**, a short-acting drug given intravenously, has been used in the past for diagnosis of myasthenia gravis, but this method of testing is unreliable, and requires resuscitation facilities on-hand to deal with severe adverse reactions. Edrophonium test distinguishes myasthenic from cholinergic crisis in patients with myasthenia gravis with acute deterioration during treatment with a cholinesterase inhibitor.
- Alzheimer's disease (e.g. **donepezil**; see **Ch. 40**).

Cholinesterase Reactivation

Spontaneous hydrolysis of phosphorylated cholinesterase is extremely slow, so poisoning with organophosphates necessitates prolonged supportive care. **Pralidoxime** (see **Fig. 14.7**) reactivates the enzyme by bringing an oxime group into close proximity with the phosphorylated esteratic site. This group is a strong nucleophile

and lures the phosphate group away from the serine hydroxyl group of the enzyme. The effectiveness of pralidoxime in reactivating plasma cholinesterase activity in a poisoned subject is shown in **Fig. 14.8**. The main limitation to its use as an antidote to organophosphate poisoning is that, within a few hours, the phosphorylated enzyme undergoes a chemical change ('ageing') that renders it no longer susceptible to reactivation, so that pralidoxime must be given early in order to work. Pralidoxime does not enter the brain, but related compounds have been developed to treat the central effects of organophosphate poisoning.

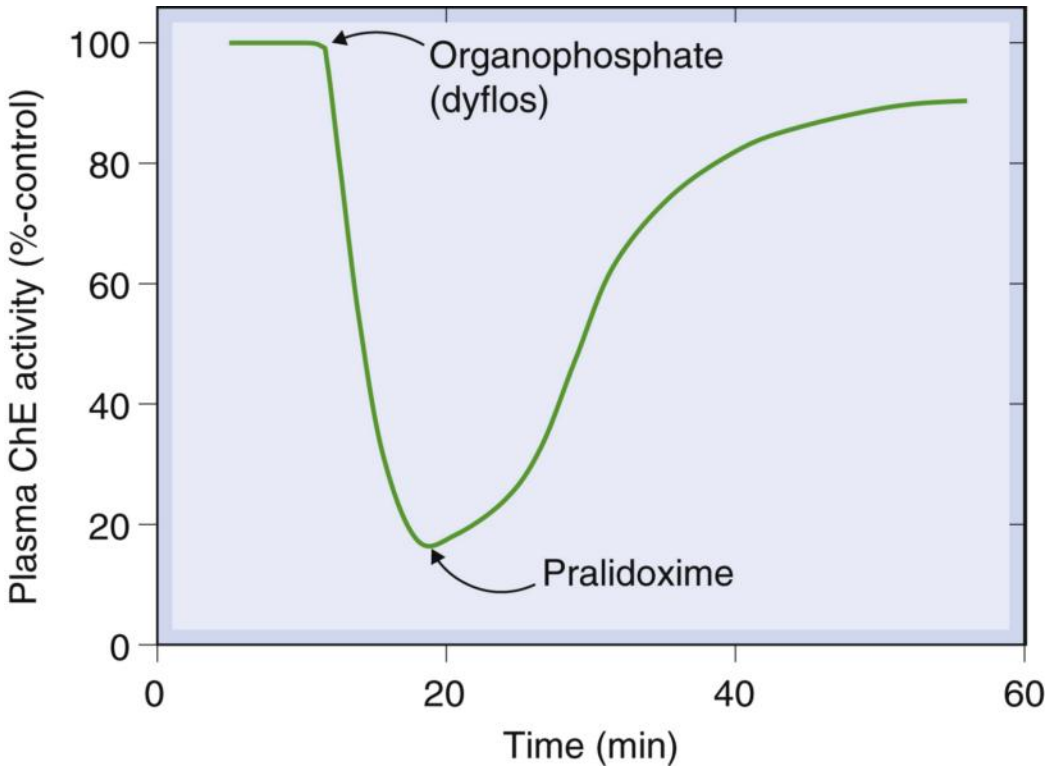

FIG. 14.8 Reactivation of plasma cholinesterase (ChE) in a volunteer subject by intravenous injection of pralidoxime.

Myasthenia gravis

The neuromuscular junction seldom fails, myasthenia gravis and the Lambert–Eaton myasthenic syndrome (see further) being two of the few disorders that affect it. Myasthenia gravis affects about 1 in 2000 individuals, often, but by no means always, young women who are susceptible to autoimmune disorders. It is characterised by weakness and increased fatigability of skeletal muscles resulting from impaired neuromuscular transmission. The tendency for transmission to fail during repetitive activity can be seen in **Fig. 14.9**. Muscles cannot produce prolonged contractions, resulting in the characteristic drooping eyelids and double vision on attempting to sustain lateral gaze. The effectiveness of anticholinesterase drugs in improving muscle strength in myasthenia was discovered in 1931, long before the pathophysiology of the disease was understood.

The cause of the transmission failure is an autoimmune response to nAChRs of the neuromuscular junction, first revealed in studies showing that the number of bungarotoxin-binding sites at the endplates of myasthenic patients was reduced by about 70% compared with normal. It had been suspected that myasthenia had an immunological basis, because the disease is sometimes accompanied by a tumour of the thymus gland and removal of the thymus improves the motor symptoms. Immunisation of rabbits with purified ACh receptor causes, after a delay, a disorder reminiscent of human myasthenia gravis. The presence of antibody directed against the ACh receptor protein can be detected in the serum of myasthenic patients, but the reason for the development of the autoimmune response in humans is unknown (**Gilhus, 2016**).

The improvement of neuromuscular function by anticholinesterase treatment (shown in **Fig. 14.9**) can be dramatic, but if the disease progresses too far, the number of receptors remaining may be insufficient to produce an adequate epp, and anticholinesterase drugs cease to be effective.

Alternative approaches to the treatment of myasthenia are to remove circulating antibody by plasma exchange, which is transiently effective, or, for a more prolonged effect, to inhibit antibody production with immunosuppressant drugs (e.g. **prednisolone**, **azathioprine, mycophenolate, cyclosporine** and **tacrolimus**; see **Ch. 25**) or thymectomy.

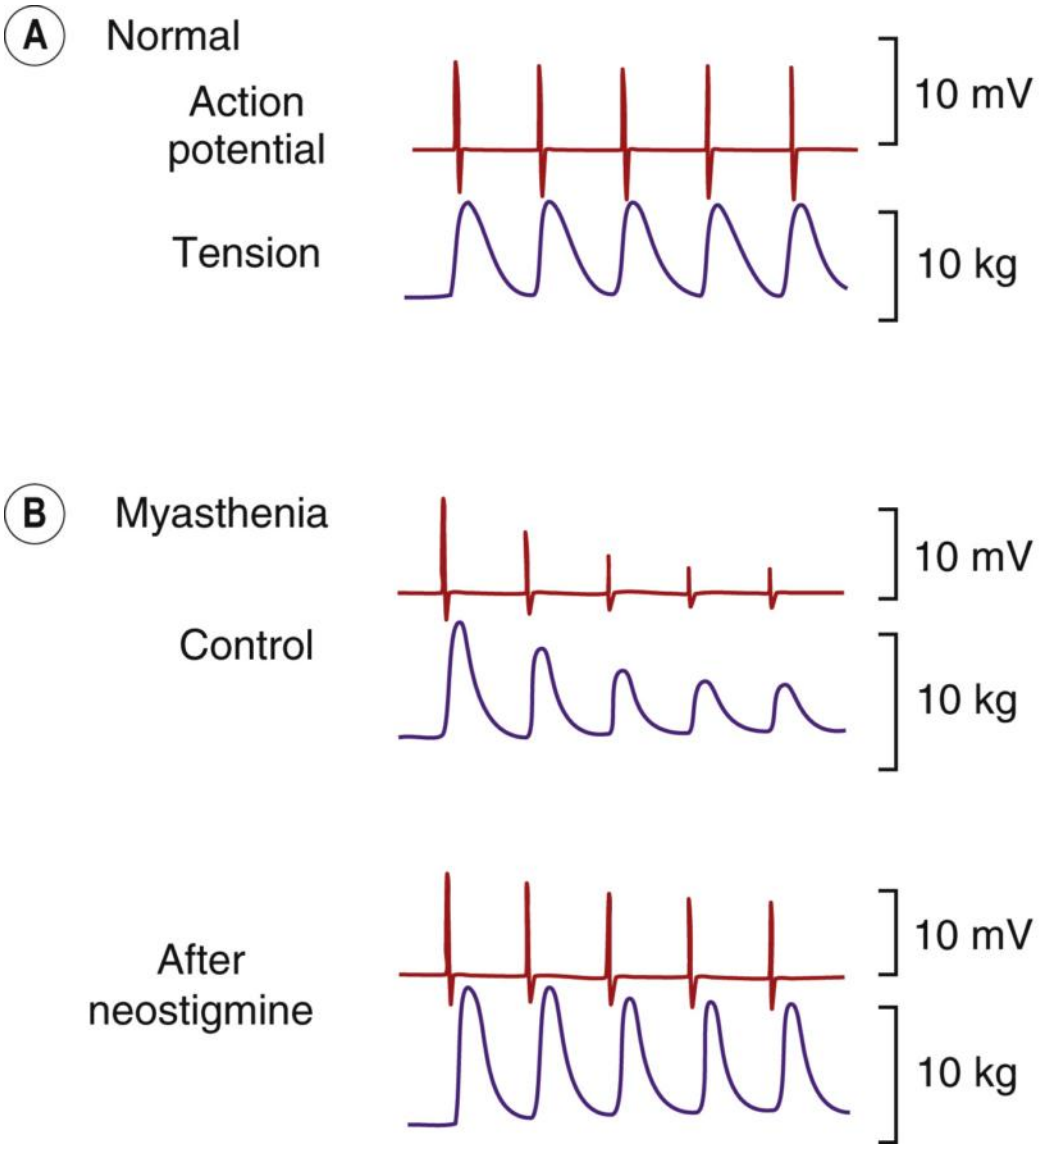

FIG. 14.9 Neuromuscular transmission in a normal and a myasthenic human subject.Electrical activity was recorded with a needle electrode in the adductor pollicis muscle, in response to ulnar nerve stimulation (3 Hz) at the wrist. In a normal subject, electrical and mechanical response is well sustained. In a myasthenic patient, transmission fails rapidly when the nerve is stimulated. Treatment with

neostigmine improves transmission. From Desmedt, J.E., 1962. Bull. Acad. R. Med. Belg. VII 2, 213.

Other Drugs that Enhance Cholinergic Transmission

It was observed many years ago that **tetraethylammonium**, a potassium-channel blocker and ganglion-blocking drug, could reverse the neuromuscular-blocking action of tubocurarine by prolonging the action potential in the nerve terminal and hence increasing the release of transmitter evoked by nerve stimulation. Subsequently, more potent and selective potassium-channel blocking drugs, such as **amifampridine**, were developed. These drugs are not selective for cholinergic nerves but increase the evoked release of many different transmitters. Amifampridine is used to treat the muscle weakness associated with Lambert–Eaton myasthenic syndrome, a complication of certain neoplastic diseases in which ACh release is inhibited when antitumour antibodies cross react with and inhibit Ca^{2+} channels on the prejunctional membrane.

QUESTIONS

QUESTION 14.1

Acetylcholine (ACh) mediates a range of biological functions mediated through nicotinic and muscarinic receptors.

Which of the following statements about cholinergic function is incorrect?

OPTIONS:

A. The channel conductance of the nicotinic receptor varies depending upon the agonist.

B. Bolus intravenous doses of ACh produce a transient fall in blood pressure.

C. ACh evokes secretion from sweat glands.

D. ACh-induced vasodilation is mediated by release of nitric oxide.

E. M_2 receptors act by inhibiting adenylyl cyclase.

QUESTION 14.2

Regulation of ACh release from the nerve terminals is key in controlling its physiological effects.

Which of the following agents would cause a prolonged postsynaptic effect of ACh?

OPTIONS:

A. Suxamethonium

B. Tubocurarine

C. Vesamicol

D. Neostigmine

E. Botulinum

QUESTION 14.3

Modulation of the physiological effects of ACh can be utilised for therapeutic benefit.

Which of the following agents would not be beneficial for the given indication?

OPTIONS:

A. The use of atropine in glaucoma

B. The use of neostigmine in myasthenia gravis

C. The use of tiotropium in chronic obstructive pulmonary disorder

D. The use of suxamethonium in tracheal intubation

E. The use of hyoscine in motion sickness

ANSWERS

ANSWER 14.1

RATIONALE:

A.

B. This is due to arteriolar vasodilatation and slowing of the heart – muscarinic effects that are abolished by atropine.

C. Sweat glands are innervated by cholinergic fibres of the sympathetic nervous system.

D. ACh causes generalised vasodilatation, even though most blood vessels have no parasympathetic innervation. This is an indirect effect: ACh acts on vascular endothelial cells to release nitric oxide.

E. M_2 (and M_4) acts through G_i to open potassium (K_{ir}) channels, causing membrane hyperpolarisation which inhibits voltage-dependent Ca^{2+} channels, and to inhibit adenylyl cyclase.

CORRECT ANSWER WITH EXPLANATION:

A. The channel conductance of the nicotinic receptor varies depending upon the agonist.

The channel conductance produced by different agonists is the same, whereas the mean channel lifetime varies according to the efficacy of the agonist.

ANSWER 14.2

RATIONALE:

A. Suxamethonium acts directly on postsynaptic nicotinic receptors to cause an initial depolarisation before ganglion block, independent of endogenous ACh.

B. These non-depolarising blocking agents act as competitive antagonists of ACh at the endplate, causing motor paralysis.

C. Vesamicol is an experimental drug that inhibits the uptake and accumulation of ACh in presynaptic vesicles.

D.

E. Botulinum inhibits ACh release from presynaptic nerve terminals.

CORRECT ANSWER WITH EXPLANATION:

D. Neostigmine

Neostigmine is an anticholinesterase and so inhibits the breakdown of ACh in the synaptic cleft, prolonging its actions.

ANSWER 14.3

RATIONALE:

A.

B. Neostigmine prevents the breakdown of ACh in the postsynaptic cleft so the concentration rises and can compete for binding with the autoantibodies to evoke a receptor response.

C. Tiotropium is a muscarinic antagonist used as a bronchodilator.

D. Suxamethonium is used for brief surgical procedures as a muscle relaxant.

E. Hyoscine has a centrally acting antiemetic effect.

CORRECT ANSWER WITH EXPLANATION:

A. The use of atropine in glaucoma

Activation of the constrictor pupillae muscle by muscarinic agonists lowers intraocular pressure in glaucoma, so antagonists would further raise the intraocular pressure.

---

[1] Unlike most other antagonists, gallamine acts *allosterically* (i.e. at a site distinct from the ACh binding site).

[2] Also known as **succinylcholine**.

[3] Based on their structural similarity to ACh, these compounds were originally assumed to compete with ACh for its binding site. However, they are now known to act mainly by blocking the ion channel rather than the receptor itself.

[4] Animals killed by curare-tipped arrows are safe to eat because of this.

[5] The risk of patients waking up paralysed during surgery, and subsequently recalling this (awareness during anaesthesia), is a serious concern.

[6] Among the more spectacular outbreaks of botulinum poisoning was an incident on Loch Maree in Scotland in 1922, when all eight members of a fishing party died after eating duck pâté for their lunch. Their ghillies, consuming humbler fare no doubt, survived. The innkeeper committed suicide.

[7] Otherwise known as the ordeal bean. In the Middle Ages, extracts of these beans were used to determine the guilt or innocence of those accused of crime or heresy. Death implied guilt.

[8] On February 13, 2017, Kin Jong-nam, half-brother of North Korean leader Kim Jong-un, died after an assault in Kuala Lumpur International Airport. According to the authorities he was murdered by poisoning with VX, which was found on his face. The authorities further reported that one of the women suspected of applying the nerve agent experienced some physical symptoms of VX poisoning. The director of a research program of the Middlebury Institute of International Studies at Monterey stated that VX fumes would have killed the suspected attackers even if they had been wearing gloves, suggesting that the VX was applied as two non-lethal components

that would mix to form VX only on the victim's face (Wikipedia, accessed June 9, 2021).

15: Noradrenergic transmission

OVERVIEW

Peripheral noradrenergic neurons and the structures that they innervate are fundamental components of autonomic function and are the targets of many therapeutic drugs of great clinical importance. In this chapter we describe the physiology of noradrenergic neurons and the properties of adrenoceptors (the receptors on which noradrenaline and adrenaline act) and discuss the various classes of drugs that affect them. For ease of reference, much drug-specific detail is summarised in tables.

Catecholamines

Catecholamines contain a catechol moiety (a benzene ring with two adjacent hydroxyl groups) and an amine side chain (**Fig. 15.1**). The most important are:

- *noradrenaline (norepinephrine)*, a transmitter released by sympathetic nerve terminals;
- *adrenaline (epinephrine)*, a hormone secreted by chromaffin cells in the adrenal medulla;

- *dopamine,* the metabolic precursor of noradrenaline and adrenaline, also a transmitter/neuromodulator in the central nervous system (CNS);
- *isoprenaline (isoproterenol)*, a synthetic derivative of noradrenaline and pharmacological tool.

Classification of Adrenoceptors

In 1896, Oliver and Schafer discovered that intravenous injection of extracts of adrenal gland in anaesthetised cats caused a rise in arterial pressure. Adrenaline was identified as the active principle and was shown by Dale in 1913 to cause two distinct kinds of vascular effect, namely vasoconstriction in certain vascular beds and vasodilatation in others. Dale showed that the vasoconstrictor component disappeared if the animal was first injected with an ergot derivative [1] (see **Ch. 16**), and noticed that adrenaline then caused a fall, instead of a rise, in arterial pressure, reminiscent of his demonstration of the separate muscarinic and nicotinic components of the action of acetylcholine (see **Ch. 14**). He avoided interpreting it in terms of different types of receptor, but later pharmacological work, beginning with that of Ahlquist, showed clearly the existence of several subclasses of adrenoceptor with distinct tissue distributions and actions (**Table 15.1**).

In 1948 Ahlquist found that the rank order of the potencies of various catecholamines, including adrenaline, noradrenaline and isoprenaline, fell into two distinct patterns, depending on what response was being measured. He postulated the existence of two kinds of receptor, α and β, defined in terms of agonist potencies as follows:

α: noradrenaline > adrenaline > isoprenaline
β: isoprenaline > adrenaline > noradrenaline

It was then recognised that certain ergot alkaloids, which Dale had studied, act as selective α-receptor antagonists and that Dale's adrenaline reversal experiment reflected the unmasking of the β effects of adrenaline by α-receptor blockade. Selective β-receptor antagonists were not developed until 1955, when their effects fully confirmed Ahlquist's original classification and also suggested the existence of further subdivisions of both α and β receptors. Subsequently it has emerged that there are two α-receptor subtypes (α_1 and α_2), each comprising three further subclasses (α_{1A}, $\alpha_{1B,}$ α_{1D} and α_{2A}, α_{2B}, α_{2C}) and three β-receptor subtypes (β_1, β_2 and β_3) – altogether nine distinct subtypes – all of which are typical G protein–coupled receptors (**Table 15.2**). Genetic variants of both β_1 and β_2 receptors occur in humans and influence the effects of agonists and antagonists (see **Ahles and Engelhardt, 2014**). Evidence from specific agonists and antagonists, as well as studies on receptor knockout mice, have shown that α_1 receptors are particularly important in the cardiovascular system and lower urinary tract, while α_2 receptors are predominantly neuronal, acting to inhibit transmitter release both in the brain and at autonomic nerve terminals in the periphery. The α_{2B} subtype appears to be involved in neurotransmission in the spinal cord, and α_{2C}, in regulating catecholamine release from adrenal medulla (**Alexander et al., 2019**), but the distinct functions of the different subclasses of α_1 and α_2 adrenoceptors remain for the most part unclear; they are frequently co-expressed in the same tissues,

and may form heterodimers, making pharmacological analysis difficult.

α 2 -Adrenoceptors and imidazoline (I) receptors. The antihypertensive drug **clonidine** (see later) was synthesised in the 1960s. It works in the CNS to reduce sympathetic outflow and was found to be an α_2-adrenoceptor agonist. Bousquet and his colleagues subsequently discovered that clonidine interacts not only with the α_2-adrenoceptors but also with a distinct imidazoline preferring binding site, located in the brainstem particularly in the nucleus reticularis lateralis in the rostroventral medulla oblongata. Three subtypes (I_1, I_2 and I_3) have subsequently been identified and some at least are G-protein coupled although the receptor structures have not yet been elucidated. Endogenous agonists remain enigmatic although several potential candidates have been identified. Microinjection experiments showed that selective agonists at I_1 and at α_2-adrenoceptors act independently of each other to lower blood pressure but they synergise with one another when both receptors are stimulated. I_2 agonists cause analgesia and I_3 agonists, while much less studied, can produce metabolic effects by influencing insulin secretion from pancreatic B-cells. There is on-going interest in the therapeutic potential of drugs of this class (see **Bousquet et al., 2020**, for a review).

FIG. 15.1 Structures of the major catecholamines.

Each of the three main adrenoceptor subtypes is associated with a specific second messenger system (see **Table 15.2**). Thus α_1 receptors are coupled through Gq to phospholipase C and produce their effects mainly by the release of intracellular Ca^{2+}; α_2 receptors couple through Gi/Go to inhibit adenylyl cyclase, and thus reduce cAMP formation as well as inhibiting Ca^{2+} channels and activating K^+ channels. All three types of β receptor couple through Gs to stimulate adenylyl cyclase and downstream transduction pathways, e.g. kinases implicated in trophic actions (see **Ch. 3** and further in the chapter). The main effects of adrenoceptors, and the drugs that act on them, are shown in Tables **15.1** and **15.2**.

The distinction between β_1 and β_2 receptors is an important one, because β_1 receptors are found mainly in the heart, where they are responsible for the positive inotropic and chronotropic effects of catecholamines (see **Ch. 20**), whereas β_2 receptors are responsible for causing smooth muscle relaxation in many organs, most importantly in the lungs, where they relax the bronchioles and relieve bronchoconstriction in asthmatics (see **Ch. 28**). The cardiac effects can be harmful, predisposing to cardiac dysrhythmia and increasing myocardial oxygen demand (see **Ch. 20**); consequently, considerable efforts have been made to discover selective β_2 agonists to relax smooth muscle without affecting the heart, and selective β_1 antagonists to exert a useful blocking effect on the heart without blocking β_2 receptors at the same time (see **Table 15.1**). The available drugs are not completely specific and marketed

selective β_1 antagonists have appreciable affinity for β_2 receptors, which can cause unwanted effects in asthmatics such as bronchoconstriction or blunted bronchodilator response to β_2 agonists.

In relation to vascular control, it is important to note that both α- and β-receptor subtypes are expressed in smooth muscle cells, nerve terminals and endothelial cells, and their role in physiological regulation and pharmacological responses of the cardiovascular system is only partly understood (see **Guimaraes and Moura, 2001**).

Classification of adrenoceptors

- Main pharmacological classification into α and β subtypes, based originally on order of potency among agonists, later on selective antagonists.
- Adrenoceptor subtypes:
  - two main α-adrenoceptor subtypes, α_1 and α_2, each divided into three further subtypes (α_{1A}, α_{1B}, α_{1D} and α_{2A}, α_{2B}, α_{2C})
  - three β-adrenoceptor subtypes (β_1, β_2, β_3)
  - all belong to the superfamily of G protein–coupled receptors (see **Ch. 3**).
- Second messengers:
  - α_1 receptors activate phospholipase C via G_q, producing inositol trisphosphate and diacylglycerol as second messengers

  - α_2 receptors modulate Ca^{2+} and K^+ channels via βα G-protein subunits and inhibit adenylyl cyclase via α_i (but cytoplasmic cAMP in nerve terminals is usually low under basal conditions, limiting the importance of this second mechanism).
  - all types of β receptor stimulate adenylyl cyclase via G_s.
- The main effects of receptor activation are:
  - α_1 receptors: vasoconstriction, relaxation of gastrointestinal smooth muscle, and hepatic glycogenolysis
  - α_2 receptors: inhibition of transmitter release (including noradrenaline and acetylcholine release from autonomic nerves) caused by opening of K^+ channels and inhibition of Ca^{2+} channels; platelet aggregation; vascular smooth muscle contraction; inhibition of insulin release
  - β_1 receptors: increased cardiac rate and force
  - β_2 receptors: bronchodilatation; vasodilatation; relaxation of visceral smooth muscle; hepatic glycogenolysis; muscle tremor
  - β_3 receptors: lipolysis and thermogenesis; bladder detrusor muscle relaxation.

Physiology of Noradrenergic Transmission

The Noradrenergic Neuron

Noradrenergic neurons in the periphery are postganglionic sympathetic neurons whose cell bodies are situated in sympathetic ganglia (see **Ch. 13**). They generally have long ^{2} axons that end in a series of varicosities strung along the branching terminal network. These varicosities contain numerous synaptic vesicles, which are the sites of synthesis and release of noradrenaline and of co-released mediators such as ATP and neuropeptide Y (see **Ch. 13**), which are stored in vesicles and released by exocytosis (see **Ch. 4**). In most peripheral tissues, the tissue content of noradrenaline closely parallels the density of the sympathetic innervation. With the exception of the adrenal medulla, sympathetic nerve terminals account for all the noradrenaline content of peripheral tissues. Organs such as the heart, spleen, vas deferens and some blood vessels are particularly rich in noradrenaline (5–50 nmol/g of tissue) and have been widely used for studies of noradrenergic transmission. For detailed information on noradrenergic neurons, see **Robertson (2012)** and **Cooper et al. (2003)**.

Noradrenaline and Adrenaline Synthesis

The biosynthetic pathway for noradrenaline synthesis is shown in **Fig. 15.1**. The metabolic precursor for noradrenaline is *L-tyrosine*,

an aromatic amino acid that is present in body fluids and is taken up by adrenergic neurons. *Tyrosine hydroxylase*, a cytosolic enzyme that catalyses the conversion of tyrosine to *dihydroxyphenylalanine* (dopa), is expressed only in catecholamine-containing cells. It is a rather selective enzyme; unlike other enzymes involved in catecholamine metabolism, it does not accept indole derivatives as substrates, and is not involved in 5-hydroxytryptamine (5-HT) synthesis. This first hydroxylation step is the main control point for noradrenaline synthesis. Tyrosine hydroxylase activity is inhibited by noradrenaline, and this provides the mechanism for the moment-to-moment regulation of the rate of synthesis; much slower regulation, taking hours or days, occurs by changes in the rate of production of the enzyme.

The tyrosine analogue **α-methyltyrosine** strongly inhibits tyrosine hydroxylase and has been used experimentally to block noradrenaline synthesis.

The next step, conversion of dopa to dopamine, is catalysed by *dopa decarboxylase*, a cytosolic enzyme that is not confined to catecholamine-synthesising cells. It is relatively non-specific and catalyses the decarboxylation of various other L-aromatic amino acids, such as *L-histidine* and *L-tryptophan*, which are precursors in the synthesis of histamine (see **Ch. 17**) and 5-HT (see **Ch. 16**), respectively. Dopa decarboxylase activity is not rate-limiting for noradrenaline synthesis and its activity does not regulate noradrenaline synthesis.

Dopamine-β-hydroxylase (DBH) is also a relatively non-specific enzyme but is restricted to catecholamine-synthesising cells. It is located in synaptic vesicles, mainly in membrane-bound form. A

small amount of the enzyme is released from adrenergic nerve terminals in company with noradrenaline, representing the small proportion in a soluble form within the vesicle. Unlike noradrenaline, the released DBH is not subject to rapid degradation or uptake, so its concentration in plasma and body fluids can be used as an index of overall sympathetic nerve activity.

Many drugs inhibit DBH, including copper-chelating agents and **disulfiram** (a drug used mainly for its effect on ethanol metabolism; see **Ch. 49**). Such drugs can cause a partial depletion of noradrenaline stores and interference with sympathetic transmission. A rare genetic disorder, DBH deficiency, causes failure of noradrenaline synthesis resulting in severe orthostatic hypotension (see **Ch. 21**).

Phenylethanolamine N-*methyl transferase* (PNMT) catalyses the *N*-methylation of noradrenaline to form adrenaline. The main location of this enzyme is in the adrenal medulla, which contains a population of adrenaline-releasing (A) cells separate from the smaller proportion of noradrenaline-releasing (N) cells. The A cells, which appear only after birth, lie adjacent to the adrenal cortex, and the production of PNMT is induced by an action of the steroid hormones secreted by the adrenal cortex (see **Ch. 33**). PNMT is also found in a few neurons in the medulla oblongata, where adrenaline may function as a transmitter, but little is known about its role in the CNS.

In peripheral tissues, the turnover time of noradrenaline is generally about 5–15 h, but it becomes much shorter if sympathetic nerve activity is increased. Under normal circumstances, the rate of synthesis closely matches the rate of release, so that the

noradrenaline content of tissues is constant regardless of how fast it is being released.

Noradrenaline Storage

Most of the noradrenaline in nerve terminals and adrenal medulla is contained in vesicles; only a little is free in the cytoplasm under normal circumstances. The concentration in the vesicles is very high (0.3–1.0 mol/L) and is maintained by the *vesicular monoamine transporter* (VMAT), which shares some features of the amine transporter responsible for noradrenaline uptake into the nerve terminal (see **Ch. 13**) but uses the transvesicular proton gradient as its driving force. Certain drugs, such as **reserpine** (**Table 15.3**), block this transport and cause nerve terminals to become depleted of their vesicular noradrenaline stores. The vesicles contain two major constituents besides noradrenaline, namely ATP (about four molecules per molecule of noradrenaline) and a protein called *chromogranin A*. These substances are released along with noradrenaline, and it is generally assumed that a reversible complex, depending partly on the opposite charges on the molecules of noradrenaline and ATP, is formed within the vesicle. This would serve both to reduce the osmolarity of the vesicle contents and to reduce the tendency of noradrenaline to leak out of the vesicles within the nerve terminal.

ATP itself has a transmitter function at sympathetic nerve synapses (see **Fig. 13.5**; **Ch. 16**), being responsible for the fast-excitatory synaptic potential and the rapid phase of contraction produced by sympathetic nerve activity in many smooth muscle tissues.

Noradrenaline Release

The processes linking the arrival of a nerve impulse at a nerve terminal, Ca^{2+} entry, and the release of transmitter are described in **Chapter 4**. Drugs that affect noradrenaline release are summarised in **Table 15.6**.

Table 15.3

For details, see **Gainetdinov, R.R., Caron, M.G., 2003**. Monoamine transporters: from genes to behaviour. Annu. Rev. Pharmacol. Toxicol. 43, 261–284.

A, Adrenaline; *EMT,* extraneuronal monoamine transporter; *ISO,* isoprenaline; *MPP* $^{+}$ *,* toxic metabolite of MPTP (see and **Ch. 41**); *NA,* noradrenaline; *NET,* norepinephrine transporter; *VMAT,* vesicular monoamine transporter.

[a] Amphetamine is transported slowly, so acts both as a substrate and as an inhibitor of noradrenaline uptake.

An unusual feature of the release mechanism at the varicosities of noradrenergic nerves is that the probability of release, even of a single vesicle, when a nerve impulse arrives at a varicosity is very low (less than 1 in 50). A single neuron possesses many thousand varicosities, so one impulse leads to the discharge of a few hundred vesicles, scattered over a wide area. This contrasts sharply with the neuromuscular junction (see **Ch. 14**), where the release probability at a single terminal is high, and release of acetylcholine is sharply localised.

Regulation of noradrenaline release

Noradrenaline release is affected by a variety of substances that act on presynaptic receptors (see **Ch. 13**). Many different types of nerve terminal (cholinergic, noradrenergic, dopaminergic, 5-HT-ergic, etc.) are subject to this type of control, and many different mediators (acetylcholine acting through muscarinic receptors, catecholamines acting through α and β receptors, angiotensin II, prostaglandins, purine nucleotides, neuropeptides, etc.) can act on presynaptic terminals. Presynaptic modulation represents an important physiological control mechanism throughout the nervous system.

Noradrenaline, by acting on presynaptic α_2 receptors, can down-regulate its own release, and that of co-released ATP (see **Ch. 13**). This is believed to occur physiologically, so that released noradrenaline exerts a local inhibitory effect on the terminals from which it came – the so-called *autoinhibitory feedback* mechanism (**Fig. 15.2**; see **Gilsbach and Hein, 2012**). Agonists or antagonists affecting presynaptic receptors can have large effects on sympathetic transmission. However, the physiological significance of presynaptic autoinhibition in the sympathetic nervous system is still somewhat contentious, and there is evidence that, in most tissues, it is less influential than biochemical measurements of transmitter overflow would seem to imply. Thus, although blocking autoreceptors causes large changes in noradrenaline *overflow* – the amount of noradrenaline released into the bathing solution or the bloodstream when sympathetic nerves are stimulated – the associated changes in the tissue response are often rather small. This suggests that what is measured in overflow experiments may

not be the physiologically important component of transmitter release.

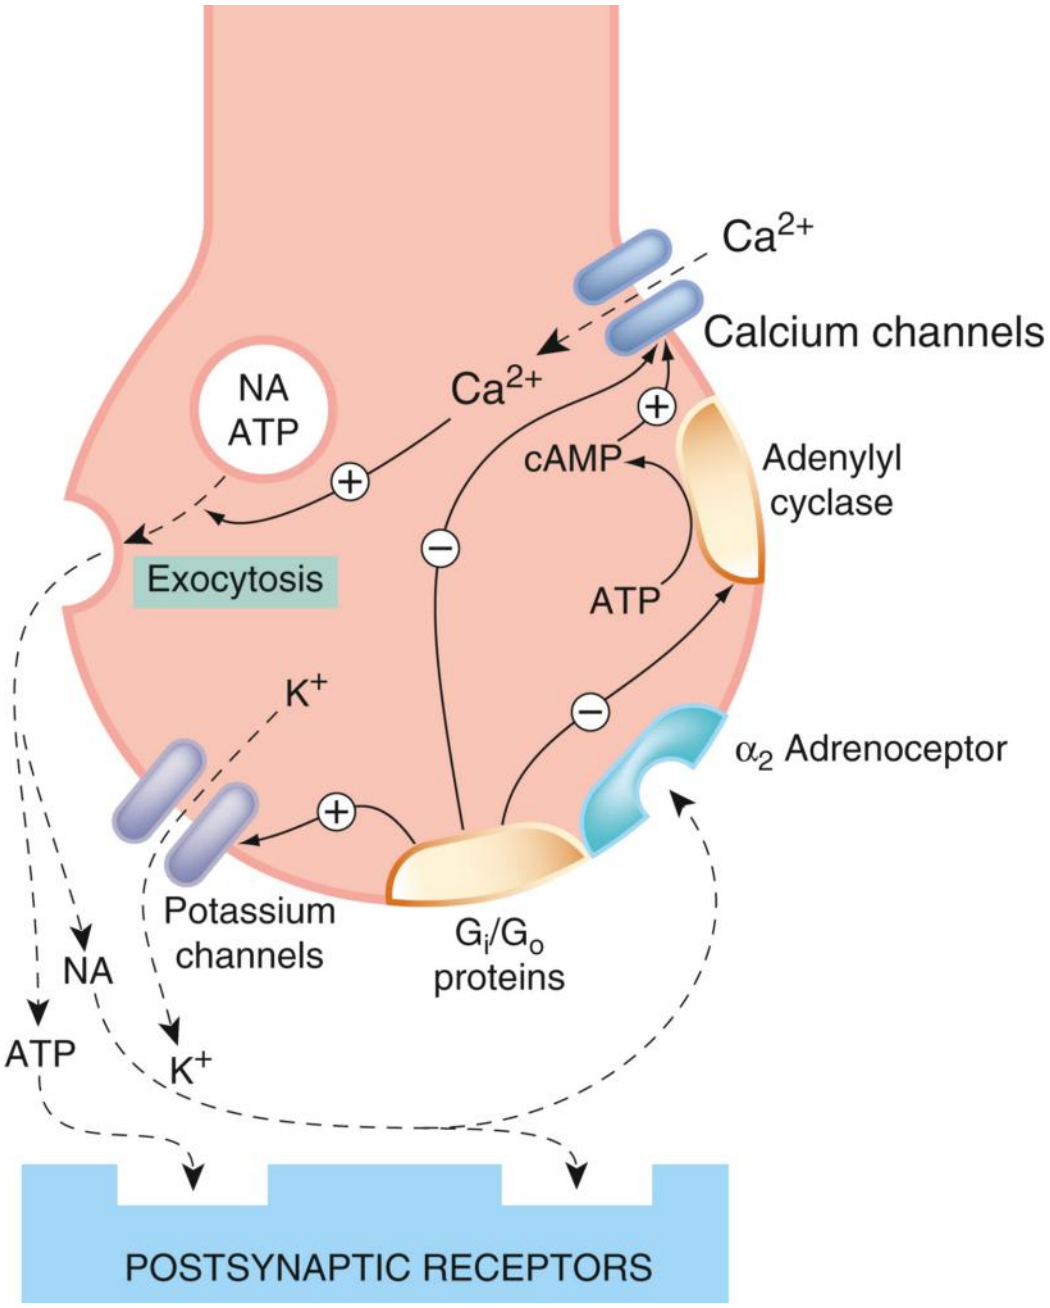

FIG. 15.2 Feedback control of noradrenaline *(NA)* release.The presynaptic α_2 receptor inhibits Ca^{2+} influx in response to membrane depolarisation via an action of the βγ subunits of the associated G protein on the voltage-dependent Ca^{2+} channels (see **Ch. 3**).

The inhibitory feedback mechanism operates through α_2 receptors, which inhibit adenylyl cyclase and prevent the opening of calcium channels (see **Fig. 15.2**). Sympathetic nerve terminals also possess β_2 receptors, coupled to activation of adenylyl cyclase, which *increase* noradrenaline release. Whether these have any physiological function is not clear.

Uptake and Degradation of Catecholamines

The action of released noradrenaline is terminated mainly by reuptake of the transmitter into noradrenergic nerve terminals. Some is also sequestered by other cells in the vicinity. Circulating adrenaline and noradrenaline are degraded enzymically, but much more slowly than acetylcholine (see **Ch. 14**), where synaptically located acetylcholinesterase inactivates the transmitter in milliseconds. The two main catecholamine-metabolising enzymes are located intracellularly, so uptake into cells necessarily precedes metabolic degradation.

Uptake of Catecholamines

The characteristics of noradrenergic transporters are summarised in **Table 15.3**. About 75% of the noradrenaline released by sympathetic neurons is recaptured and repackaged into vesicles. This serves to cut short the action of the released noradrenaline, as well as recycling it. The remaining 25% is captured by non-neuronal cells in the vicinity, limiting its local spread. These two uptake mechanisms depend on distinct transporter molecules. Neuronal uptake is performed by the plasma membrane noradrenaline transporter (generally known as NET, the *norepinephrine transporter*), which belongs to the family of neurotransmitter

transporter proteins which include the dopamine transporter (DAT) and serotonin transporter (SERT) as well as the NET. These are specific for different amine transmitters, described in **Chapter 13**; and act as co-transporters of Na^+, Cl^- and the amine in question, using the electrochemical gradient for Na^+ as a driving force. Packaging into vesicles occurs through the VMAT, driven by the proton gradient between the cytosol and the vesicle contents. Extraneuronal uptake is performed by the *extraneuronal monoamine transporter* (EMT), which belongs to a large and widely distributed family of organic cation transporters (OCTs, see **Ch. 9**). NET is relatively selective for noradrenaline, with high affinity and a low maximum rate of uptake, and it is important in maintaining releasable stores of noradrenaline. NET is blocked by tricyclic antidepressant drugs and **cocaine**. EMT has lower affinity and higher transport capacity than NET, and transports adrenaline and isoprenaline as well as noradrenaline. The effects of several important drugs that act on noradrenergic neurons depend on their ability either to inhibit NET or to enter the nerve terminal with its help. **Table 15.3** summarises the properties of neuronal and extraneuronal uptake.

Metabolic Degradation of Catecholamines

Endogenous and exogenous catecholamines are metabolised mainly by two intracellular enzymes: *monoamine oxidase* (MAO) and *catechol-O-methyl transferase* (COMT). MAO (of which there are two distinct isoforms, MAO-A and MAO-B; see Ch. **48**) is bound to the surface membrane of mitochondria. It is abundant in noradrenergic nerve terminals but is also present in liver, intestinal

epithelium and other tissues. MAO converts catecholamines to their corresponding aldehydes, [3] which, in the periphery, are rapidly metabolised by *aldehyde dehydrogenase* to the corresponding carboxylic acid (3,4-dihydroxyphenylglycol being formed from noradrenaline; **Fig. 15.3**). MAO can also oxidise other monoamines, including dopamine and 5-HT. It is inhibited by various drugs which are used mainly for their antidepressant effects in the CNS (see **Ch. 48**), where these three amines all have transmitter functions (see **Ch. 39**). These drugs have important harmful effects that are related to disturbances of peripheral noradrenergic transmission. Within sympathetic neurons, MAO controls the content of dopamine and noradrenaline, and the releasable store of noradrenaline increases if the enzyme is inhibited. MAO and its inhibitors are discussed in more detail in **Chapter 48**.

The second major pathway for catecholamine metabolism involves methylation of one of the catechol hydroxyl groups by COMT to give a methoxy derivative. COMT is absent from noradrenergic neurons but present in the adrenal medulla and many other tissues. The final product formed by the sequential action of MAO and COMT is *3-methoxy-4-hydroxyphenylglycol* (MHPG; see **Fig. 15.3**). This is partly conjugated to sulfate or glucuronide derivatives, which are excreted in the urine and reflect noradrenaline release in brain, but most of it is converted to *vanillylmandelic acid* (VMA; see **Fig. 15.3**) and excreted in the urine in this form. In patients with tumours of chromaffin tissue that secrete these amines (a rare cause of high blood pressure), the

urinary excretion of VMA is markedly increased, this being used as a diagnostic test for such tumours.

In the periphery, neither MAO nor COMT is primarily responsible for the termination of transmitter action, most of the released noradrenaline being quickly recaptured by NET. Circulating catecholamines are sequestered and inactivated by a combination of NET, EMT and COMT, the relative importance of these processes varying according to the agent concerned. Thus circulating noradrenaline is removed mainly by NET, whereas adrenaline is more dependent on EMT. Isoprenaline, however, is not a substrate for NET, and is removed by a combination of EMT and COMT.

In the CNS (see **Ch. 39**), MAO is more important as a means of terminating transmitter action than it is in the periphery, and MAO knockout mice show a greater enhancement of noradrenergic transmission in the brain than do NET knockouts, in which neuronal stores of noradrenaline are much depleted (see **Gainetdinov and Caron, 2003**). The main excretory product of noradrenaline released in the brain is MHPG.

Drugs Acting on Noradrenergic Transmission

Many clinically important drugs, particularly those used to treat cardiovascular, respiratory and psychiatric disorders (see Chs **20**, **21**, **28**, **48** and **49**), work by affecting noradrenergic neuron function, acting on adrenoceptors, transporters or catecholamine-

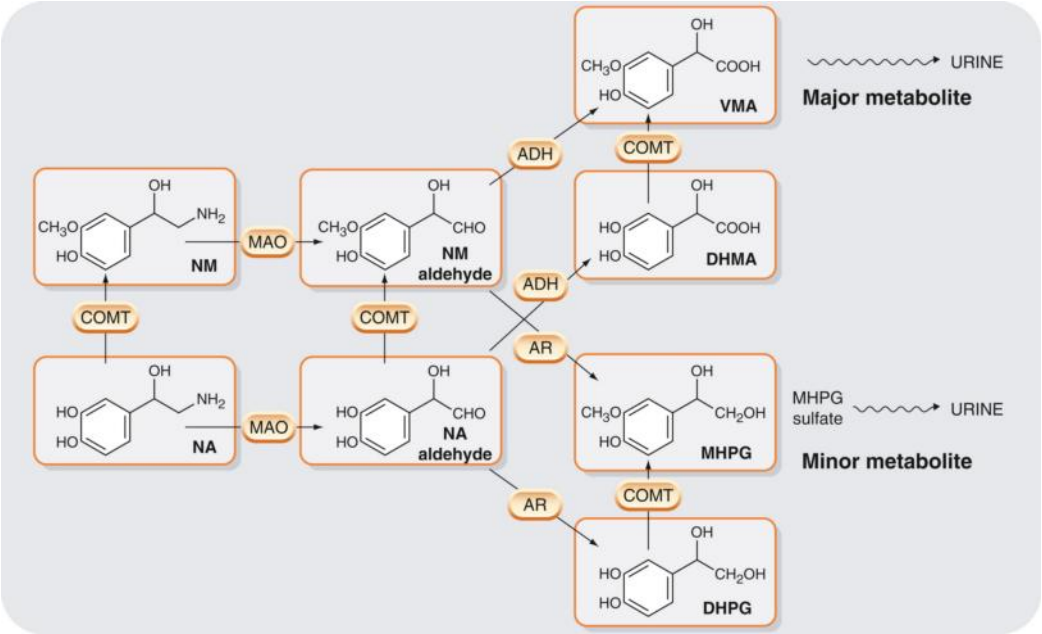

FIG. 15.3 The main pathways of noradrenaline metabolism.The oxidative branch (catalysed by aldehyde dehydrogenase [ADH]) predominates, giving vanillylmandelic acid (VMA) as the main urinary metabolite. The reductive branch (catalysed by aldehyde reductase [AR]) produces the less abundant metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG), which is conjugated to MHPG sulfate before being excreted; MHPG sulfate excretion reflects noradrenaline (NA) release in brain. *COMT,* Catechol-*O*-methyl transferase; *DHMA,* 3,4-dihydroxymandelic acid; *DHPG,* 3,4-dihydroxyphenylglycol; *MAO,* monoamine oxidase; *NM,* normetanephrine.

Noradrenergic transmission

- Transmitter synthesis involves the following:
  - L-tyrosine is converted to dopa by tyrosine hydroxylase (rate-limiting step). Tyrosine hydroxylase occurs only in catecholaminergic neurons.
  - Dopa is converted to dopamine by dopa decarboxylase.
  - Dopamine is converted to noradrenaline by DBH, located in synaptic vesicles.
  - In the adrenal medulla, noradrenaline is converted to adrenaline by phenylethanolamine *N*-methyltransferase.
- Transmitter storage: noradrenaline is stored at high concentration in synaptic vesicles, together with ATP, chromogranin and DBH, which are co-released by exocytosis. Transport of noradrenaline into vesicles occurs by a reserpine-sensitive transporter, VMAT. Noradrenaline content of cytosol is normally low due to MAO in nerve terminals.
- Transmitter release occurs normally by Ca^{2+}-mediated exocytosis from varicosities on the terminal network. Non-exocytotic release occurs in response to indirectly acting sympathomimetic drugs (e.g. **tyramine** and **amphetamine**), which displace noradrenaline from vesicles. Noradrenaline escapes via the NET (reverse transport).
- Transmitter action is terminated mainly by reuptake of noradrenaline into nerve terminals via the NET transporter.

NET is blocked by tricyclic antidepressant drugs and **cocaine.**

- Noradrenaline release is controlled by autoinhibitory feedback mediated by α_2 receptors.
- Co-transmission occurs at many noradrenergic nerve terminals, ATP and neuropeptide Y being frequently co-released with NA. ATP mediates the early phase of smooth muscle contraction in response to sympathetic nerve activity.

metabolising enzymes. The properties of important drugs in this category are summarised in Tables **15.4**–**15.6**.

Drugs Acting on Adrenoceptors

The overall activity of these drugs is governed by their affinity, efficacy and selectivity with respect to different types of adrenoceptor, and intensive research has been devoted to developing drugs with the right properties for specific clinical indications. As a result, the pharmacopoeia is awash with adrenoceptor ligands. Many clinical needs are met, it turns out, by drugs that relax smooth muscle in different organs of the body [4] and those that block the cardiac stimulant effects of the sympathetic nervous system; on the other hand, cardiac stimulation is generally undesirable in chronic disease.

Table 15.4

CNS, Central nervous system; *COMT,* catechol-*O*-methyl transferase; *MAO,* monoamine oxidase.

Table 15.5

Table 15.6

CNS, Central nervous system; *MAO,* monoamine oxidase; *NA,* noradrenaline; *NET,* norepinephrine transporter; *VMAT,* vesicular monoamine transporter.

Broadly speaking, β_2-adrenoceptor agonists are useful as smooth muscle relaxants (especially in the airways), while β_1-adrenoceptor antagonists (often called β blockers) are used mainly for their cardiodepressant effects. α_1-Adrenoceptor antagonists are used mainly for their vasodilator effects in cardiovascular indications and also for the treatment of prostatic hyperplasia. Adrenaline, with its mixture of cardiac stimulant, vasodilator and vasoconstrictor actions, is uniquely important in cardiac arrest (see **Ch. 20**). α_1-Adrenoceptor agonists are widely used (intranasally or systemically) as decongestants.

Adrenoceptor Agonists

Examples of adrenoceptor agonists (also known as *directly-acting sympathomimetic* drugs) are given in **Table 15.2**, and the characteristics of individual drugs are summarised in **Table 15.4**.

Actions

The major physiological effects mediated by different types of adrenoceptor are summarised in **Table 15.1**.

Smooth muscle tone

All types of smooth muscle, except that of the gastrointestinal tract, contract in response to stimulation of α_1 adrenoceptors, through activation of the G_q signal transduction mechanism, leading to intracellular Ca^{2+} release as described in **Chapter 4**. Although vascular smooth muscle possesses both α_1 and α_2 receptors, it appears that α_1 receptors lie close to the sites of noradrenaline release (and are mainly responsible for neurally mediated vasoconstriction), while α_2 receptors lie elsewhere on the muscle fibre surface or on nerve terminals.

When α_1 agonists are given systemically to experimental animals or humans, the most important action is on vascular smooth muscle, particularly in the small arteries and arterioles in skin and splanchnic vascular beds, which are strongly constricted increasing total peripheral vascular resistance. Smooth muscle cells in the walls of large arteries and veins also contract, resulting in decreased arterial compliance and increased central venous pressure, which contribute to an increase in arterial and venous pressure and increased cardiac work. Some vascular beds (e.g. cerebral, coronary and pulmonary) are relatively little affected.

In the whole animal, baroreceptor reflexes are activated by the rise in arterial pressure produced by α_1 agonists, limiting the rise in blood pressure and causing reflex bradycardia.

Smooth muscle in the vas deferens, spleen capsule and eyelid retractor muscles (or nictitating membrane, in some species) is also stimulated by α_1 agonists, and these organs were once widely used for pharmacological studies. Contraction of the erector pili muscles literally causes the hair to stand on end in some species, and in humans causes a very unpleasant sensation like insects crawling

over one's body ('formication' after the Latin word for 'ant' – pronounce with care!).

Stimulation of β receptors relaxes most kinds of smooth muscle by increasing cAMP formation (see **Ch. 4**). β-Receptor activation enhances Ca^{2+} extrusion and intracellular Ca^{2+} sequestration, both effects acting to reduce cytoplasmic Ca^{2+} concentration. In the vascular system, β_2-mediated vasodilatation (particularly in humans) is mainly endothelium dependent and mediated by nitric oxide (see **Ch. 19**). It occurs in many vascular beds and is especially marked in skeletal muscle.

The powerful inhibitory effect of the sympathetic system on gastrointestinal smooth muscle is produced by both α and β receptors, the gut being unusual in that α receptors cause relaxation in most regions other than the sphincters. Part of the effect is due to stimulation of presynaptic α_2 receptors (see later), which inhibit the release of excitatory transmitters (e.g. acetylcholine) from intramural nerves, but there are also α_1 and α_2 receptors on the muscle cells, stimulation of which hyperpolarises the cell by increasing the membrane permeability to K^+ and inhibits action potential discharge. The *sphincters* of the gastrointestinal tract are contracted by α-receptor activation.

Bronchial smooth muscle is relaxed by activation of β_2 adrenoceptors, and selective β_2 agonists are important in the treatment of asthma (see **Ch. 28**). Uterine smooth muscle responds similarly, and these drugs are also used to delay premature labour (see **Ch. 35**). Bladder detrusor muscle is relaxed by activation of β_3 adrenoceptors, and selective β_3 agonists are used

to treat symptoms of overactive bladder (see **Sacco and Bientinesi, 2012**).

α_1 Adrenoceptors have long-lasting trophic effects stimulating smooth muscle proliferation in blood vessels and in the prostate gland. *Benign prostatic hyperplasia* (see **Ch. 29**) is commonly treated with α_1-adrenoceptor antagonists. 'Cross-talk' between the α_1 adrenoceptor and the growth factor signalling pathways (see **Ch. 3**) probably contributes to the clinical effect, in addition to immediate symptomatic improvement which is probably mediated by smooth muscle relaxation in the prostatic capsule that encases the gland.

Nerve terminals

Presynaptic adrenoceptors are present on both cholinergic and noradrenergic nerve terminals (see Chs **4** and **13**). As mentioned previously, the main effect (α_2-mediated) is inhibitory; spinal α_2-adrenoceptors play an important role in pain modulation and α_2-agonists may prove to be useful to treat neuropathic pain (see **Bahari and Meftafi, 2019**, and **Ch. 43**). A weaker facilitatory action of β receptors on noradrenergic nerve terminals has also been described. Clinical uses of α_2-agonists in humans (see 'Clinical uses of adrenoceptor agonists' clinical box) are currently limited, but **dexmedetomidine** is licensed for use in intensive care patients because of its sedative and analgesic properties; its effects can be reversed by an α_2-antagonist, although this is seldom appropriate since analgesic as well as sedative effects are reversed.

Effects on cardiac structure and function

Catecholamines, acting on β_1 receptors, exert a powerful stimulant effect on the heart (see **Ch. 20**). Both the heart rate (*chronotropic effect*) and the force of contraction (*inotropic effect*) are increased, resulting in a markedly increased cardiac output and cardiac oxygen consumption. Cardiac efficiency (see **Ch. 20**) is reduced. Catecholamines can also disturb cardiac rhythm, culminating in ventricular fibrillation. (Paradoxically, but importantly, adrenaline is also used to treat ventricular fibrillation arrest as well as other forms of cardiac arrest; see **Ch. 20**). **Fig. 15.4** shows the overall pattern of cardiovascular responses to catecholamine infusions in humans, reflecting their actions on both the heart and vascular system.

Cardiac hypertrophy occurs in response to activation of both β_1 and α_1 receptors, probably by a mechanism similar to the hypertrophy of vascular and prostatic smooth muscle. This may be important in the pathophysiology of hypertension and of cardiac failure (which is associated with sympathetic overactivity); see Chs **20** and **21**. Beta receptors are also implicated in the pathological growth of blood vessels in severe childhood haemangiomas (see later).

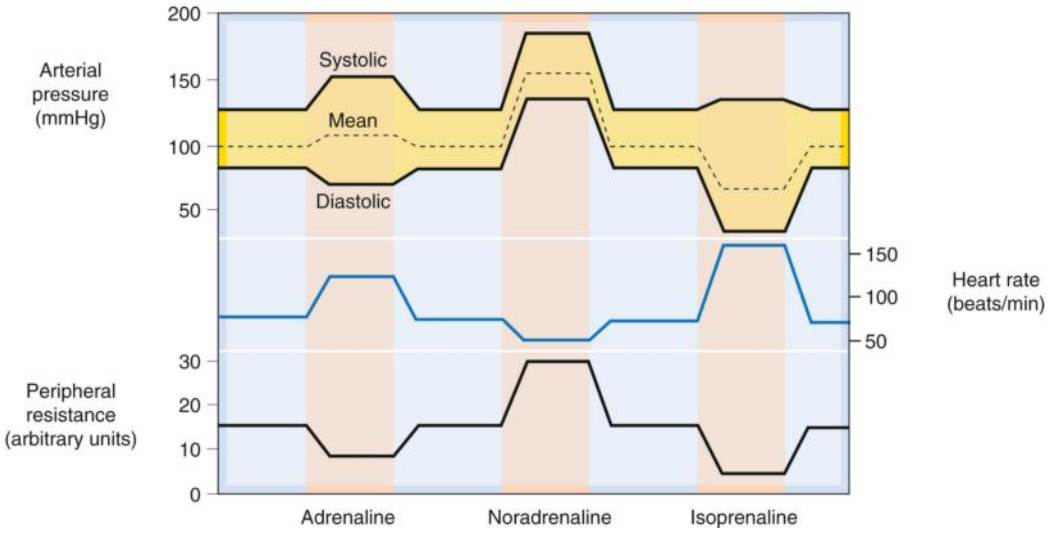

FIG. 15.4 Schematic representation of the cardiovascular effects of intravenous infusions of adrenaline, noradrenaline and isoprenaline in humans.Noradrenaline (predominantly α agonist) causes vasoconstriction and increased systolic and diastolic pressure, with a reflex bradycardia. Isoprenaline (β agonist) is a vasodilator, but strongly increases cardiac force and rate. Mean arterial pressure falls. Adrenaline combines both actions.

Metabolism

Catecholamines convert energy stores (glycogen and fat) to freely available fuels, increasing the plasma concentration of glucose and free fatty acids. The detailed biochemical mechanisms (see review by **Nonogaki, 2000**) vary from species to species, but in most cases the effects on carbohydrate metabolism of liver and muscle (**Fig. 15.5**) are mediated through β_1 receptors and the stimulation of lipolysis and thermogenesis is produced by β_3 receptors (see

Table 15.1). Activation of α_2 receptors inhibits insulin secretion, further contributing to the hyperglycaemia. The production of *leptin* by adipose tissue (see **Ch. 32**) is also inhibited. Adrenaline-induced hyperglycaemia in humans is blocked completely by a combination of α and β antagonists but not by either on its own.

Other effects

Skeletal muscle is affected by adrenaline, acting on β_2 receptors, although the effect is far less dramatic than that on the heart. The twitch tension of fast-contracting fibres (white muscle) is increased by adrenaline, particularly if the muscle is fatigued, whereas the twitch of slow (red) muscle is reduced. These effects depend on an action on the contractile proteins, rather than on the membrane, and the mechanism is poorly understood. In humans, adrenaline and other β_2 agonists cause a marked tremor, the shakiness that accompanies fear, excitement, withdrawal from alcohol (see **Ch. 50**) or the excessive use of β_2 agonists (e.g. **salbutamol**) in the treatment of asthma being examples of this. It probably results from an increase in muscle spindle discharge, coupled with an effect on the contraction kinetics of the fibres, these effects combining to produce an instability in the reflex control of muscle length. β-Receptor antagonists are sometimes used to control pathological tremor. Increased susceptibility to cardiac dysrhythmias associated with β_2 agonists is thought to be partly due to hypokalaemia, caused by an increase in K^+ uptake by skeletal muscle. β_2 Agonists also cause long-term changes in the expression of sarcoplasmic reticulum proteins that control contraction kinetics, and thereby increase the rate and force of contraction of skeletal muscle.

Clenbuterol, an 'anabolic' drug used illicitly by athletes to improve performance (see **Ch. 59**), is a β_2 agonist that acts in this way.

Histamine release by human and guinea pig lung tissue in response to anaphylactic challenge (see **Ch. 17**) is inhibited by catecholamines, acting on β_2 receptors.

Lymphocytes and other cells of the immune system also express adrenoceptors (mainly β adrenoceptors). Lymphocyte proliferation, lymphocyte-mediated cell killing and production of many cytokines are inhibited by β-adrenoceptor agonists. The physiological and clinical importance of these effects has not yet been established, despite intense current interest in neuroimmunology (**Schiller et al., 2021**). For a review of the effects of the sympathetic nervous system on immune function, see **Elenkov et al., 2000**.

Adrenoceptor agonists

- **Noradrenaline** and **adrenaline** show relatively little receptor selectivity.
- Selective α_1 agonists include **phenylephrine, midodrine** and **oxymetazoline.**
- α_2 agonists include **clonidine** and **α-methylnoradrenaline.** Clonidine also acts on a distinct imidazoline I_1 receptor; **moxonidine** and **rilmenidine** have greater I_1/α_2 selectivity than clonidine and cause less drowsiness than clonidine when used to treat hypertension. Methylnoradrenaline is selective for α_2 adrenoceptors over I_1. It is formed as a false transmitter from **methyldopa**,

developed as a hypotensive drug (now largely obsolete, except for use during pregnancy, because it causes drowsiness).

- Selective β_1 agonists include **dobutamine.** Increased cardiac contractility may be useful clinically, but all β_1 agonists can cause cardiac dysrhythmias.
- Selective β_2 agonists include **salbutamol**, **terbutaline** and **salmeterol**; used mainly for their bronchodilator action in asthma.
- A selective β_3 agonist, **mirabegron**, is used to treat overactive bladder; β_3 agonists promote lipolysis and have potential in the treatment of obesity.

Clinical use

The main clinical uses of adrenoceptor agonists are summarised in the 'Clinical uses of adrenoceptor agonists' clinical box and **Table 15.4**, the most important being the use of β-adrenoceptor agonists for the treatment of asthma (see **Ch. 28**).

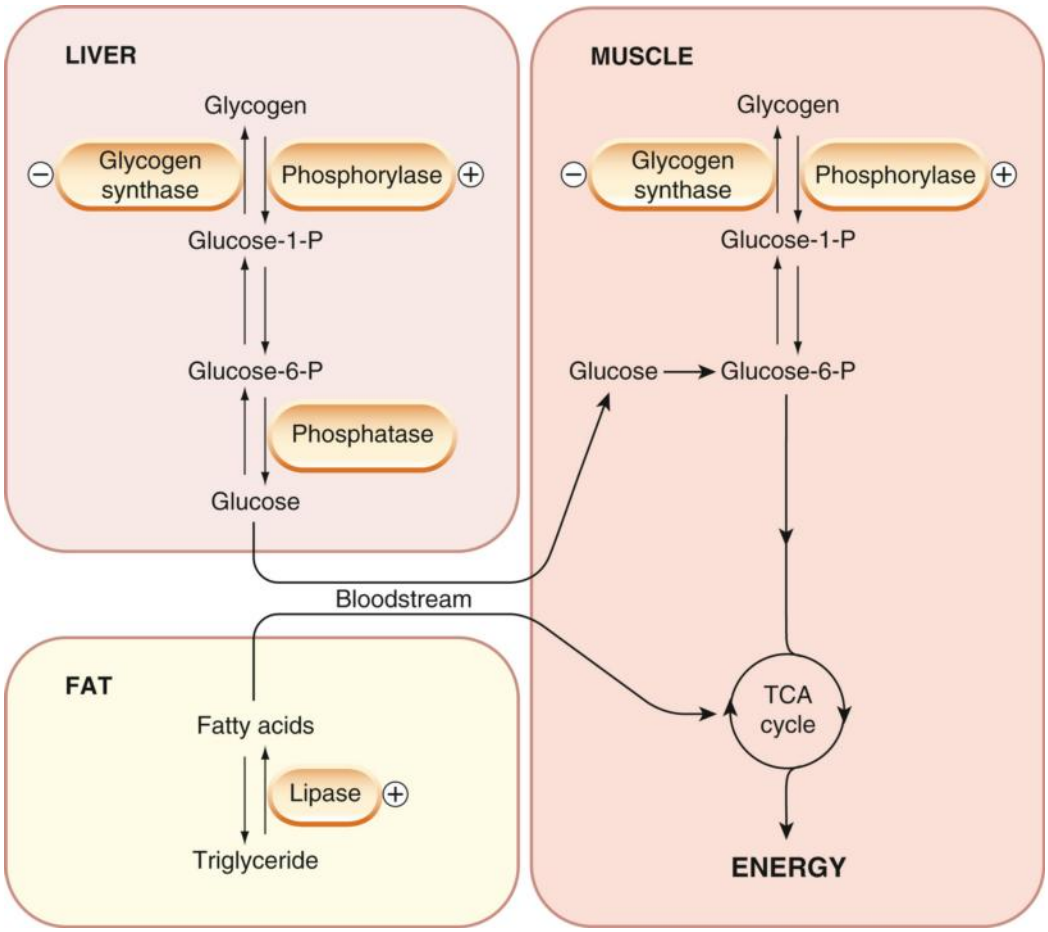

FIG. 15.5 Regulation of energy metabolism by catecholamines.The main enzymic steps that are affected by β-adrenoceptor activation are indicated by + and – signs, denoting stimulation and inhibition, respectively. The overall effect is to mobilise glycogen and fat stores to meet energy demands. *TCA,* Tricarboxylic acid.

Clinical uses of adrenoceptor agonists

- Cardiovascular system:
  - cardiac arrest: **adrenaline**

  - cardiogenic shock (see Chs **20** and **21**): **dobutamine** (β_1 agonist)
  - severe postural hypotension: **midodrine** (α_1 agonist).
- Anaphylaxis (acute hypersensitivity, see Chs **17** and **28**): **adrenaline.**
- Respiratory system:
  - asthma (see **Ch. 28**): selective β_2-receptor agonists (**salbutamol**, **terbutaline**, **salmeterol**, **formoterol**)
  - nasal decongestion: **phenylephrine** by mouth or drops containing **xylometazoline** or **ephedrine** for short-term use.
- Miscellaneous indications:
  - **adrenaline**: with local anaesthetics to prolong their action (see **Ch. 44**)
  - premature labour (**salbutamol**; see **Ch. 35**)
  - α_2 agonists (e.g. **clonidine**, **lofexidine**): to lower blood pressure, but are now seldom prescribed. **Dexmedetomidine** is licensed for analgesia and sedation in intensive care; **lofexidine** is used as an adjunct during opioid withdrawal, to reduce menopausal flushing, especially when **oestrogen** is contraindicated as in patients with breast cancer; and to reduce frequency of migraine attacks (see **Ch. 42**). Tourette syndrome, characterised by multiple tics and outbursts of foul language, is an unlicensed indication
  - A β_3 agonist, **mirabegron**: to treat urgency, increased micturition frequency and incontinence (overactive bladder symptoms).

Adrenoceptor Antagonists

The main drugs are listed in **Table 15.2**, and further information is given in **Table 15.5**. Most are selective for α or β receptors, and many are also subtype-selective.

α-Adrenoceptor antagonists

The main groups of α-adrenoceptor antagonists are:

- non-selective between subtypes (e.g. **phenoxybenzamine**, **phentolamine**)
- α_1-selective (e.g. **prazosin**, **doxazosin**, **terazosin**)
- α_2-selective (e.g. **yohimbine**, **idazoxan**)

In addition, *ergot derivatives* (e.g. **ergotamine**, **dihydroergotamine**) block α receptors as well as having many other actions, notably on 5-HT receptors. They are described in **Chapter 16**. Their action on α adrenoceptors is of pharmacological interest but not used therapeutically.

Non-selective α-adrenoceptor antagonists

Phenoxybenzamine is not specific for α receptors, and also antagonises the actions of acetylcholine, histamine and 5-HT. It is long lasting because it binds covalently to the receptors. **Phentolamine** is more selective, but it binds reversibly and its action is short lasting. In humans, these drugs cause a fall in arterial pressure (because of block of α-receptor-mediated vasoconstriction) and postural hypotension. The cardiac output and heart rate are increased. This is a reflex response to the fall in arterial pressure,

mediated through β receptors. The concomitant block of α_2 receptors tends to increase noradrenaline release, which has the effect of enhancing the reflex tachycardia that occurs with any blood pressure-lowering agent. Phenoxybenzamine retains a niche use in preparing patients with *phaeochromocytoma* (see **Ch. 21**, and later) for surgery.

Labetalol and **carvedilol** [5] are mixed α_1- and β-receptor-blocking drugs, although at doses used clinically they act predominantly on β receptors. Carvedilol is used mainly to treat hypertension and heart failure (see Chs **20** and **21**); labetalol is used to treat hypertension in pregnancy, as well as hypertensive emergencies (where intravenous administration is required).

Selective α_1 antagonists

Prazosin was the first selective α_1 antagonist/inverse agonist; it acts on all three subtypes of α_1 receptor (**Alexander et al., 2019**). Similar drugs with longer half-lives (e.g. **doxazosin**, **terazosin**), which have the advantage of allowing once-daily dosing, are now preferred. They are highly selective for α_1 adrenoceptors and cause vasodilatation and fall in arterial pressure, but less tachycardia than occurs with non-selective α-receptor antagonists, presumably because they do not increase noradrenaline release from sympathetic nerve terminals. Mild postural hypotension is common but is less problematic than with shorter-acting prazosin.

The α_1-receptor antagonists relax smooth muscle in the bladder neck and prostate capsule, and inhibit hypertrophy of these tissues, and are therefore useful in treating symptoms associated with *benign prostatic hypertrophy*. **Tamsulosin**, an α_{1A}-receptor

antagonist, shows some selectivity for the urogenital tract, and causes less hypotension than the less selective α_1-receptor antagonists.

It is believed that α_{1A} receptors play a part in the pathological hypertrophy not only of prostatic and vascular smooth muscle, but also in the cardiac hypertrophy that occurs in hypertension and heart failure (**Papay et al., 2013**), and the use of selective α_{1A}-receptor antagonists to treat these chronic conditions is under investigation.

Selective α_2 antagonists

Yohimbine is a naturally occurring alkaloid; various synthetic analogues have been made, such as **idazoxan**. These drugs are used experimentally to analyse α-receptor subtypes, and yohimbine, possibly by virtue of its vasodilator effect, historically enjoyed notoriety as an aphrodisiac, but they are not used therapeutically in humans. Their occasional use to reverse the sedative effect of an α_2 agonist in veterinary medicine is mentioned previously.

α-Adrenoceptor antagonists

- Selective α_1 antagonists (e.g. **doxazosin**, **terazosin**) are used in treating hypertension and for benign prostatic hypertrophy. Postural hypotension, stress incontinence and impotence are unwanted effects. **Prazosin** (short acting) was the first such agent.
- **Tamsulosin** is α_{1A} selective and acts mainly on the urogenital tract. It is used to treat benign prostatic

hypertrophy and may cause less postural hypotension than other α_1 agonists.

- **Yohimbine** is a selective α_2 antagonist. It is not used clinically in humans.

Clinical uses and unwanted effects of α-adrenoceptor antagonists

The main uses of α-adrenoceptor antagonists are related to their cardiovascular actions and are summarised in the 'Clinical uses of α-adrenoceptor antagonists' clinical box.

Phaeochromocytoma is a catecholamine-secreting tumour of chromaffin tissue, which causes severe and initially episodic hypertension. A combination of α- and β-receptor antagonists is the most effective way of controlling the blood pressure. The tumour may be surgically removable, and it is essential to block α and β receptors before surgery is begun, to avoid the effects of a sudden release of catecholamines when the tumour is disturbed. Phenoxybenzamine, an irreversible α antagonist which reduces the maximum of the agonist dose–response curve (see **Ch. 2**, **Fig. 2.4B**) is combined with a β-adrenoceptor antagonist for this purpose.

Clinical uses of α-adrenoceptor antagonists

- Severe hypertension (see **Ch. 21**): α_1-selective antagonists (e.g. **doxazosin**) in combination with other drugs.

- Benign prostatic hypertrophy (e.g. **tamsulosin**, a selective α_{1A}-receptor antagonist).
- Phaeochromocytoma: **phenoxybenzamine** (irreversible antagonist) in preparation for surgery. A β-adrenoceptor antagonist is administered and up-titrated after α-blockade (evidenced by postural hypotension) has been established and before surgery.

β-Adrenoceptor antagonists

β-Adrenoceptor antagonists remain extremely therapeutically important. They were discovered in 1958, 10 years after Ahlquist had postulated the existence of β adrenoceptors. The first compound, **dichloroisoprenaline**, was a partial agonist. Further development led to **propranolol**, which is much more potent and a pure antagonist that blocks β_1 and β_2 receptors equally. The potential clinical advantages of drugs with some partial agonist activity, and/or with selectivity for β_1 receptors, led to the development of **oxprenolol** and **alprenolol** (non-selective with considerable partial agonist activity), and others, e.g. **atenolol, metoprolol** and **bisoprolol** (β_1-selective with no agonist activity). Two newer drugs are **carvedilol** (a non-selective β-adrenoceptor antagonist with additional α_1-blocking activity) and **nebivolol** (a β_1-selective antagonist with vasodilator nitric oxide-mediated activity; see **Ch. 19**). Both these drugs have proven more effective than conventional β-adrenoceptor antagonists in treating heart failure (see Chs **21** and **22**). The characteristics of the most important compounds are set out in **Table 15.5**. Most clinically

available β-receptor antagonists are inactive on β_3 receptors so do not affect lipolysis.

Actions

The main pharmacological actions of β-receptor antagonists can be deduced from **Table 15.1**. The acute effects produced in humans depend on the degree of sympathetic activity and are modest in subjects at rest. The most important effects are on the cardiovascular system and on bronchial smooth muscle (see Chs **21**, **22** and **28**).

In a healthy subject at rest, propranolol causes modest changes in heart rate, cardiac output or arterial pressure, but β-blockade dramatically reduces the effect of exercise or excitement on these variables (**Fig. 15.6**). Drugs with partial agonist activity, such as oxprenolol, increase the heart rate at rest but reduce it during exercise or excitement. Maximum exercise tolerance is considerably reduced in normal subjects, partly because of the limitation of the cardiac response, and partly because the β-mediated vasodilatation in skeletal muscle is reduced. Coronary flow is reduced, but relatively less than the myocardial oxygen consumption, so oxygenation of the myocardium is improved – of great importance in the treatment of angina pectoris (see **Ch. 20**). In healthy subjects, the reduction of the force of contraction of the heart is not important, in contrast to patients with heart disease (see later).

An important, and initially somewhat unexpected, effect of β-receptor antagonists is their antihypertensive action (see **Ch. 21**). Patients with hypertension show a gradual fall in arterial pressure

that takes several days to develop fully. The mechanism is complex and involves the following:

- reduction in cardiac output;
- reduction of renin release from the juxtaglomerular cells of the kidney;
- a central action, reducing sympathetic nervous output, is less important.

Vasodilatation contributes to the antihypertensive action of those β-receptor antagonists (e.g. carvedilol and nebivolol, see earlier) that possess additional vasodilator properties.

Blockade of the facilitatory effect of presynaptic β receptors on noradrenaline release (see **Table 15.1**) may also contribute to the antihypertensive effect. The antihypertensive effect of β-receptor antagonists remains clinically useful. Because reflex vasoconstriction is preserved, postural and exercise-induced hypotension is less troublesome than with many other antihypertensive drugs but they are now seldom used as first-line agents in uncomplicated hypertension (see **Ch. 21**).

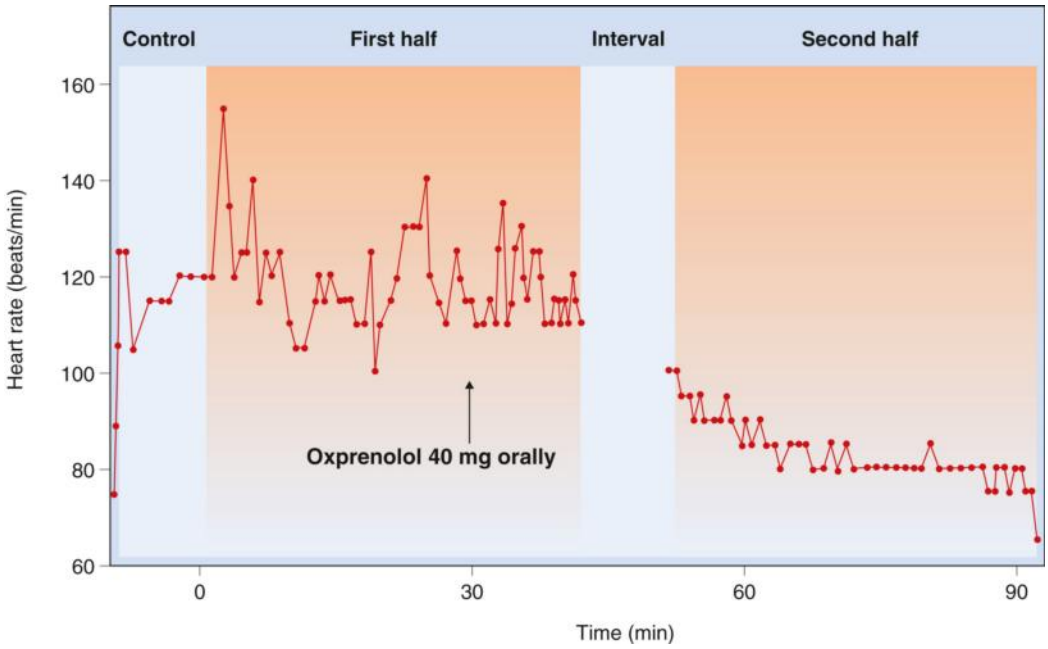

FIG. 15.6 Heart rate recorded continuously in a spectator watching a live football match, showing the effect of the β-adrenoceptor 'antagonist' oxprenolol – strictly a partial agonist. From Taylor, S.H., Meeran, M.K., 1973. In: Burley, D.M., Fryer, J.H., Rowdel, R.K., et al. (Eds). New Perspectives in Beta-Blockade. CIBA Laboratories, Horsham.

β-Receptor antagonists have several important antidysrhythmic effects on the heart (see **Ch. 20**).

Airways resistance in normal subjects is only slightly increased by β-receptor antagonists, and this is of no consequence. In asthmatic subjects, however, non-selective β-receptor antagonists (such as propranolol) can cause severe bronchoconstriction, which does not, of course, respond to the usual doses of drugs such as salbutamol or adrenaline. This danger is less with β_1-selective antagonists, but none is so selective in humans that the risk can be ignored.

Despite the involvement of β receptors in the hyperglycaemic actions of adrenaline, β-receptor antagonists cause only minor metabolic changes in healthy people. They do not affect the onset of hypoglycaemia following an injection of insulin, but somewhat delay the recovery of blood glucose concentration. In patients with diabetes, however, the use of β-receptor antagonists increases the likelihood of exercise-induced hypoglycaemia, because the normal adrenaline-induced release of glucose from the liver is diminished. Furthermore, β-receptor antagonists may alter the awareness of hypoglycaemia by blunting its symptoms (see **Ch. 31** and further in the chapter).

β-Adrenoceptor antagonists

- Non-selective between β_1 and β_2 adrenoceptors: **propranolol**, **alprenolol**, **oxprenolol.**
- β_1-selective: **atenolol**, **metoprolol**, **bisoprolol**, **nebivolol.**
- **Alprenolol** and **oxprenolol** have partial agonist activity.
- Many clinical uses (see 'Clinical uses of β-adrenoceptor antagonists' clinical box).
- Important hazards are bronchoconstriction in asthmatics, and bradycardia and cardiac failure if administered to unstable patients with deteriorating cardiac function.
- Adverse effects include cold extremities, insomnia, vivid dreams, depression and fatigue.
- Some (e.g. propranolol) show rapid first-pass metabolism, hence poor bioavailability.

- Some drugs (e.g. **labetalol**, **carvedilol**) block both α and β adrenoceptors.

Clinical use

The main uses of β-receptor antagonists are connected with their effects on the cardiovascular system and are discussed in **Chapters 20** and **21**. They are summarised in the 'Clinical uses of β-adrenoceptor antagonists' clinical box.

The use of β-receptor antagonists in cardiac failure deserves special mention, as clinical opinion underwent a U-turn. Patients with unstable heart disease may rely on a degree of sympathetic drive to the heart to maintain an adequate cardiac output and removal of this by blocking β receptors can exacerbate cardiac failure, so using these drugs in patients with cardiac failure was considered ill-advised at best. In theory, drugs with partial agonist activity (e.g. oxprenolol, alprenolol) offer an advantage because they can, by their own agonist action, maintain a degree of β_1-receptor activation, while at the same time blunting the cardiac response to increased sympathetic nerve activity or to circulating adrenaline. Clinical trials, however, have not shown a clear advantage of these drugs measurable as a reduced incidence of cardiac failure, and one such drug (**xamoterol**, since withdrawn) with particularly marked agonist activity clearly made matters worse.

Paradoxically, β-receptor antagonists, commenced in low doses with supervised up-titration to well-compensated patients with cardiac failure, unambiguously improves survival (see **Ch. 21**) (**Bristow, 2011**). **Carvedilol**, **bisoprolol, metoprolol** and **nebivolol** are among the drugs demonstrated to improve survival

in randomised controlled trials and now routinely used to treat chronic stable heart failure, in combination with other categories of drugs (see **Ch. 21**).

Infantile haemangioma is the commonest soft-tissue tumour in children, occurring in 3%–10% of infants and usually regressing without treatment. Approximately 12% are complicated by impingement on vital organs such as the eye and require intervention. In 2008 a chance observation that treatment of heart failure with propranolol in two young children with severe haemangiomas was associated with their regression led to clinical trials that confirmed the effectiveness of propranolol for this indication. Such use has been approved by the FDA as well as in Europe, and propranolol is now standard therapy for severe infantile haemangioma. The evidence of such marked efficacy (**Léauté-Labrèze et al., 2015**) highlights the importance of β-adrenoceptor-mediated trophic actions, at the least in this paediatric endothelial tumour. Milder uncomplicated forms of infantile haemangioma are sometimes treated with topical timolol or propranolol.

Clinical uses of β-adrenoceptor antagonists

- Cardiovascular (see Chs **20** and **21**):
  - angina pectoris
  - myocardial infarction, and following infarction
  - prevention of recurrent dysrhythmias (especially if triggered by sympathetic activation)
  - heart failure (in well-compensated patients)

– hypertension (no longer first choice; see **Ch. 21**).

• Other uses:

– severe/complicated infantile haemangioma
– glaucoma (e.g. **timolol** eye drops)
– thyrotoxicosis (see **Ch. 34**), as adjunct to definitive treatment (e.g. preoperatively and during initiation of carbimazole treatment)
– anxiety (see **Ch. 45**), to control somatic symptoms (e.g. palpitations, tremor)
– migraine prophylaxis (see **Ch. 42**)
– benign essential tremor (a familial disorder).

Unwanted effects

The principal unwanted effects of β-receptor antagonists in therapeutic use result from their main (receptor-blocking) action.

Bronchoconstriction

As explained earlier, this is of little importance in the absence of airways disease, but in asthmatic patients the effect can be life-threatening. It is also of clinical importance in patients with other forms of obstructive lung disease (e.g. chronic bronchitis, emphysema), although the risk–benefit balance may favour cautious treatment in individual patients.

Cardiac depression

As described previously, these negative inotropes are contraindicated in acute decompensated heart failure. Patients suffering from chronic stable heart failure who are started on β-

receptor antagonists may deteriorate symptomatically in the first few weeks before the beneficial effect develops (hence the advice to start at very low doses and titrate gently upwards). The desired beneficial effect in the long-term is improved left ventricular function and survival.

Bradycardia

Sinus bradycardia can progress to life-threatening heart block, particularly if β-adrenoceptor antagonists are co-administered with other antidysrhythmic drugs that impair cardiac conduction (see **Ch. 20**).

Hypoglycaemia

Glucose release in response to adrenaline is a safety mechanism in insulin-treated patients with diabetes and other individuals prone to hypoglycaemic attacks. The sympathetic response to hypoglycaemia produces symptoms (especially tachycardia) that warn patients of the urgent need for carbohydrate (usually in the form of a sugary drink). β-Receptor antagonists reduce these symptoms, so incipient hypoglycaemia is more likely to go unnoticed by the patient. There is a theoretical advantage in using β_1-selective agents, because glucose release from the liver is controlled by β_2 receptors.

Fatigue

This is probably due to reduced cardiac output and reduced muscle perfusion in exercise. It is a common symptom of patients taking β-adrenoceptor-blocking drugs.

Cold extremities

This is common, due to a loss of β-receptor-mediated vasodilatation in cutaneous vessels in hands and feet. Theoretically, β_1-selective drugs are less likely to produce this effect, which may also be less marked in patients treated with β-adrenoceptor antagonists with additional vasodilating properties.

Nightmares, which occur mainly with CNS-penetrant β-adrenoceptor antagonists, may be a direct result of β-receptor blockade, but the mechanism is not understood. This is an issue in the treatment of infantile haemangioma, where behavioural disturbances are sometimes of concern, and the efficacy of non–brain penetrant drugs has not been fully established.

Drugs that Affect Noradrenergic Neurons

Emphasis in this chapter is placed on peripheral sympathetic transmission. The same principles, however, are applicable to the CNS (see **Ch. 39**, where many of the drugs mentioned here also act). The major drugs and mechanisms are summarised in **Table 15.6**.

Drugs that Affect Noradrenaline Synthesis

α-Methyltyrosine, which inhibits tyrosine hydroxylase, is used experimentally but not clinically. Indeed, few clinically important drugs affect catecholamine synthesis directly. **Carbidopa**, a hydrazine derivative of dopa which inhibits dopa decarboxylase in the periphery but does not penetrate the blood–brain barrier, is an important exception and is used as an important adjunct to levodopa in the treatment of parkinsonism (see **Ch. 40**).

Methyldopa, still used in the treatment of hypertension during pregnancy (see **Ch. 21**), is taken up by noradrenergic neurons,

where it is converted to the false transmitter α-methylnoradrenaline. This is not deaminated within the neuron by MAO, so it accumulates and displaces noradrenaline from the synaptic vesicles. α-Methylnoradrenaline is released by exocytosis in the same way as noradrenaline but is less active than noradrenaline on α_1 receptors and thus is less effective in causing vasoconstriction. However, it is more active on presynaptic (α_2) receptors, so the autoinhibitory feedback mechanism operates more strongly than normal, thus reducing transmitter release. Each effect, both in the periphery and more importantly in the CNS, contributes to its hypotensive action. It produces adverse effects typical of centrally acting antiadrenergic drugs (e.g. sedation), as well as carrying 'off-target' risks of immune haemolytic anaemia (see **Ch. 58**) and liver toxicity, so it is now little used, except for hypertension in the second half of pregnancy where there is considerable experience of its use without harm to the unborn baby.

6-Hydroxydopamine (identical with dopamine except for an extra hydroxyl group) is a neurotoxin of the Trojan horse kind. It is taken up selectively by noradrenergic nerve terminals, where it is converted to a reactive quinone, which destroys the nerve terminal, producing a 'chemical sympathectomy'. The cell bodies survive, and eventually the sympathetic innervation recovers. The drug is useful for experimental purposes but has no clinical uses. If injected directly into the brain, it selectively destroys those nerve terminals (i.e. dopaminergic, noradrenergic and adrenergic) that take it up, but it does not reach the brain if administered systemically.

MPTP (**1-methyl-4-phenyl-1,2,3,5-tetrahydropyridine**; see **Ch. 40**) is a similar selective neurotoxin acting on dopaminergic

neurons.

Droxidopa (dihydroxyphenylserine, L-DOPS) is under investigation for treating hypotension. It penetrates the blood–brain barrier and is a prodrug being converted to noradrenaline by dopa decarboxylase, bypassing the DBH-catalysed hydroxylation step. It raises blood pressure by increasing noradrenaline release.

Drugs that Affect Noradrenaline Storage

Reserpine is an alkaloid from the shrub *Rauwolfia*, which has been used in India for centuries for the treatment of mental disorders. Reserpine potently blocks the transport of noradrenaline and other amines into storage vesicles, by blocking VMAT. Noradrenaline accumulates instead in the cytoplasm, where it is degraded by MAO. The noradrenaline content of tissues drops and sympathetic transmission is blocked. Reserpine also depletes 5-HT and dopamine from neurons in the brain, where these amines are transmitters (see **Ch. 39**). Reserpine is now used only experimentally but was previously used in Europe and the United States as an antihypertensive drug. Its central effects, especially depression, which probably result from impairment of noradrenergic and 5-HT-mediated transmission in the brain (see **Ch. 48**), were a serious dose-related problem.

Drugs that Affect Noradrenaline Release

Drugs can affect noradrenaline release in four main ways:

- by directly blocking release (noradrenergic neuron-blocking drugs)

- by evoking noradrenaline release in the absence of nerve terminal depolarisation (indirectly acting sympathomimetic drugs)
- by acting on presynaptic receptors that indirectly inhibit or enhance depolarisation-evoked release; examples include α_2 agonists (see above), angiotensin II, dopamine and prostaglandins
- by increasing or decreasing available stores of noradrenaline (e.g. reserpine, see earlier; MAO inhibitors, see **Ch. 48**).

Noradrenergic Neuron-Blocking Drugs

Noradrenergic neuron-blocking drugs (e.g. **guanethidine**) were discovered in the mid-1950s when alternatives to ganglion-blocking drugs were being sought for use in the treatment of hypertension. They are of pharmacological interest but are now seldom if ever used clinically. The main effect of guanethidine is to inhibit the release of noradrenaline from sympathetic nerve terminals. It has little effect on the adrenal medulla, and none on nerve terminals that release transmitters other than noradrenaline. Related drugs include **bretylium**, **bethanidine** and **debrisoquin** (now of interest mainly as a probe for studying drug metabolism; see **Ch. 12**).

Actions

Drugs of this class reduce or abolish the response of tissues to sympathetic nerve stimulation.

The action of guanethidine on noradrenergic transmission is complex. It is selectively accumulated by noradrenergic nerve terminals, being a substrate for NET (see **Table 15.6**). Its initial

activity is due to block of impulse conduction in the nerve terminals that selectively accumulate the drug – acting as a local anaesthetic selective for noradrenergic nerves, the selectivity being down to its concentration by NET in the terminals of these axons. Consequently, its action is prevented by drugs such as *tricyclic antidepressants* (see **Ch. 48**) that block NET.

Guanethidine is also concentrated in synaptic vesicles by means of the vesicular transporter VMAT, possibly interfering with their ability to undergo exocytosis, and displacing noradrenaline. In this way, it causes a gradual and long-lasting depletion of noradrenaline in sympathetic nerve endings, similar to the effect of reserpine.

Large doses of guanethidine cause structural damage to noradrenergic neurons, probably due to its accumulation in high concentration in the nerve terminals.

Although extremely effective in lowering standing blood pressure, they produce severe adverse effects associated with the loss of sympathetic nerve function. The most troublesome include postural hypotension, diarrhoea, nasal congestion and failure of ejaculation. They fail to lower blood pressure effectively at night, when patients are lying flat.

Indirectly Acting Sympathomimetic Amines

Mechanism of action and structure–activity relationships

Tyramine, **amphetamine** and **ephedrine** are structurally related to noradrenaline and, although much less potent, have qualitatively similar effects. However, rather than acting directly on adrenoceptors they mainly act indirectly by releasing endogenous noradrenaline from the sympathetic nerve endings. Drugs that act

similarly and are used for their central effects (see **Ch. 49**) include **methylphenidate** and **atomoxetine**.

These drugs have only weak direct actions on adrenoceptors, but sufficiently resemble noradrenaline to be transported into nerve terminals by NET. Once inside the nerve terminals, they are taken up into the vesicles by VMAT, in exchange for noradrenaline, which escapes into the cytosol. Cytosolic noradrenaline escapes via NET, in exchange for the foreign monoamine, to act on postsynaptic receptors (**Fig. 15.7**). Exocytosis is not involved in the release process, so their actions do not require an elevation of cytoplasmic Ca^{2+}. They are not completely specific in their actions, and act partly by a direct effect on adrenoceptors, partly by inhibiting NET (thereby enhancing the effect of the released noradrenaline) and partly by inhibiting MAO.

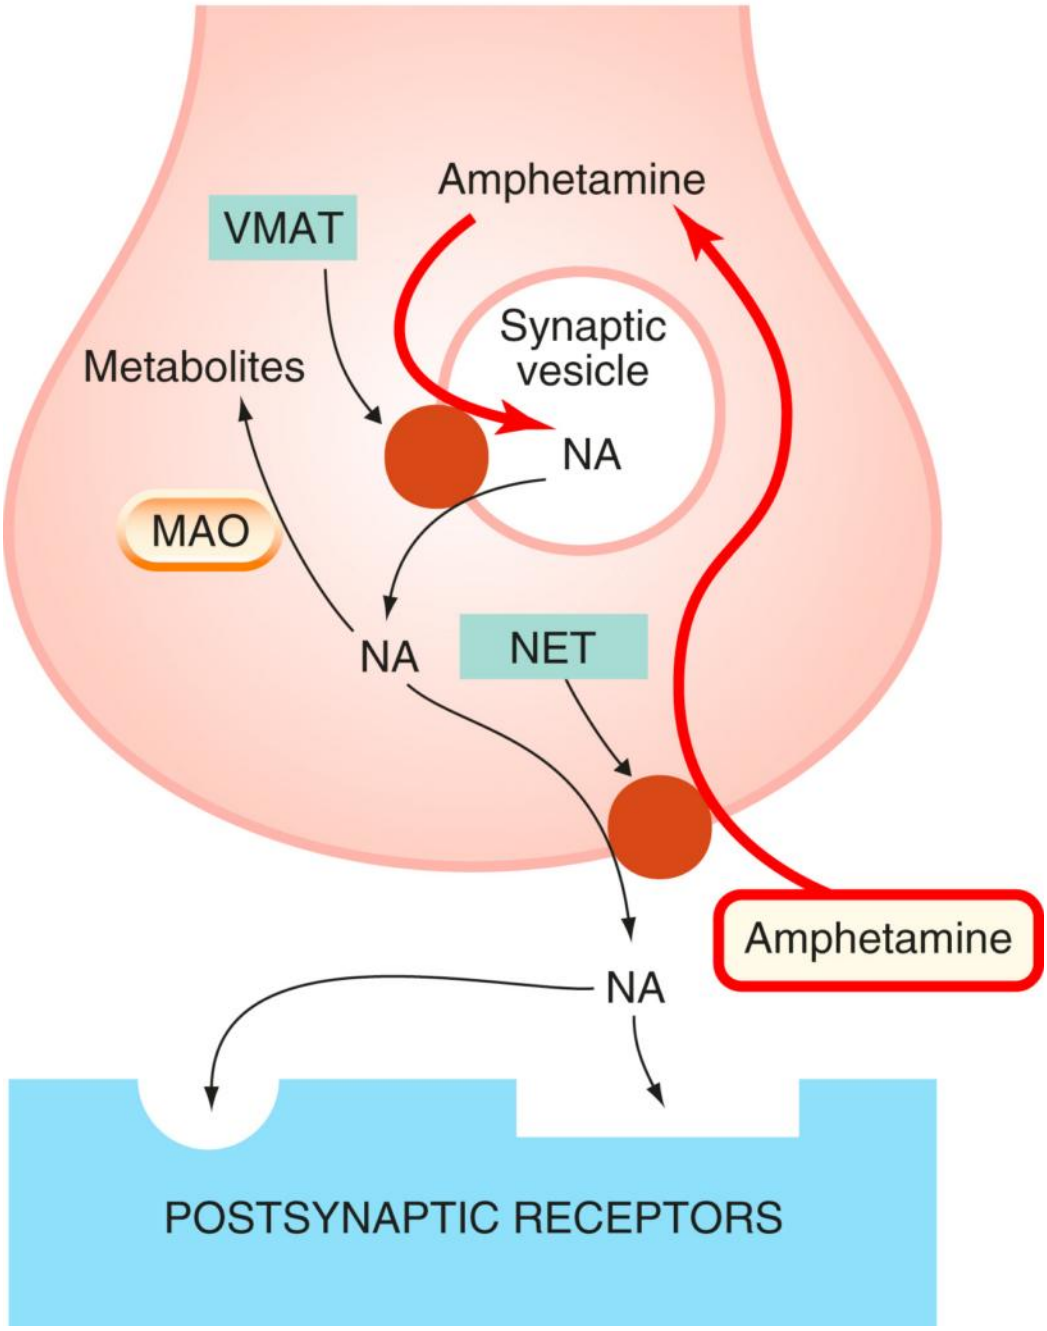

FIG. 15.7 The mode of action of amphetamine, an indirectly acting sympathomimetic amine.Amphetamine enters the nerve terminal via the noradrenaline transporter (NET) and enters synaptic vesicles via the vesicular

monoamine transporter (VMAT), in exchange for noradrenaline (NA), which accumulates in the cytosol. Some of the NA is degraded by monoamine oxidase (MAO) within the nerve terminal and some escapes, in exchange for amphetamine via NET, to act on postsynaptic receptors. Amphetamine also reduces NA reuptake via the transporter, so enhancing the action of the released NA.

As would be expected, the effects of these drugs are strongly influenced by other drugs that modify noradrenergic transmission. Thus, reserpine and 6-hydroxydopamine abolish their effects by depleting the terminals of noradrenaline. MAO inhibitors, on the other hand, strongly potentiate their effects by preventing inactivation, within the terminals, of the transmitter displaced from the vesicles. MAO inhibition particularly enhances the action of tyramine, because this substance is itself a substrate for MAO. Normally, dietary tyramine is destroyed by MAO in the gut wall and liver before reaching the systemic circulation. When MAO is inhibited this is prevented, and ingestion of tyramine-rich foods such as fermented cheese (e.g. ripe Brie) can then provoke a sudden and dangerous rise in blood pressure. Inhibitors of NET, such as **imipramine** (see **Table 15.6**) and **amphetamine**, which is transported slowly by NET, so acts both as a substrate of NET and as an inhibitor of noradrenaline uptake, interfere with the effects of indirectly acting sympathomimetic amines by preventing their uptake into the nerve terminals.

These drugs, especially amphetamine, have important effects on the CNS (see Chs **49** and **50**) that depend on their ability to release not only noradrenaline, but also 5-HT and dopamine from nerve terminals in the brain. An important characteristic of the effects of indirectly acting sympathomimetic amines is that marked tolerance develops. Repeated doses of amphetamine or tyramine, for example, produce progressively smaller pressor responses. This is probably caused by depletion of the releasable store of noradrenaline. Tolerance to the central effects also develops with repeated administration.

Actions

The peripheral actions of the indirectly acting sympathomimetic amines include bronchodilatation, raised arterial pressure, peripheral vasoconstriction, increased heart rate and force of myocardial contraction and inhibition of gut motility. Their central actions account for their significant abuse potential and for limited therapeutic applications (see Chs **49**, **50** and **59**). Apart from ephedrine, which is still used as a nasal decongestant because its central action is minor, these drugs are no longer used for their peripheral sympathomimetic effects.

Inhibitors of Noradrenaline Uptake

Reuptake of released noradrenaline by NET is the most important mechanism by which its action is terminated. Many drugs inhibit NET, and thereby enhance the effects of both sympathetic nerve activity and circulating noradrenaline. NET is not responsible for clearing circulating adrenaline, so these drugs do not affect responses to this amine.

The main class of drugs whose primary action is inhibition of NET are the *tricyclic antidepressants* (see **Ch. 48**), for example **imipramine**. These drugs have their major effect on the CNS but also cause tachycardia and cardiac dysrhythmias, reflecting their peripheral effect on sympathetic transmission. **Cocaine**, known mainly for its abuse liability (see Chs **49** and **50**) and local anaesthetic activity (see **Ch. 44**), enhances sympathetic transmission, causing tachycardia and increased arterial pressure (and, with chronic use, cardiomyopathy and cardiac hypertrophy). Its central effects of euphoria and excitement (see **Ch. 49**) are probably a manifestation of the same mechanism acting via dopamine and 5-HT in the brain. It strongly potentiates the actions of noradrenaline in experimental animals or in isolated tissues provided the sympathetic nerve terminals are intact.

Many drugs that act mainly on other steps in sympathetic transmission also inhibit NET to some extent, presumably because the carrier molecule has structural features in common with other noradrenaline recognition sites, such as receptors and degradative enzymes.

The EMT, which is important in clearing circulating adrenaline from the bloodstream, is not affected by most of the drugs that block NET. It is inhibited by **phenoxybenzamine**, however, and by various *corticosteroids*. This action of corticosteroids may have some relevance to their therapeutic effect in conditions such as asthma but is probably of minor importance.

The main sites of action of drugs that affect adrenergic transmission are summarised in **Fig. 15.8**.

Drugs acting on noradrenergic nerve terminals

- Drugs that inhibit noradrenaline synthesis include:
  - **α-methyltyrosine**: blocks tyrosine hydroxylase; not used clinically
  - **carbidopa**: blocks peripheral dopa decarboxylase and is used to potentiate the central action of levodopa to treat Parkinson's disease (see **Ch. 40**)
- **α-Methyldopa** gives rise to false transmitter (α-methylnoradrenaline), which is a potent α_2 agonist, thus causing powerful presynaptic inhibitory feedback in CNS and periphery. Its use as an antihypertensive agent is now limited mainly to during pregnancy.
- **Reserpine** blocks noradrenaline accumulation in vesicles by VMAT, thus depleting noradrenaline stores and blocking transmission. Effective in hypertension but may cause severe depression, so clinically obsolete.
- Noradrenergic neuron-blocking drugs (e.g. **guanethidine**, **bethanidine**) are selectively concentrated in terminals and in vesicles (by NET and VMAT respectively), and block transmitter release, partly by local anaesthetic action. Effective in hypertension but cause severe side effects (postural hypotension, diarrhoea, nasal congestion, etc.), so now little used.
- **6-Hydroxydopamine** is selectively neurotoxic for noradrenergic neurons, because it is taken up and converted

to a toxic metabolite. Used experimentally to eliminate noradrenergic neurons, not used clinically.

- Indirectly acting sympathomimetic amines (e.g. **amphetamine**, **ephedrine**, **tyramine**) are accumulated by NET and displace noradrenaline from vesicles, allowing it to escape. The effect is much enhanced by MAO inhibition, which can lead to severe hypertension following ingestion of tyramine-rich foods by patients treated with MAO inhibitors.
- Indirectly acting sympathomimetic agents are CNS stimulants. **Methylphenidate** and **atomoxetine** block NET and DAT but are not themselves transported by them so they do not displace endogenous transmitter monoamines; they are used to treat attention deficit–hyperactivity disorders (see **Ch. 49**).
- Drugs that inhibit NET include cocaine and **tricyclic antidepressant** drugs. Sympathetic effects are enhanced by such drugs.

QUESTIONS

QUESTION 15.1

Endogenous catecholamines mediate a range of physiological effects by activation of different receptor subtypes and activation of different second messenger signalling pathways.

Which of the following statements about the pharmacological effects of the endogenous catecholamines is incorrect?

OPTIONS:

A. The order of potency for the endogenous catecholamines at α receptors is noradrenaline (NA) > adrenaline > isoprenaline.

B. α_2 Receptors mainly act as presynaptic inhibitory receptors.

C. α_1 Receptors couple to adenylate cyclase.

D. β_2 Receptors are G protein–coupled receptors.

E. Agonists at I_1 receptors synergise with a_2-adrenoceptors.

QUESTION 15.2

NA is synthesised within the nerve terminals and stored in vesicles until released by neuronal activation.

Which of the following statements concerning the release and termination of noradrenergic transmission is correct?

OPTIONS:

A. Synthesis of NA involves the hydroxylation of L-dopa.

B. Dopa decarboxylase activity is rate-limiting for NA synthesis.

C. Reserpine increases the uptake of NA into vesicles.

D. Termination of the signal occurs mainly by degradation of the transmitter in the synapse.

E. Catechol-*O*-methyl transferase (COMT) enzymes are present in noradrenergic terminals to metabolise catecholamines to methoxy derivatives.

QUESTION 15.3

Activation of adrenoceptors mediates a range of physiological effects.

Which of the following is not a physiological effect of the endogenous catecholamines and directly acting sympathomimetic drugs?

OPTIONS:

A. Contraction of smooth muscle, mediated via α_1 receptors

B. Relaxation of vascular smooth muscle mediated by β_2 receptors

C. β_3 Receptor-mediated contraction of the bladder detrusor muscle

D. Increased cardiac output mediated by β_1 receptors

E. Bronchorelaxation mediated by β_2 receptors

QUESTION 15.4

Many pathological conditions are associated with an imbalance of catecholamine levels in the body. Therapeutic agents that function to modulate catecholamine release or uptake from and into nerve terminals have been proven efficacious in a range of conditions.

Which agent would reduce/suppress the effects of NA?

OPTIONS:

A. Guanethidine

B. Amphetamine

C. Imipramine

D. Cocaine

E. Monoamine oxidase (MAO) inhibitors

ANSWERS

ANSWER 15.1

RATIONALE:

A. α Receptors show a higher affinity for NA; this is the reverse of the observed potency at β receptors.

B. α_2 Receptors are predominantly neuronal and act to inhibit transmitter release.

C.

D. All noradrenergic receptor subtypes are G protein–coupled receptors.

E. Selective agonists at I_1 and at a_2-adrenoceptors act independently of each other to lower blood pressure but they synergise with one another when both receptors are stimulated.

CORRECT ANSWER WITH EXPLANATION:

C. α_1 Receptors couple to adenylate cyclase.

α_1 Receptors couple to phospholipase C (PLC) and cause a rise in intracellular Ca^{2+} to mediate vasoconstriction.

ANSWER 15.2

RATIONALE:

A. Synthesis of NA involves the hydroxylation of L-tyrosine.

B.

C. Reserpine blocks uptake of NA into the vesicles by the vesicular monoamine transporter (VMAT) transporter and depletes the nerve terminal of transmitter.

D. Termination of the signal is mainly by reuptake and degradation in cells/nerve terminals.

E. Monoamine oxidases (MAOs) are present in the nerve terminals. COMT is only found in the adrenal medulla and other tissues.

CORRECT ANSWER WITH EXPLANATION:

B. Dopa decarboxylase activity is rate-limiting for NA synthesis.

Conversion of dopa to dopamine, is catalysed by *dopa decarboxylase*, a relatively non-specific, cytosolic enzyme that is not

confined to catecholamine-synthesising cells. Dopa decarboxylase activity is not rate-limiting for NA synthesis.

ANSWER 15.3

RATIONALE:

A. Activation of α_1 receptors causes a rise in intracellular Ca^{2+} and contraction of smooth muscle except in the gut. Vascular smooth muscle is most affected by adrenergic stimulation.

B. β Receptor activation causes smooth muscle relaxation via an increase in cAMP and reduction in Ca^{2+}.

C.

D. β_1 Receptor activation has a positive chronotropic (increase in heart rate) and ionotropic (increase in force of contraction) effect on the heart.

E. Bronchial smooth muscle is relaxed by β_2 receptor activation.

CORRECT ANSWER WITH EXPLANATION:

C. β_3 Receptor-mediated contraction of bladder detrusor muscle

Activation of β_3 receptors causes relaxation of the bladder detrusor muscle and selective agonists are useful in the treatment of an overactive bladder.

ANSWER 15.4

RATIONALE:

A.

B. Amphetamine displaces NA in the vesicles, which can leak from the nerve terminal and act postsynaptically, enhancing NA-mediated responses.

C. Tricyclic antidepressants (TCAs), such as imipramine, inhibit the reuptake of NA by the norepinephrine transporter (NET), prolonging the duration of the NA in the synapse.

D. Cocaine acts to enhance sympathetic transmission and so potentiates the effects of NA.

E. MAO is responsible for the metabolism and degradation of NA; thus inhibitors of these enzymes would prolong NA effects.

CORRECT ANSWER WITH EXPLANATION:

A. Guanethidine

This agent inhibits the release of NA and causes depletion of the amine in the nerve terminal.

---

[1] Dale was a new recruit in the laboratories of the Wellcome pharmaceutical company, given the job of checking the potency of batches of adrenaline coming from the factory. He tested one batch at the end of a day's experimentation on a cat that he had earlier injected with an ergot preparation. Because it produced a fall in blood pressure rather than the expected rise, he advised that the whole expensive consignment should be rejected. Unknown to him, he was given the same sample to test a few days later and reported it to be normal. How he explained this to Wellcome's management is not recorded.

[2] Just how long may be appreciated by scaling up the 20 μm diameter of a neuronal cell body to that of a golf ball (~40,000 μm diameter, a scaling factor of about 2000); proportionately the axon (length from sympathetic chain ganglion to, say, a blood vessel in the calf (approximately 1 m in humans, never mind giraffes)), will

now reach about 2 km – some challenge in terms of command and control!

[3] Aldehyde metabolites are potentially neurotoxic, and are thought to play a role in certain degenerative CNS disorders (see Ch. 40).

[4] And conversely, contracting smooth muscle is often bad news. This bald statement must not be pressed too far, but the exceptions (such as nasal decongestants and drugs acting on the eye) are surprisingly few. Even adrenaline (potentially lifesaving in cardiac arrest) dilates some vessels while constricting others to less immediately essential tissues such as skin).

[5] Carvedilol is also a biased agonist, acting through the arrestin pathway (Ch. 3).

16: 5-Hydroxytryptamine and the purines

OVERVIEW

In this chapter we discuss two small molecule transmitters which have a surprisingly complex pharmacology. *5-Hydroxytryptamine* (5-HT) is a local hormone of ancient lineage, widely conserved and present in many primitive animals, even those lacking nervous systems. 5-HT played an important part in the development of pharmacology as a discipline and today it is recognised as an important neurotransmitter both in the brain and in the periphery where it fulfils many other important physiological functions. We describe its synthesis, storage and release, its role in normal physiology and the pathophysiology of disorders including carcinoid syndrome and pulmonary hypertension. We also review the pharmacology of the numerous drugs that act at a large family of 5-HT receptors.

Purines are, of course, also ancient molecules. Amongst their many roles, they comprise the building blocks of DNA or RNA as well as the phosphorylated nucleotides which play a crucial role in the energy economy of the cell. In contrast to 5-HT, however, the discovery that purine nucleosides and nucleotides function as extracellular chemical mediators is relatively recent. In this chapter we discuss the basic biology of purinergic mediators, the drugs that act through purinergic

signalling pathways and the receptors that transduce these effects.

5-Hydroxytryptamine

A biologically active, low-molecular-weight factor originally detected in the 1930s in extracts of gut ('enteramine') and in blood serum ('serotonin') was eventually identified chemically in 1949 as *5-hydroxytryptamine* (5-HT) (**Fig. 16.1**). Today, the terms *5-HT* and *serotonin* are used interchangeably. 5-HT was subsequently found in the central nervous system (CNS) and shown to function both as a neurotransmitter and as a local hormone in the peripheral vascular system. This chapter deals with the metabolism, distribution and physiological roles of 5-HT in the periphery, and with the different types of 5-HT receptor and the drugs that act on them. Further information on the role of 5-HT in the brain, its relationship to psychiatric disorders and the actions of psychotropic drugs is presented in **Chapters 39**, **45**, **47** and **48**. The use of drugs that modulate 5-HT in the gut is dealt with in **Chapter 30**.

Distribution, Biosynthesis and Degradation

The highest concentrations of 5-HT in the body are found in three organs:

- *In the wall of the intestine.* Over 90% of the total amount in the body is present in the *enterochromaffin* cells (endocrine cells with distinctive staining properties) in the gut. These cells are derived from the neural crest and resemble those of the adrenal medulla. They are found mainly in the stomach

and small intestine interspersed with mucosal cells. Some 5-HT also occurs in nerve cells of the myenteric plexus, where it functions as an excitatory neurotransmitter.

- *In blood*. Platelets contain high concentrations of 5-HT. They accumulate it from the plasma by an active transport system and release it from cytoplasmic granules when they aggregate (hence the high concentration of 5-HT in serum from clotted blood; see **Ch. 23**).
- *In the CNS*. 5-HT is a transmitter in the CNS and is present in in most brain areas with its neuronal cell bodies localised to regions of the midbrain (see **Ch. 39**).

Although 5-HT is present in the diet, most of this is metabolised before entering the bloodstream. Endogenous 5-HT arises from a biosynthetic pathway similar to that of noradrenaline (see **Ch. 15**), except that the precursor amino acid is *tryptophan* instead of tyrosine. Tryptophan is converted to 5-hydroxytryptophan in chromaffin cells and neurons by the action of *tryptophan hydroxylase*, an enzyme confined to 5-HT-producing cells (but not present in platelets). The 5-hydroxytryptophan is then decarboxylated to 5-HT by the ubiquitous *L-aromatic acid decarboxylase*, which also participates in the synthesis of catecholamines and histamine (see **Ch. 17**).

Platelets (and neurons) possess a high-affinity 5-HT uptake mechanism. Platelets become loaded with 5-HT as they pass through the intestinal circulation, where the local concentration is relatively high. Because the mechanisms of synthesis, storage, release and reuptake of 5-HT are very similar to those of noradrenaline, many drugs affect both processes indiscriminately

(see **Ch. 15**). However, *selective serotonin reuptake inhibitors* (SSRIs) have been developed and are important therapeutically as anxiolytics and antidepressants (see Chs **45** and **48**). 5-HT is often stored in neurons and chromaffin cells as a co-transmitter, acting together with various peptide hormones, such as *somatostatin*, *substance P* or *vasoactive intestinal polypeptide* (see **Ch. 17**).

Degradation of 5-HT occurs mainly through oxidative deamination, catalysed by *monoamine oxidase A*, followed by oxidation to *5-hydroxyindoleacetic acid* (5-HIAA), the pathway again being the same as that of noradrenaline catabolism. 5-HIAA is excreted in the urine and serves as an indicator of 5-HT production in the body. This is used, for example, in the diagnosis of carcinoid syndrome (see later).

FIG. 16.1 Biosynthesis and metabolism of 5-hydroxytryptamine.

Distribution, biosynthesis and degradation of 5-hydroxytryptamine(5-HT)

- Tissues rich in 5-HT are:
  - gastrointestinal tract (chromaffin cells and enteric neurons)
  - platelets
  - CNS.
- Metabolism closely parallels that of noradrenaline.
  - 5-HT is formed from dietary tryptophan, which is converted to 5-hydroxytryptophan by tryptophan hydroxylase, then to 5-HT by a non-specific decarboxylase.
- 5-HT is transported into cells by a specific SERT.
  - Degradation occurs mainly by monoamine oxidase, forming 5-HIAA, which is excreted in urine.

Actions and functions of 5-hydroxytryptamine (5-HT)

- Important actions are:

  - increased gastrointestinal motility (direct excitation of smooth muscle and indirect action via enteric neurons)
  - contraction of other smooth muscle (bronchi, uterus)
  - mixture of vascular constriction (direct and via sympathetic innervation) and dilatation (endothelium dependent)
  - platelet aggregation
  - stimulation of peripheral nociceptive nerve endings
  - excitation/inhibition of CNS neurons.
- Postulated physiological and pathophysiological roles include:
  - in periphery: peristalsis, vomiting, platelet aggregation and haemostasis, inflammation, sensitisation of nociceptors and microvascular control
  - in CNS: many postulated functions, including control of appetite, sleep, mood, hallucinations, stereotyped behaviour, pain perception and vomiting.
- Clinical conditions associated with disturbed 5-hydroxytryptamine (5-HT) include:
  - migraine, carcinoid and serotonin syndrome, pulmonary hypertension, mood disorders and anxiety.

Classification of 5-HT Receptors

It was realised long ago that the actions of 5-HT are not all mediated by receptors of the same type. Various pharmacological classifications have come and gone, and the nomenclature of these receptors has changed several times which makes for difficulties when reading some older papers. The current system is summarised

in **Table 16.1**. This classification takes into account sequence data derived from cloning, signal transduction mechanisms and pharmacological specificity as well as the phenotypes of 5-HT receptor 'knock-out' mice.

Their diversity is astonishing. Currently, there are some 14 known receptor subtypes (together with an extra gene in mouse). These are divided into seven classes (5-$HT_{1–7}$), one of which (5-HT_3) is a ligand-gated cation channel while the remainder are G protein–coupled receptors (GPCRs; see **Ch. 3**). The six GPCR families are further subdivided into some 13 receptor subtypes based on their sequence and pharmacology. Most subtypes are found in all species so far examined, but there are some exceptions (the 5-HT_{5B} gene is found in mouse but has not been found in humans). The sequences of 5-HT_1 and 5-HT_2 receptors are highly conserved among species, but the 5-$HT_{4–7}$ receptors are more diverse and are grouped together largely on pharmacological grounds. Most 5-HT GPCRs signal through adenylyl cyclase/cAMP, but some (the 5-HT_2 subtype) activate phospholipase C to generate phospholipid-derived second messengers (see **Ch. 3**). In addition to these main subtypes, many genetic polymorphisms have been found, giving rise to four or more variants of some of these receptors. The pharmacological and pathophysiological relevance of these genetic isoforms is often unclear.

Table 16.1

The list of agonists and antagonists is not exhaustive and many drugs shown are not used clinically or are not currently available in the United Kingdom (e.g. **tropisetron**), but are included as they are often used experimentally or referred to in the literature.

2-Me-5-HT, 2-Methyl-5-hydroxytryptamine; *5-HT,* 5-hydroxytryptamine; *8-OH-DPAT,* 8-hydroxy-2-(di-n-propylamino) tetraline; *CNS, central nervous system*; *GI,* gastrointestinal; *IA,* inverse agonist; *IP_3*, inositol trisphosphate; *LSD,* lysergic acid diethylamide; *PA,* partial agonist.

Source: **www.guidetopharmacology.org**

Genetically altered mice lacking functional members of this receptor family have been produced (see for example **Bonasera and Tecott, 2000**). The functional deficits in such animals are generally quite subtle, suggesting that these receptors may serve to modulate, rather than to enable, physiological responses. With the exception of 5-HT_3-selective agents, many 5-HT receptor agonists and antagonists are relatively non-selective with respect to different receptor subtypes. This makes their pharmacology difficult to interpret and summarise. Some of the more significant drug targets include the following.

5-HT_1 receptors

Those of pharmacological significance occur mainly in the brain, the subtypes being distinguished on the basis of their regional distribution and their pharmacological specificity. Their function is

mainly inhibitory. The 5-HT_{1A} subtype is particularly important in regulating 5-HT neuronal activity in the CNS and is found as an autoreceptor on the cell bodies of 5-HT neurons where activation leads to a reduction in neuronal firing. It is an important receptor in relation to mood and behaviour and 5-HT_1 'knock-out' mice exhibit defects in sleep regulation, learning ability and other CNS functions. Receptor polymorphisms may be associated with increased susceptibility to substance abuse. The 5-$HT_{1B/D/F}$ subtypes, which are expressed in neurons innervating cerebral blood vessels, are believed to be important in migraine and are the target for **triptans** (e.g. **sumatriptan) and the ditans** (i.e. **lasmiditan**), which together constitute an important group of drugs used to treat acute attacks (see **Ch. 42**). Unfortunately, the 5-HT_{1B} receptor is also present in the vasculature of the heart and elsewhere, explaining some of the unwanted effects associated with triptan therapy. In the CNS, 5-HT_{1B} receptors are found at the terminals of 5-HT neurons where activation inhibits further transmitter release provide a mechanism of negative feedback regulating endogenous 5-HT release. In an unfortunate instance of the pharmacological 'cancel culture', the hapless '5-HT_{1C}' receptor – actually the first to be cloned – has been officially declared non-existent, having been ignominiously reclassified as the 5-HT_{2C} receptor when it was found to be linked to inositol trisphosphate production rather than adenylyl cyclase.

5-HT_2 receptors

These are present in the CNS but are also particularly important in the periphery. The effects of 5-HT on smooth muscle and platelets,

which have been known for many years, are mediated by the 5-HT_{2A} receptor, as are some of the behavioural effects of agents such as **lysergic acid diethylamide** (LSD). 5-HT_2 receptors are linked to phospholipase C and thus stimulate inositol trisphosphate formation. The 5-HT_{2A} subtype is functionally the most important, the others having a more limited distribution and functional role. The role of 5-HT_2 receptors in normal physiology is probably a minor one, but it becomes more prominent in pathological conditions such as asthma and vascular thrombosis (see Chs **23** and **28**). Mice lacking 5-HT_2 receptors also exhibit defects in colonic motility (5-HT_{2A}), heart defects (5-HT_{2B}) and CNS disorders (5-$HT_{2A/C}$).

5-HT_3 receptors

5-HT_3 receptors are exceptional in being membrane cation channels (see **Ch. 3**) and cause excitation directly, without involvement of any secondary messenger signalling system. The receptor itself consists of a homo- or hetero-pentameric assembly of distinct subunits which are designated by further subscript letters (e.g. 5-$HT_{3A–E}$ in humans). 5-HT_3 receptors occur mainly in the peripheral nervous system, particularly on nociceptive sensory neurons (see **Ch. 42**) and on autonomic and enteric neurons, where 5-HT exerts a strong excitatory effect. 5-HT evokes pain when injected locally and, when given intravenously, elicits a fine display of autonomic reflexes resulting from excitation of many types of vascular, pulmonary and cardiac sensory nerve fibres. 5-HT_3 receptors also occur in the brain, particularly in the *area postrema,* a region of the medulla involved in the vomiting reflex, and selective 5-HT_3

antagonists are used as antiemetic drugs (see **Ch. 30**). Genetic polymorphisms in the subunits are associated with increased susceptibility to nausea and vomiting.

5-HT_4 receptors

These occur in the brain, as well as in peripheral organs such as the gastrointestinal tract, bladder and heart. Their main physiological role appears to be in the former, where they produce neuronal excitation and mediate the effect of 5-HT in stimulating peristalsis. Mice deficient in the 5-HT_4 receptor exhibit a complex phenotype including abnormal feeding behaviour in response to stress.

5-HT_5, 5-HT_6 and 5-HT_7 receptors

Less is known about these receptors. All are present in the CNS as well as other tissues. There are two genes for 5-HT_5 isoforms but only one codes for a functional receptor in humans although both may be functional in rodents. In addition to its action on 5-$HT_{1B/D}$ receptors, **sumatriptan** is also an antagonist at the 5-HT_7 receptor suggesting this receptor may also be a significant target for migraine treatment (**Agosti, 2007**). 5-$HT_{6/7}$ receptors are thought to be involved in various CNS functions, homeostatic and other effects of the transmitter.

5-Hydroxytryptamine (5-HT) receptors

- There are seven families (5-$HT_{1–7}$), with further subtypes of 5-HT_1 (A–F) and 5-HT_2 (A–C). Many polymorphisms and splice variants have also been observed.

- All are GPCRs, except 5-HT_3, which are ligand-gated cation channels.
  - 5-HT_1 receptors occur mainly in the CNS (all subtypes) and some blood vessels (5-$HT_{1B/D}$ subtypes). Some effects are mediated through inhibition of adenylyl cyclase, including neural inhibition and vasoconstriction. Specific agonists include triptans and ditans (used in migraine therapy) and **buspirone** (used in anxiety). Specific antagonists include **spiperone** and **methiothepin.**
  - 5-HT_2 receptors occur in the CNS and many peripheral sites (especially blood vessels, platelets, autonomic neurons). Neuronal and smooth muscle effects are excitatory and some blood vessels are dilated as a result of nitric oxide release from endothelial cells. 5-HT_2 receptors act through the phospholipase C/inositol trisphosphate pathway. Ligands include **LSD** (agonist in CNS, antagonist in periphery). Specific antagonists include **ketanserin.**
  - 5-HT_3 receptors occur in the peripheral nervous system, especially nociceptive afferent neurons and enteric neurons, and in the CNS. Effects are excitatory, mediated through direct receptor-coupled ion channels. **2-Methyl-5-HT** is a specific agonist. Specific antagonists include **ondansetron** and **palonosetron.** Antagonists are used mainly as antiemetic drugs but may also be anxiolytic.
  - 5-HT_4 receptors occur mainly in the enteric nervous system (also in the CNS). Effects are excitatory, through

stimulation of adenylyl cyclase, causing increased gastrointestinal motility. Specific agonists include **metoclopramide** (used to stimulate gastric emptying).

- 5-HT_5 receptors (one subtype in humans) are located in the CNS. Little is known about their role.
- 5-HT_6 receptors are located in the CNS and on leukocytes. Little is known about their role in humans.
- 5-HT_7 receptors are located in the CNS and the gastrointestinal tract. Little is known about their role in humans but emerging data show they may also be important in migraine.

Pharmacological Effects

As one might predict from the profusion of 5-HT receptor subtypes, the biological actions of 5-HT are numerous and complex and there is considerable species variation. The main sites of action in humans are as follows.

Gastrointestinal tract

Most 5-HT receptor subtypes are present in the gut with the exception of those of the $5\text{-HT}_{5/6}$ family. About 10% of 5-HT in the intestine is located in neurons, where it acts as a neurotransmitter, while the remainder is located in the enterochromaffin cells, which act as sensors to transduce information about the state of the gut, and which release 5-HT into the lamina propria. Broadly speaking, 5-HT receptors are present on most neuronal components of the enteric nervous system as well as smooth muscle, secretory and other cells. Their main function is to regulate peristalsis, intestinal

motility, secretion and visceral sensitivity; the responses observed are complex and the reader is referred to **Guzel and Mirowska-Guzel (2022)** for a more comprehensive account.

The importance of 5-HT in the gut is underlined by the widespread distribution in the enteric nervous system and the intestinal mucosa, of the *serotonin uptake transporter* (SERT) which rapidly and efficiently removes extracellular 5-HT, thus limiting its action. Inhibitors of this transporter such as the SSRIs exaggerate the action of 5-HT in the gut, explaining some of the common gastrointestinal side effects of these drugs. Interestingly, there is evidence for genetic changes in this reuptake system linked to irritable bowel syndrome, which might explain the rather bewildering symptoms of the disease.

Smooth muscle

In many species (although only to a minor extent in humans), smooth muscle outside of the gastrointestinal tract (e.g. uterus and bronchial tree) is also contracted by 5-HT.

Blood vessels

The effect of 5-HT on blood vessels depends on various factors, including the size of the vessel, the species and the prevailing sympathetic activity. Large vessels, both arteries and veins, are usually constricted by 5-HT, although the sensitivity varies greatly. This is the result of a direct action on vascular smooth muscle cells, mediated through 5-HT_{2A} receptors. 5-HT can also cause vasodilatation indirectly by releasing nitric oxide from vascular endothelial cells (see **Ch. 19**) and inhibiting noradrenaline release from sympathetic nerve terminals. Dilatation of large intracranial

vessels contributes to headache whereas activation of 5-$HT_{1B/D}$ receptors causes constriction, perhaps contributing to the antimigraine action of some of these drugs. If 5-HT is injected intravenously, the blood pressure initially rises, because of the constriction of large vessels, and then falls, owing to arteriolar dilatation. 5-HT may play a role in the pathology of *pulmonary hypertension* (see later in this chapter and **Ch. 21**).

Platelets

5-HT causes platelet aggregation (see **Ch. 23**) by acting on 5-HT_{2A} receptors, and these platelets can then release further 5-HT. If the endothelium is intact, 5-HT release from adherent platelets causes vasodilatation, which helps to sustain blood flow; if it is damaged however (e.g. by atherosclerosis), 5-HT causes constriction and impairs blood flow further. These effects of platelet-derived 5-HT are thought to be important in vascular disease.

Nerve endings

5-HT stimulates nociceptive (pain-mediating) sensory nerve endings, an effect mediated mainly by 5-HT_3 receptors. If injected into the skin, 5-HT causes pain; when given systemically, it elicits a variety of autonomic reflexes through stimulation of afferent fibres in the heart and lungs, which further complicate interpretation of the cardiovascular response. In some species, mast cells release 5-HT when stimulated and nettle stings contain 5-HT among other mediators. 5-HT also inhibits transmitter release from adrenergic neurons in the periphery.

Central nervous system

5-HT is an important neurotransmitter in the CNS and several important antipsychotic and antidepressant drugs act on these pathways by interfering with its disposition or action. **LSD** is a relatively non-selective 5-HT receptor agonist/partial agonist, which acts centrally as a potent hallucinogen. However, its actions are complex: 5-HT excites some neurons and inhibits others; it also acts presynaptically to inhibit transmitter release from nerve terminals and this might underlie some of the actions of serotonergic drugs in migraine. Different receptor subtypes mediate these effects.

Drugs Acting at 5-HT Receptors

Table 16.1 lists some significant agonists and antagonists at the different receptor types. Many are only partly selective. Our increasing understanding of the location and function of the different receptor subtypes has raised the possibility of developing compounds with improved receptor selectivity.

Important drugs that act on 5-HT receptors in the periphery include the following:

- Although not clinically useful, selective 5-HT_{1A} agonists, such as 8-hydroxy-2-(di-*n*-propylamino) **tetralin** (8-OH-DPAT), are potent hypotensive agents, acting through a central mechanism. They are useful experimental drugs.
- 5-$HT1_{B/D}$ receptor agonists (e.g. the triptans) are used for treating migraine.
- 5-$HT1_{F}$ receptor agonists such as **lasmiditan** (e.g. the ditans) are also useful for treating migraine.
- 5-HT_2 receptor antagonists (e.g. **methysergide**, **ketanserin**) act mainly on 5-HT_{2A} receptors but may also

block other 5-HT receptors, as well as α-adrenoceptors and histamine receptors (see **Ch. 17**). **Ergotamine** and **methysergide** belong to the 'ergot family' (see later) and have historically been used mainly for migraine prophylaxis (although rarely used these days). Other 5-HT_2 antagonists are used to control the symptoms of carcinoid tumours.

- 5-HT_3 receptor antagonists (e.g. **granisetron**, **ondansetron**, **palonosetron**) are used as antiemetic drugs (see Chs **30** and **57**), particularly for controlling the severe nausea and vomiting that occur with many forms of cancer chemotherapy.
- 5-HT_4 receptor agonists that stimulate coordinated peristaltic activity (known as a 'prokinetic action') could be used for treating gastrointestinal disorders. **Metoclopramide** acts in this way, as well as by blocking dopamine receptors. Similar but more selective drugs such as **cisapride** and **tegaserod** were introduced to treat irritable bowel syndrome but were later withdrawn because of adverse cardiovascular side effects.

Ergot Alkaloids

Whilst largely of historical interest today, ergot alkaloids have preoccupied pharmacologists for more than a century. As a group, they stubbornly resist classification. Many act on 5-HT receptors, but not selectively, so that their effects are complex and diverse.

Ergot, an extract of the fungus *Claviceps purpurea* that infests cereal crops, contains many active substances, and it was the study of their pharmacological properties in the early years of the 20th

century that led Dale to many important discoveries concerning acetylcholine, histamine and catecholamines. Epidemics of ergot poisoning have occurred, and still occur, when contaminated grain is used for food. The symptoms include mental disturbances and intensely painful peripheral vasoconstriction leading to gangrene [1] .

Chemically, ergot alkaloids are complex molecules derived from lysergic acid. The important members of the group include various naturally occurring and synthetic derivatives with different substituent groups arranged around a common nucleus; these include including **ergotamine**, **dihydroergotamine**, **ergometrine** as well as related compounds such as **bromocriptine** and **methysergide**. These compounds display diverse pharmacological actions, and it is difficult to discern any clear relationship between chemical structure and pharmacological properties.

Actions

Most of the effects of ergot alkaloids appear to be mediated through adrenoceptors, 5-HT or dopamine receptors, although some may be produced through other mechanisms. All alkaloids stimulate smooth muscle, some being relatively selective for vascular smooth muscle while others act mainly on the uterus. **Ergotamine** and **dihydroergotamine** are, respectively, a partial agonist and an antagonist at α-adrenoceptors. **Bromocriptine** is an agonist of dopamine receptors, particularly in the CNS, and **methysergide** is primarily an antagonist at 5-HT_{2A} receptors.

The clinical use of ergot agents has diminished as more selective and safer drugs have been introduced but nevertheless, they remain

important tools for pharmacologists. As one would expect of agents having so many actions, their physiological effects are complex and often rather poorly understood. **Ergotamine**, **dihydroergotamine** and **methysergide** are discussed here; further information on **ergometrine** and **bromocriptine** is given in **Chapters 33**, **35** and **40**.

Vascular effects

When injected into an anaesthetised animal, **ergotamine** activates α-adrenoceptors, causing vasoconstriction and a sustained rise in blood pressure. At the same time, **ergotamine's** partial agonism means it reverses the pressor effect of **adrenaline** (epinephrine; see **Ch. 15**). The vasoconstrictor effect of **ergotamine** is responsible for the peripheral gangrene of St Anthony's fire, and probably also for some of the effects of ergot on the CNS. **Methysergide** and **dihydroergotamine** have much less vasoconstrictor effect. **Methysergide** is a potent 5-HT_{2A} receptor antagonist, whereas **ergotamine** and **dihydroergotamine** antagonise 5-HT_1 receptors, which may account for their antimigraine activity.

Clinical use

The only use of **ergotamine** is in the treatment of attacks of migraine unresponsive to simple analgesics (see **Ch. 42**). **Methysergide** was formerly used for migraine prophylaxis, and for treating the symptoms of carcinoid tumours, but is seldom used today. All these drugs can be used orally or by injection.

Unwanted effects

Ergotamine often causes nausea and vomiting, and it must be avoided in patients with peripheral vascular disease because of its vasoconstrictor action. **Methysergide** also causes nausea and vomiting, but its most serious side effect, which considerably restricts its clinical usefulness, is *retroperitoneal* and *mediastinal fibrosis*, which impairs the functioning of the gastrointestinal tract, kidneys, heart and lungs. The mechanism of this is unknown, but it is noteworthy that similar fibrotic reactions also occur in carcinoid syndrome, in which there is a high circulating level of 5-HT which may also contribute to the pathogenesis of pulmonary hypertension.

Ergot alkaloids

- These active substances are produced by a fungus that infects cereal crops and are responsible for occasional poisoning incidents. The most important compounds are:
  - **ergotamine**, formerly used in migraine prophylaxis, and **dihydroergotamine**
  - **ergometrine**, originally used in obstetrics to prevent postpartum haemorrhage
  - **methysergide**, formerly used to treat carcinoid syndrome, and migraine prophylaxis
  - **bromocriptine**, used in parkinsonism and endocrine disorders.
- The main sites of action are 5-HT receptors, dopamine receptors and adrenoceptors (mixed agonist, antagonist and partial agonist effects).

- Unwanted effects include nausea and vomiting, vasoconstriction (ergot alkaloids are contraindicated in patients with peripheral vascular disease).

Clinical Conditions in Which 5-HT Plays a Role

The use of 5-HT_3 antagonists for treating drug-induced emesis is discussed in **Chapter 30**. Modulation of 5-HT-mediated transmission in the CNS is an important mechanism of action of antidepressant and antipsychotic drugs, although the role of 5-HT in the pathophysiology of these disorders is unclear (see Chs **39**, **45**, **47** and **48**). The role of 5-HT in migraine is dealt with in **Chapter 42** and in this section, we discuss two other situations where the peripheral actions of 5-HT are believed to be important, and which are not covered elsewhere, namely *serotonin and carcinoid syndrome* and *pulmonary hypertension*.

Serotonin and Carcinoid Syndrome

Serotonin syndrome is a rare drug-induced side effect (see also **Ch. 58**). It is usually provoked by the administration of SSRIs particularly if there is concurrent treatment with another serotonergic agent. Fever is a common symptom; others include cardiovascular effects such as tachycardia and hypertension, neuromuscular symptoms including tremor and rigidity and mental symptoms such as confusion, agitation and anxiety (**Werneke et al., 2020**).

The condition seems to be increasing in frequency possibly because of the increasing number of prescriptions for monoamine oxidase inhibitors or SSRIs for depression and associated conditions, although some 'street drugs' such as *novel psychoactive substances* (NPSs), which sometimes include serotonergic agents, may provoke the condition (**Schifano et al., 2021**) as can some antiepileptic drugs (**Prakash et al., 2021**). Treatment is initiated by discontinuing the SSRI or, in some cases, administration of anti-serotonergic agents such as **cyproheptadine.** Fatalities are rare but possible if the condition is not treated.

Carcinoid syndrome is also caused by an excess of 5-HT, but in this case, a rare neuroendocrine disorder is the culprit. It manifests when malignant tumours of enterochromaffin cells, which usually arise in the small intestine and metastasise to the liver. These tumours secrete a variety of vasoactive chemical mediators: 5-HT is the most important, but neuropeptides such as substance P, and other agents such as histamine, prostaglandins and bradykinin (see **Ch. 17**), are also produced.

A *carcinoid crisis* occurs in only about 5% of such cases following a sudden release of these substances into the bloodstream. Sometimes this is caused by physical manipulation of the tumour or, if it is in the GI tract, when the metabolic capability of liver is overwhelmed, and these mediators enter into the systemic bloodstream. The end result is the appearance of several unpleasant symptoms, including flushing, abdominal cramps, diarrhoea, bronchoconstriction and hypotension, which may cause dizziness or fainting. More insidiously, cognitive impairment may develop and sometimes fibrotic stenosis of heart valves, leading to cardiac

failure. It is reminiscent of the retroperitoneal and mediastinal fibrosis seen with **methysergide** and some other serotonergic agents and appears to be related to overproduction of 5-HT acting through 5-HT_{2B} receptors to drive the proliferation of connective tissue (**Mota et al., 2016**).

Clinical diagnosis can be confirmed by measuring the urinary excretion of the main metabolite of 5-HT, 5-HIAA. This may increase by as much as 20-fold when the disease is active and is raised even when the tumour is asymptomatic. 5-HT_2 antagonists, and the mixed 5-HT/histamine antagonist **cyproheptadine**, are effective in controlling some of the symptoms of carcinoid syndrome, but a more useful drug is **octreotide** (a long-acting agonist at somatostatin receptors), which suppresses hormone secretion from neuroendocrine, including carcinoid, cells (see **Ch. 33**) or **telotristat**, a tryptophan hydroxylase inhibitor. The condition and its treatment have been reviewed recently by **Gade et al. (2020)**.

Pulmonary Hypertension

Pulmonary hypertension (see also **Ch. 21**) is an incurable disease characterised by the progressive remodelling of the pulmonary vascular tree leading to a stiffening and narrowing. This leads to an inexorable rise in pulmonary arterial pressure which, if untreated (and this is difficult), inevitably leads to right heart failure and death.

There are several types of pulmonary hypertension, and in the 1990s the role of 5-HT was suggested by the fact that at least one form of the condition was precipitated by appetite suppressants (e.g.

dexfenfluramine and **fenfluramine** and others) that were at one time widely prescribed as 'weight loss' or 'slimming' aids (and maybe are still produced by some unscrupulous manufacturers). These drugs block SERT and increase 5-HT which, acting through the $5HT_{1B}$ receptor, stimulates the growth and proliferation of pulmonary arterial smooth muscle cells and also produces a net vasoconstrictor effect in this vascular bed. *Seretonylation*, the process whereby 5-HT is linked to proteins by transglutaminase enzymes, may also be involved in the chronic stimulation of this process (**Penumatsa et al., 2014**). The use of SSRI antidepressants in late pregnancy may lead to pulmonary hypertension in the newborn (**Masarwa et al., 2019**) although the overall rate is low.

Some types of pulmonary hypertension (idiopathic and familial) are more prevalent in females and sex hormones may therefore be of relevance in the pathogenesis. The interested reader is referred to **MacLean (2018)** for an accessible account of the current thinking in this area, and to **Chapter 21**, where this topic is also discussed.

More generally, the ability of 5-HT to drive connective tissue proliferation may be important in *systemic sclerosis*, an autoimmune disorder in which fibrotic tissue proliferates in many organs including the vasculature (**Sagonas and Daloussis, 2021**). Such an idea is entirely consistent with the fact that serotonergic drugs such as **methysergide** can produce similar adverse effects in connective tissue.

Purines

Nucleosides such as adenosine and nucleotides (especially ADP and ATP) will already be familiar to you because of their crucial role in DNA/RNA synthesis and energy metabolism, but it came as a surprise to the pharmacological community to learn that they also function extracellularly as signalling molecules which can produce a wide range of unrelated pharmacological effects.

The finding, in 1929, that adenosine injected into anaesthetised animals caused bradycardia, hypotension, vasodilatation and inhibition of intestinal movements foreshadowed these discoveries but the true origins of the field can really be traced to the crucial observations in 1970 by Burnstock and his colleagues, who provided first convincing evidence that ATP is a neurotransmitter (see 'Further Reading' list). After a period during which this radical idea was treated with scepticism, it has become clear that the 'purinergic' signalling system is not only of ancient evolutionary origin but participates in many physiological control mechanisms, including the regulation of coronary blood flow and myocardial function (see Chs **20** and **21**), platelet aggregation and immune responses (see Chs **17** and **23**), as well as neurotransmission in both the central and peripheral nervous system (see Chs **13** and **39**).

The full complexity of purinergic control systems, their importance in many pathophysiological mechanisms and the therapeutic relevance of the various receptor subtypes is now emerging. As a result, there is an increasing interest in purine pharmacology and the prospect of developing novel 'purinergic' drugs for the treatment of pain and a variety of other disorders, particularly of thrombotic and inflammatory origin. Here we will focus our discussion on a few prominent areas.

Purinergic Receptors

Fig. 16.2 summarises the mechanisms by which purines are stored, released and interconverted, and **Table 16.2** lists the main receptor types through which they act and summarises what is currently known about their signalling systems, their endogenous ligands and antagonists of pharmacological interest. It should be noted, however, that the action of drugs and ligands at purinergic receptors can be confusing. In part, this is because nucleotides are rapidly degraded by ecto-enzymes and there is also evidence of interconversion of species by phosphate exchange. ATP released from cells may be rapidly dephosphorylated by tissue-specific nucleotidases, producing ADP and adenosine, both of which may produce further receptor-mediated effects. Thus, ATP may produce effects at all purinergic receptor subclasses depending upon the extent of its enzymatic conversion to ADP, AMP and adenosine. The role of intracellular ATP as a regulator of membrane potassium channels that control vascular smooth muscle (see **Ch. 21**) and insulin secretion (see **Ch. 31**) is quite distinct from these effects.

The subtypes in each family of purinergic receptors are distinguished on the basis of their molecular structure as well as their agonist and antagonist selectivity. The P2Y group is particularly problematic: several receptors have been cloned on the basis of homology with other family members, but their ligands have yet to be identified (in other words they are ‘orphan receptors’). In addition, since some members of this group also recognise pyrimidines such as UTP and UDP as well as purines, they are sometimes classed as pyrimidinoceptors.

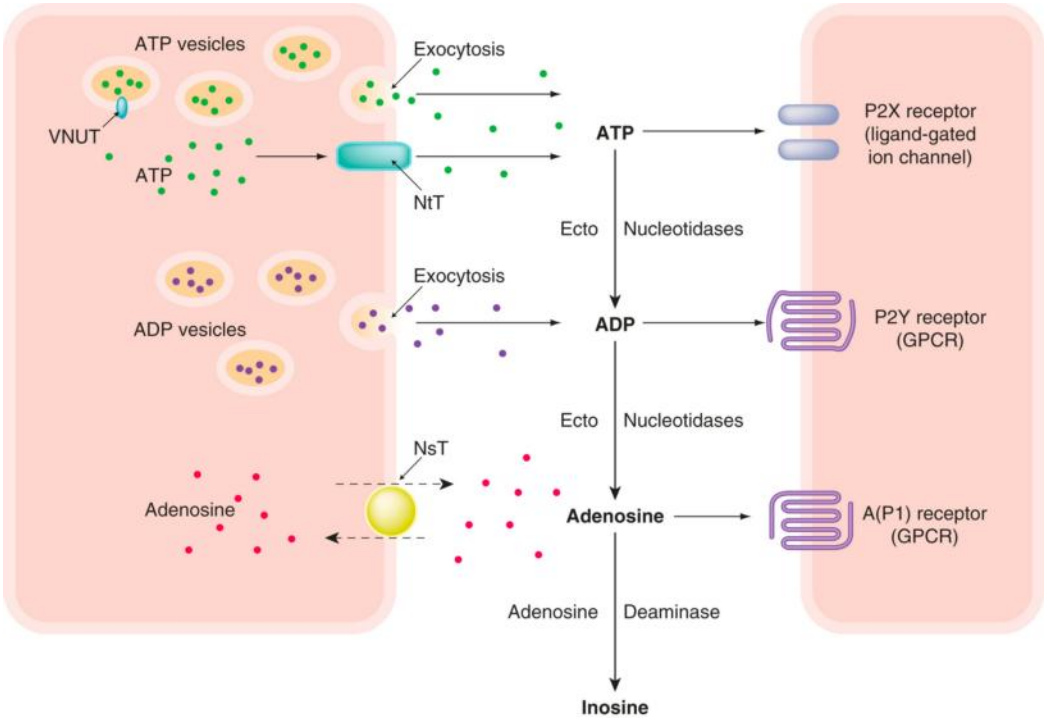

FIG. 16.2 Purines as mediators. ATP (and, in platelets, ADP) is present in the cytosol of cells (and released following cellular damage) or concentrated into vesicles by the vesicular nucleotide transporter (VNUT). Nucleotides may be released by exocytosis or through membrane channels such as pannexins (Pnx) or transporters (NtT). Once released, ATP can be converted to ADP and to adenosine by the action of ectonucleotidases. Adenosine is present in the cytosol of all cells and is released and taken up via a specific membrane transporter(s) (NsT), which is blocked by dipyridamole. Adenosine itself can be hydrolysed to inosine by the enzyme adenosine deaminase. ATP acts directly upon the P2X receptors (ligand-gated ion channels) but

also upon P2Y receptors (G protein–coupled receptors [GPCRs]), the principal target for ADP. Adenosine itself acts on A receptors (also called P1 receptors), which are also GPCRs. **Chapter 4** contains more details of exocytotic and other secretory mechanisms.

Table 16.2

A, Agonist*; An,* antagonist; *PA,* partial agonist.

Source: **www.guidetopharmacology.org**

The three main families of purine receptor are:

- *Adenosine receptors* (A_1, A_{2A}, A_{2B} and A_3), formerly known as P1 receptors before the agonist was discovered to be adenosine. These are GPCRs that act through adenylyl cyclase/cAMP, or by direct effects on Ca^{2+} and K^+ channels, as described in **Chapter 3**.
- The simplest of the purines, adenosine, is found in biological fluids throughout the body. It exists free in the cytosol of all cells and is transported in by active transport from, and out to the interstitial fluid mainly by membrane transporters (of which there are several types). Little is known about the way in which this is controlled, but the extracellular concentrations are usually quite low compared with intracellular levels. Adenosine in extracellular fluid comes partly from this intracellular source and partly from

hydrolysis of released ATP or ADP by nucleotidases such as CD39 and CD73. Adenosine can be inactivated by *adenosine deaminase*, yielding *inosine*, providing yet another level of control of this biologically active molecule, and another potential drug target. Virtually all cells express one or more of these adenosine receptors and so adenosine produces many pharmacological effects, both in the periphery and in the CNS.

- *P2Y metabotropic receptors* ($P2Y_{1–14}$). ADP is usually stored in vesicles in cells and released by exocytosis (see **Ch. 4**). It exerts its direct biological effects predominantly through the P2Y family of receptors. These are GPCRs that utilise either phospholipase C activation or cAMP as their signalling system (see **Ch. 3**); they respond to various adenosine nucleotides, generally preferring ATP over ADP or AMP. Some also recognise pyrimidines such as UTP.
- *P2X ionotropic receptors* ($P2X_{1–7}$), which are trimeric (in many cases heterotrimeric) ATP-gated cation channels. ATP is present in all cells in millimolar concentrations and is released if the cells are damaged (e.g. by ischaemia). The mechanism of release can be through exocytosis of vesicles containing ATP, through ATP transporters or through *pannexin* or *connexin* channels in the cell membrane. While some other actions of ATP in mammals are mediated through the P2Y receptors, it primarily exerts its action through P2X receptors. The extracellular domain of these trimeric receptors can bind three molecules of ATP. When activated by binding of two or three ATP molecules, the

channels become permeable to Ca^{2+} and Na^{+} ions, activating Ca^{2+}-sensitive pathways and causing membrane depolarisation. **Suramin** (a drug originally developed to treat trypanosome infections) antagonises ATP and has broad-spectrum inhibitory activity at both P2X and P2Y receptors.

The Purinergic System in Health and Disease

It is now clear that the purinergic system plays an important role in the regulation of normal physiology as well as in several pathological states (**Khakh and North, 2006**) and we will now turn our attention to some prominent aspects of purinergic pharmacology. Adenosine, ADP and ATP are all implicated but because of the facile interconversion of purinergic species, their effects are often far from straightforward and can be difficult to understand (**Chen et al., 2013**). The purinergic literature has burgeoned in recent years and space does not permit us a comprehensive review. Instead, we will concentrate upon a few key areas.

Purines as mediators

- *Adenosine* acts through A_1, A_{2A}, A_{2B} and A_3 G protein receptors, coupled to inhibition or stimulation of adenylyl cyclase. Adenosine receptors are blocked by methylxanthines such as **caffeine** and **theophylline. Dipyridamole** blocks adenosine uptake.

  - *Adenosine* affects many cells and tissues, including smooth muscle and nerve cells. It is not a conventional transmitter but may be important as a local hormone and 'homeostatic modulator'.
  - Important sites of action include the heart and the lung. Adenosine is very short-acting and is sometimes used for its antidysrhythmic effect.
- *ADP* acts through the $P2Y_{1-14}$ 'metabotropic' G protein–receptor family. These are coupled to cAMP or PLCβ.
  - Important sites of action include platelets where ADP released from granules promotes aggregation by acting on the PY_{12} receptor. This is antagonised by the drugs **clopidogrel**, **prasugrel, ticagrelor** and **cangrelor.**
- *ATP* is stored in vesicles and released by exocytosis or through membrane channels when cells are damaged. It also functions as an intracellular mediator, inhibiting the opening of membrane potassium channels.
  - ATP acts on P2X receptors: these are ligand-gated ion channels. It can also act on P2Y receptors.
  - **Clodronate** blocks **ATP** release from cells and **suramin** blocks ATP actions at most receptors.
  - Important sites of ATP action include the CNS, peripheral and central pathways and inflammatory cells.
  - When released, ATP is rapidly converted to ADP and adenosine yielding products that may act on other purinergic receptors.

The Cardiovascular System

Adenosine itself has a well-established role within the cardiovascular system and it is likely that all four of the adenosine receptors are involved in these effects. It inhibits cardiac pacemaker activity and atrioventricular node conduction and may be given as an intravenous bolus injection to terminate supraventricular tachycardia (see **Ch. 20**). Because of its short duration of action (it is destroyed or taken up within a few seconds of intravenous administration) it is considered safer than alternatives such as β-adrenoceptor antagonists or **verapamil**. The selective A_{2A} agonist **regadenoson** produces a powerful vasodilator effect and is used for diagnostic tests of cardiac function, while **dipyridamole** (a vasodilator and antiplatelet drug: see **Ch. 23**) blocks adenosine uptake by cells, thus effectively increasing its extracellular concentration.

Based on its ability to minimise the metabolic requirements of cells, another of adenosine's cardiovascular functions may be to act as an 'acute' defensive agent to produce vasodilation and cardioprotective effects being released immediately when tissue integrity is threatened by tissue hypoxia, ischaemia, inflammatory or other pathological changes (**Guieu et al., 2020**; **Reiss et al., 2019**). Under less extreme conditions, variations in adenosine release can control local blood flow and (through effects on the carotid bodies) tissue respiration, matching their metabolic requirements. The differential action of adenosine at A_{2A} and A_{2B} receptors in different vascular beds (**Cooper et al., 2022**) probably confers some regional specificity on the actions of this purine. Adenosine also regulates cholesterol trafficking through an

action on its A_{2A} receptor, providing a defence against vascular damage associated with the development of plaque (**Reiss et al., 2019**).

Asthma and Inflammation

Adenosine receptors are found on all the cell types involved in asthma and inflammation (see **Ch. 28**). Their overall pharmacology is, however, complex (**Pasquini et al., 2021**): in asthma for example, activation of the A_{2A} subtype exerts a largely protective and anti-inflammatory effect, but when acting through its A_1 or A_{2B} receptor, adenosine promotes mediator release from mast cells, which causes enhanced mucus secretion, bronchoconstriction and leukocyte activation so an antagonist of the A_1 and A_{2B} receptor or an agonist of the A_{2A} receptor could represent a significant advance in this therapeutic area (see **Brown et al., 2008**; **Burnstock et al., 2012**). The role of the A_3 receptor has yet to be fully elucidated.

Methylxanthines, especially analogues of **theophylline** (see **Ch. 28**), are adenosine receptor antagonists and this drug is used for the treatment of asthma. Part of its beneficial activity may therefore be ascribed to its antagonism of the A_1 receptor, although methylxanthines also increase cAMP by inhibiting phosphodiesterase, and this effect also underwrites some of their pharmacological actions independently of adenosine receptor antagonism. Certain derivatives of **theophylline** are claimed to show greater selectivity for adenosine receptors over phosphodiesterase.

In contrast to the predominately anti-inflammatory effect of adenosine in airway inflammation, ATP has a pro-inflammatory role in both asthma and rheumatoid arthritis. ATP is released from stimulated, damaged or dying cells and P2X receptors are widely distributed on cells of the immune system; P2Y receptors less so. Acting through these receptors, ATP can regulate neutrophil and phagocyte chemotaxis. Activation of P2X7 (and possibly P2Y receptors) provokes the release from macrophages and mast cells of cytokines which promote local inflammatory responses in chronic inflammatory disorders (**da Silva et al., 2019**; **Faas et al., 2017**; **Hechler and Gachet, 2015**). Congruent with this idea is the observation that when the $P2X_7$ receptor is deleted genetically in mice they show a reduced capacity to develop chronic inflammation. Purinergic signalling also plays an important role in T-cell signalling. In asthma, adenosine, acting through its A_{2A} receptor, regulates the balance of immune cells such as to promote a less inflammatory phenotype (**Junger, 2011**; **Wang et al., 2018**). The subsequent hydrolysis of ATP to adenosine could therefore provide a counterbalancing anti-inflammatory input, by promoting resolution when the ongoing inflammation has achieved its purpose (**Antonioli et al., 2022**).

Inflammation is usually accompanied by pain and purines may also play a key role in nociception. ATP causes pain when injected (for example) subdermally, by activating $P2X_2$ and/or $P2X_3$ heteromeric receptors on afferent neurons involved in the transduction of nociception. The pain can be blocked by **aspirin** (see **Ch. 25**) suggesting the involvement of prostaglandins and also by a bisphosphonate inhibitor of ATP release (**clodronate**: see **Ch.**

36). There is thus considerable interest in the potential role of purinergic receptor antagonists (mainly at P2Y and P2X receptors) to treat (see **Ch. 42**) neuropathic and inflammatory pain (**Kato et al., 2017**).

Adenosine also regulates the inflammatory response elsewhere and A receptors at various locations in the eye (particularly A_{2A} receptors) have been identified as potential targets in ocular diseases, including dry eye syndrome (**Guzman-Aranguez et al., 2014**). Experimental A_3 antagonists have been observed to produce a beneficial effect in experimental models of colitis and may be useful in other inflammatory disorders, including rheumatoid arthritis and psoriasis (**Shakya et al., 2019**). Interestingly, **sulfasalazine** and **methotrexate**, which are used to treat inflammatory bowel disease (see **Ch. 30**), and which have other anti-inflammatory properties, stimulate the hydrolysis of ATP and AMP by ectonucleotidases to produce adenosine thereby increasing its effective local concentration and thus its actions.

Platelets

The secretory vesicles of blood platelets store both ATP and ADP in high concentrations and release them when the platelets are activated (see **Ch. 23**). One of the many effects of ADP is to promote platelet aggregation, so this system provides positive feedback and provides an important mechanism for amplifying this process. The receptor involved is $P2Y_{12}$ although the $P2Y_1$ receptor may also play a part in the overall regulation of platelet reactivity.

Exploitation of this finding has provided the best examples to date of the value of purinergic drugs. **Ticlopidine** (no longer used

in UK) was the original drug of this type. This is an antagonist at platelet $P2Y_{12}$ receptors which inhibits the aggregation response. This was succeeded by **clopidogrel** and **prasugrel** (prodrugs), **cangrelor** and **ticagrelor** (allosteric antagonists). They are used, often in conjunction with aspirin, for preventing arterial thromboembolic disorders (see **Ch. 23** and **Laine et al., 2016**) and provide superior protection to either of the agents when used individually.

Purines as Neurotransmitters

The idea that such workaday metabolites as adenosine or ATP might be a member of the neurotransmitter elite was resisted for a long time but is now firmly established. ATP is contained in synaptic vesicles of both adrenergic, cholinergic and motor neurons and acts as a primary transmitter and as a co-transmitter. $P2X_2$, $P2X_4$ and $P2X_6$ are the predominant receptor subtypes expressed in neurons whereas $P2X_1$ predominates in smooth muscle.

Burnstock and his colleagues demonstrated that ATP is released on nerve stimulation in a Ca^{2+}-dependent fashion, and that exogenous ATP, in general, mimics the effects of nerve stimulation in various preparations, accounting for many of the actions produced by stimulation of nerves that are not caused by acetylcholine or noradrenaline (see **Ch. 13**) such as the relaxation of intestinal smooth muscle evoked by sympathetic stimulation and contraction of the bladder produced by parasympathetic nerves. ATP may function as a conventional ‘fast’ transmitter in autonomic ganglia and possibly the CNS, or as an inhibitory presynaptic

transmitter and so the overall effect of ATP is sometimes difficult to assess.

Adenosine, produced following hydrolysis of ATP, exerts presynaptic inhibitory effects on the release of excitatory transmitters in the CNS and periphery but it is likely that this effect is only really manifest under conditions of pathological rather than physiological situations (**Ziganshin et al., 2020**).

Summary

Despite the rather prosaic chemical nature of 5-HT and purines they have turned out to have a surprisingly complex pharmacology. 5-HT in particular utilises a quite extraordinary range of different receptors to produce its pharmacological effects whilst the mutable nature of the purines, enjoying as they do such facile interconversion, has ensured that interpretation of their pharmacology is anything but straightforward.

Notwithstanding these hinderances, huge progress in researching and developing these areas over the years has resulted in very tangible therapeutic rewards – and no doubt will continue to do so. Watch this space.

QUESTIONS

QUESTION 16.1

5-Hydroxytryptamine (5-HT) is an important neurotransmitter and hormone that regulates a variety of physiological functions in the body.

Which of the following statements about 5-HT biosynthesis, distribution and metabolism is incorrect?

OPTIONS:

A. The synthesis of 5-HT involves the decarboxylation of 5-hydroxytryptophan by L-aromatic acid decarboxylase.

B. Platelets synthesise high concentrations of 5-HT which is stored in granules and released on aggregation.

C. The main storage site for 5-HT is in the enterochromaffin cells of the intestine.

D. In the CNS, the 5-HT neuronal cell bodies are localised to regions of the midbrain.

E. Degradation of 5-HT is catalysed by monoamine oxidase A.

QUESTION 16.2

Nucleosides and nucleotides (especially ADP and ATP) play a crucial role in DNA/RNA synthesis and energy metabolism but they also function extracellularly as signalling molecules which can produce a wide range of unrelated pharmacological effects.

Which of the following statements about the signalling functions of ATP, ADP and adenosine is incorrect?

OPTIONS:

A. Adenosine regulates cholesterol trafficking through an action on its A_{2A} receptor.

B. P_2X receptors are ATP-gated cation channels.

C. Binding of adenosine to A_{2A} subtype exerts a largely protective and anti-inflammatory effect.

D. ADP is usually stored in vesicles in cells and when released it promotes platelet aggregation through activation of P_2X receptors.

E. ATP, when injected, enhances nociception through the activation of P_2X receptors.

ANSWERS

ANSWER 16.1

RATIONALE:

A. Tryptophan is converted to 5-hydroxytryptophan in chromaffin cells and neurons by the action of tryptophan hydroxylase, an enzyme confined to 5-HT-producing cells. The 5-hydroxytryptophan is then decarboxylated to 5-HT by the ubiquitous L-aromatic acid decarboxylase, which also participates in the synthesis of catecholamines and histamine.

B.

C. Over 90% of the total amount of 5-HT in the body is present in the enterochromaffin cells (endocrine cells with distinctive staining properties) in the gut.

D. 5-HT is a transmitter in the central nervous system (CNS) and is present in most brain areas with its neuronal cell bodies localised to regions of the midbrain.

E. Degradation of 5-HT occurs mainly through oxidative deamination, catalysed by monoamine oxidase A, followed by oxidation to 5-hydroxyindoleacetic acid (5-HIAA), the pathway again being the same as that of noradrenaline catabolism.

CORRECT ANSWER WITH EXPLANATION:

B. Platelets synthesise high concentrations of 5-HT which is stored in granules and released on aggregation.

Platelets take up pre-synthesised 5-HT but do not synthesise it in situ as they lack the tryptophan hydroxylase enzyme.

ANSWER 16.2

RATIONALE:

A. This provides a defence against vascular damage associated with the development of plaques.

B. When activated by binding of two or three ATP molecules, the channels become permeable to Ca^{2+} and Na^{+} ions, activating Ca^{2+}-sensitive pathways and causing membrane depolarisation.

C. In asthma for example, activation of the A_{2A} subtype exerts a largely protective and anti-inflammatory effect, but when acting through its A_1 or A_{2B} receptor, adenosine promotes mediator release from mast cells, which causes enhanced mucus secretion, bronchoconstriction and leukocyte activation.

D.

E. When injected subdermally, ATP activates $P2X_2$ and/or $P2X_3$ receptors on afferent neurons involved in the transduction of nociception. The pain can be blocked by **aspirin** suggesting the involvement of prostaglandins. There is thus considerable interest in the potential role of purinergic receptor antagonists to treat neuropathic and inflammatory pain.

CORRECT ANSWER WITH EXPLANATION:

D. ADP is usually stored in vesicles in cells, and when released it promotes platelet aggregation through activation of P_2X receptors.

The receptor involved is $P2Y_{12}$ although the $P2Y_1$ receptor may also play a part in the overall regulation of platelet reactivity.

[1] This came to be known in the Middle Ages as *St Anthony's fire*, because it was believed that it could be cured by a visit to the Shrine of St Anthony (which conveniently happened to be in an ergot-free region of France).

17: Local hormones: histamine, lipids, peptides and proteins

OVERVIEW

When we discussed the function of cellular players in host defence in **Chapter 7** we alluded to the crucial role of soluble chemical regulators of inflammation. In this chapter we take a closer look at these substances. We begin with some small molecule mediators: histamine and the biologically active lipids. While having a physiological role, these are also pressed into service by host defence mechanisms when necessary and are therefore important targets for anti-inflammatory drug action. These are followed by peptide and protein mediators, which are orders of magnitude larger in molecular terms. This constitutes a very diverse group including bradykinin, neuropeptides and cytokines (interleukins, chemokines and interferons), the latter of which seem to be exclusively concerned with host defence. We have included some general introductory observations on the nature and purpose of chemical messaging and, where possible, the synthesis, secretion and metabolism of these mediators. Finally, we conclude with a few remarks on mediators that down-regulate inflammation.

Introduction

The growth of pharmacology as a discipline was attended by the discovery of numerous biologically active substances. Many were initially uncharacterised, being described only as smooth muscle contracting (or relaxing) 'factors' which appeared in blood or tissues during particular physiological or pathological events. Eventually, these factors were identified chemically, some comparatively quickly while others resisted analysis for many years and so progress in a particular pharmacological area was often tied to advances in analytical methodology. For example, 5-hydroxytryptamine (see **Ch. 16**) and histamine, which are quite simple compounds, were identified soon after their biological properties were described. In contrast, the structural elucidation of the more complex prostaglandins, which were first discovered in the 1930s, had to await the development of the gas chromatograph–mass spectrometer (GC-MS) some 30 years later before the field could really progress.

Peptide and protein structures took even longer to solve. Substance P (11 amino acids) was also discovered in the 1930s but was not characterised until 1970 when peptide sequencing techniques had been developed. The advent of molecular biology in the 1980s greatly enhanced our analytical proficiency; for example, the 21–amino acid peptide, endothelin, was discovered and fully characterised, with the sequences of the gene and peptide published within about a year and the complete information published in a single paper (**Yanagisawa et al., 1988**). Techniques including high-performance liquid chromatography, solid-phase peptide synthesis and, more recently, the use of recombinant proteins as

therapeutic agents (see **Ch. 5**) have driven development in this area. Separately, the availability of monoclonal antibodies for radioimmunoassay and immunocytochemistry has solved many quantitative problems. Transgenic animals with peptide or receptor genes deleted, overexpressed or mutated provide valuable clues about their functions, as has the use of antisense oligonucleotides, siRNA and gene editing (CRISPR-Cas9) technologies (see also **Ch. 5**) to silence these genes for experimental purposes. The control of precursor synthesis can now be studied indirectly by measuring mRNA at single cell resolution. The technique of *in situ hybridisation*, for example, enables the location and abundance of the mRNA to be mapped at microscopic resolution.

In summary, the molecular landscape has changed completely. Whereas the discovery of new 'small-molecule' mediators has slowed, the discovery of new protein and peptide mediators has ballooned. More than 100 cytokines have been discovered since interleukin 2 (IL-2) was first characterised in 1982 and on-going advances in analytical techniques continue to drive the discovery and identification of not only new individual signalling molecules but also whole classes of chemical mediators. Alongside the advent of cheap and readily available computing power, such techniques have additionally permitted the large-scale, integrated study of these small molecules at a systems level: the fields of proteomics, lipidomics and (more broadly) metabolomics.

What is a 'Mediator'?

Like regular hormones, such as thyroxine (see **Ch. 34**) or insulin (see **Ch. 31**), a *local hormone* is simply a chemical messenger that

conveys information from one cell to another. [1] Hormones such as thyroxine and insulin are released from a single endocrine gland, circulate in the blood and produce their action on other 'target' tissues. In contrast, local hormones are usually produced by cells to operate within their immediate microenvironment. The distinction is not actually completely clear-cut, however. For example, one of the 'classical' hormones, hydrocortisone, is normally released by the adrenal gland but, surprisingly, can also be produced by, and act locally upon, some other tissues such as the skin. Conversely, some cytokines, which are usually regarded as local hormones, can circulate in the blood and produce systemic actions as well.

When a local hormone is released in response to a stimulus of some kind, and produces a particular biological effect (such as contraction of smooth muscle in response to allergen challenge), it is said to be a *mediator* of this response. Traditionally, a putative mediator [2] had to satisfy certain criteria before gaining official recognition. In the 1930s, Sir Henry Dale proposed a set of five rules to validate the credentials of mediators and these guidelines have been used as a point of reference ever since. Originally formulated as a test for putative neurotransmitters, these criteria cannot easily be applied to mediators of other responses and have thus been modified on several occasions.

Currently, the experimental criteria that establish a substance as a mediator are:

- that it should be released from local cells in sufficient amounts to produce a biological action on the target cells within an appropriate time frame;

- that application of an authentic sample of the mediator should reproduce the original biological effect;
- that interference with the synthesis, release or action (e.g. using receptor antagonists, enzyme inhibitors, 'knock-down' or 'knock-out' techniques) ablates or modulates the original biological response.

We now continue this chapter with a discussion of some prominent substances which have satisfied these stringent criteria and which are generally recognised to be important local hormones with well-defined biological properties.

Histamine

In a classic study, Dale and his colleagues demonstrated that a local anaphylactic reaction (a type I or 'immediate hypersensitivity reaction' such as the response to egg albumin in a previously sensitised animal; see **Ch. 7**) was caused by antigen–antibody reactions in sensitised tissue and found that histamine mimicked this effect both in vitro and in vivo. Later studies confirmed that histamine is present in tissues and released (along with other mediators) during anaphylaxis.

Synthesis and Storage of Histamine

Histamine is a basic amine synthesised by the enzyme *histidine decarboxylase* which decarboxylates the amino acid histidine (**Fig. 17.1**). Histamine is widespread in the body but is present in particularly high concentrations in tissues in contact with the outside world (lungs, skin and gastrointestinal tract). At the cellular

level, it is found largely in mast cells (approximately 0.1–0.2 pmol/cell) and basophils (0.01 pmol/cell), but non-mast cell histamine also occurs in enterochromaffin-like cells (ECLs) in the stomach and in histaminergic neurons in the brain (see **Ch. 39**). In mast cells and basophils, histamine is complexed in intracellular granules with an acidic protein and a high-molecular-weight heparin termed *macroheparin*.

Histamine Release

Histamine is released from mast cells during inflammatory or allergic reactions by exocytosis. Stimuli include complement components C3a and C5a (see **Ch. 7**), which interact with specific surface receptors, and the combination of antigen with cell-fixed immunoglobulin (Ig) E antibodies. In common with many secretory processes (see **Ch. 4**), histamine release is initiated by a rise in cytosolic [Ca^{2+}]. Various basic drugs, such as **morphine** and **tubocurarine**, release histamine, as does *compound 48/80*, an experimental tool often used to investigate mast cell biology. Agents that increase cAMP formation (e.g. β-adrenoceptor agonists; see **Ch. 15**) inhibit histamine secretion. Replenishment of secreted histamine by mast cells or basophils is a slow process, which may take days or weeks, whereas turnover of histamine in the gastric ECL is very rapid. Histamine is metabolised by diamine oxidase and/or by the methylating enzyme histamine *N*-methyltransferase (**Fig. 17.1**).

Histamine Receptors

Four types of histamine receptor, termed $H_{1–4}$, have been identified. All are G protein–coupled receptors (GPCRs) but their downstream signalling systems differ. H_1 and H_3 receptors, for example, elevate cAMP, whereas H_2 and H_4 receptors stimulate phospholipase C (PLC). Splice variants of H_3 and H_4 receptors have been reported. All four are implicated in the inflammatory response in some capacity and good accounts have been given by **Jutel et al. (2009)**, with **Thangam et al. (2018)** focusing on how we may further translate recent insights for therapeutic benefit.

Selective antagonists of H_1, H_2 and H_3 receptors include **cetirizine**, **cimetidine** and **pitolisant**, respectively. Selective agonists for H_2 and H_3 receptors are, respectively, **dimaprit** and **(R)-methylhistamine**. Histamine H_1 antagonists are the principal antihistamines used in the treatment or prevention of inflammation (notably allergic inflammation such as hay fever). Other clinical uses of subtype antagonists may be found elsewhere in this book (e.g. Chs **25**, **26**, **27**, **30** and **45**). The pharmacology of H_4 receptors is less well developed but the evidence so far strongly suggests that the receptor also has a significant role in the inflammatory response, with eosinophils being a prominent target. **Panula et al. (2015)** have compiled a comprehensive review of histamine receptors and their pharmacology.

Histamine Actions

Smooth muscle effects. Histamine, acting on H_1 receptors, contracts the smooth muscle of the ileum, bronchi, bronchioles and uterus. The effect on the ileum is not as marked in humans as it is in the guinea pig (this tissue remains the de facto standard

preparation for histamine bioassay). Histamine reduces air flow in the first phase of bronchial asthma (see **Ch. 28**) but H_1 antagonists are not of much benefit in the human disease. It is possible that H_4 receptors are more important (**Thurmond, 2015**) in mediating these resistant histamine effects in man.

Cardiovascular effects. Histamine dilates human blood vessels and increases permeability of postcapillary venules, by an action on H_1 receptors, the effect being partly endothelium dependent in some vascular beds. It also increases the rate and the output of the heart mainly by an action on cardiac H_2 receptors. It seems that this mediator is involved mainly in regulation of cardiovascular system in pathological, rather than physiological, states. **Hattori et al. (2017)** have reviewed the area in detail.

Gastric secretion. Histamine stimulates the secretion of gastric acid by action on H_2 receptors. In clinical terms, this is the most important action of histamine, because it is implicated in the pathogenesis of peptic ulcer. It is considered in detail in **Chapter 30**.

FIG. 17.1 The synthesis and metabolism of histamine.Histamine is synthesised by histidine decarboxylase, which removes the carboxyl group from histidine. Histamine can be metabolised to inactive products by several enzymes, including diamine oxidase (histaminase), and/or by the methylating enzyme histamine *N*-methyltransferase. *AldDH*, Aldehyde dehydrogenase.

Sleep/wake homeostasis. Histamine plays a key role in regulation of the sleep/wake cycle with H_1, H_2 and H_3 receptors being differentially expressed throughout the brain. Clinically, this is relevant as antagonism/inverse agonism of the H_3 receptor can be used to treat narcolepsy, a rare disorder characterised by excessive daytime sleepiness. It also explains why first-generation antihistamines (e.g. **chlorphenamine**) which can cross the blood–brain barrier are associated with drowsiness (H_1 receptors promoting wakefulness). For further information see **Scammell et al. (2019)** and **Chapter 45**.

Effects on skin. When injected intradermally, histamine causes a reddening of the skin, accompanied by a weal with a surrounding flare. This mimics the *triple response* to scratching of the skin, first described by Sir Thomas Lewis over 80 years ago. The reddening reflects vasodilatation of the small arterioles and precapillary sphincters and the weal, the increased permeability of the postcapillary venules. These effects are mainly mediated through activation of H_1 receptors. The flare is an *axon reflex*: stimulation of sensory nerve fibres evokes antidromic impulses through

neighbouring branches of the same nerve, releasing vasodilators such as *calcitonin gene-related peptide* (CGRP). Histamine causes intense itch if injected into the skin or applied to a blister base, because it stimulates sensory nerve endings through an H_1-dependent mechanism. H_1 antagonists are used to control itch caused by allergic reactions, insect bites, etc.

Even though histamine release is manifestly capable of reproducing many of the inflammatory signs and symptoms, H_1 antagonists do not have much clinical utility in the acute inflammatory response per se, because other mediators are more important. Histamine is, however, important in type I hypersensitivity reactions such as allergic rhinitis and urticaria. Other significant actions of histamine in inflammation include effects on antigen-presenting cells, natural killer cells, epithelial cells and B and T lymphocytes, modulating both the innate and acquired immune response (**Jutel et al., 2009**; **O'Mahony et al., 2011**). The use of H_1 antagonists in these conditions is dealt with in **Chapter 25**. It is possible that the developing field of H_4 receptor pharmacology will fill in some significant gaps in our understanding of the role of histamine in inflammation in the near future (**Thurmond, 2015**).

Histamine

- Histamine is a basic amine, stored in mast cell and basophil granules, and secreted when C3a and C5a interact with specific membrane receptors or when antigen interacts with IgE fixed on cells triggering the high affinity IgE receptor.

- Histamine produces effects by acting on H_1, H_2, H_3 or H_4 receptors on target cells.
- The main actions in humans are:
  - stimulation of gastric secretion (H_2)
  - contraction of most smooth muscle, except blood vessels (H_1)
  - cardiac stimulation (H_2)
  - vasodilatation (H_1)
  - increased vascular permeability (H_1)
  - promoting waking (H_1) or sleep (H_3)
- Injected intradermally, histamine causes the 'triple response': *reddening* (local vasodilatation), *weal* (increased permeability of postcapillary venules) and *flare* (from an 'axon' reflex in sensory nerves releasing a peptide mediator).
- The main pathophysiological roles of histamine are:
  - as a stimulant of gastric acid secretion (treated with H_2-receptor antagonists)
  - as a mediator of type I hypersensitivity reactions such as urticaria and hay fever (treated with H_1-receptor antagonists)
  - as a regulator of sleep/wake behaviour (H_1-antagnoists being sedative in the CNS and H_3-inverse agonists promoting wakefulness).

Eicosanoids

General Remarks

These bioactive lipid mediators arise from two groups of 20-carbon polyunsaturated fatty acid (PUFA) precursors: (omega) ω-6 (sometimes written n-6; a denomination determined by the position of the final carbon–carbon double bond counting from the methyl end) and ω-3 (n-3) fatty acids. Mammals cannot synthesise these *essential fatty acids* (EFAs) and they (or their immediate precursors) must therefore be present in the diet to maintain health.

The term *eicosanoids* refers to a group of mediators generated from common 20-carbon fatty acids precursors. They are implicated in the control of many physiological processes, are among the most important mediators and modulators of the inflammatory reaction (Figs **17.2** and **17.3**) and are a significant target for drug action.

Interest in eicosanoids first arose in the 1930s after reports that semen contained a lipid substance, apparently originating from the prostate gland, which contracted uterine smooth muscle. Later, it became clear that *prostaglandin* (as the factor was, very reasonably, named [3]) was not a single substance but a whole family of compounds generated by virtually all cells from 20-carbon unsaturated fatty acid precursors.

With modern analytical techniques, in particular mass spectrometry–based lipidomic profiling, it has recently been possible to identify, monitor and quantify the structurally and stereochemically distinct eicosanoid and PUFA-derived species involved in both homeostasis and inflammation. These are now known to number into the hundreds, and it is manifestly clear that the ‘lipidome’ is more complex and biologically significant than previously thought. While exploration of all these PUFA moieties is

beyond the scope of this chapter, key families and their physiological, pathological and therapeutic relevance are explored. For those seeking further information, see **Han (2016)** and **Calder (2020)**.

Structure and Biosynthesis

In land-dwelling mammals, the main eicosanoid precursor is *arachidonic acid* (5,8,11,14-eicosatetraenoic acid), an omega-6, 20-carbon unsaturated fatty acid containing four unsaturated double bonds (hence the prefix *eicosa-*, referring to the 20 carbon atoms, and *tetra*-enoic, referring to the four double bonds). The principal groups of eicosanoids are prostaglandins, *thromboxanes*, *leukotrienes*, *lipoxins* and *resolvins*. The common term *prostanoids* refers to prostaglandins and thromboxanes only.

In most cell types, arachidonic acid (which exists as arachidonate in solution) is a component of phospholipids, and the intracellular concentration of the free acid is low. Eicosanoids are not stored in cells (like histamine, for example) but are synthesised and then immediately released. The initial and rate-limiting step in eicosanoid synthesis is therefore the liberation of *arachidonate*. Usually this is a one-step process catalysed by the enzyme *phospholipase A* $_2$ (PLA_2; see **Fig. 17.3**) but an alternative multi-step process involving *phospholipases C or D* in conjunction with *diacylglycerol lipase* is sometimes utilised. Several types of PLA_2 exist, but the most important is probably the highly regulated *cytosolic PLA* $_2$ ($cPLA_2$). This enzyme not only generates arachidonic acid (and thus eicosanoids) but also lysoglyceryl-phosphorylcholine

(lyso-PAF), the precursor of *platelet-activating factor* (PAF), another inflammatory mediator.

Cytosolic PLA_2 is activated by phosphorylation, and this may be triggered by signal transduction systems activated by various stimuli, such as the action of thrombin on platelets, C5a on neutrophils, bradykinin on fibroblasts and antigen–antibody reactions on mast cells. Cellular injury (caused, for instance, by ischaemia) also triggers $cPLA_2$ activation. The free arachidonic acid is metabolised separately (or sometimes jointly) by several pathways, including the following.

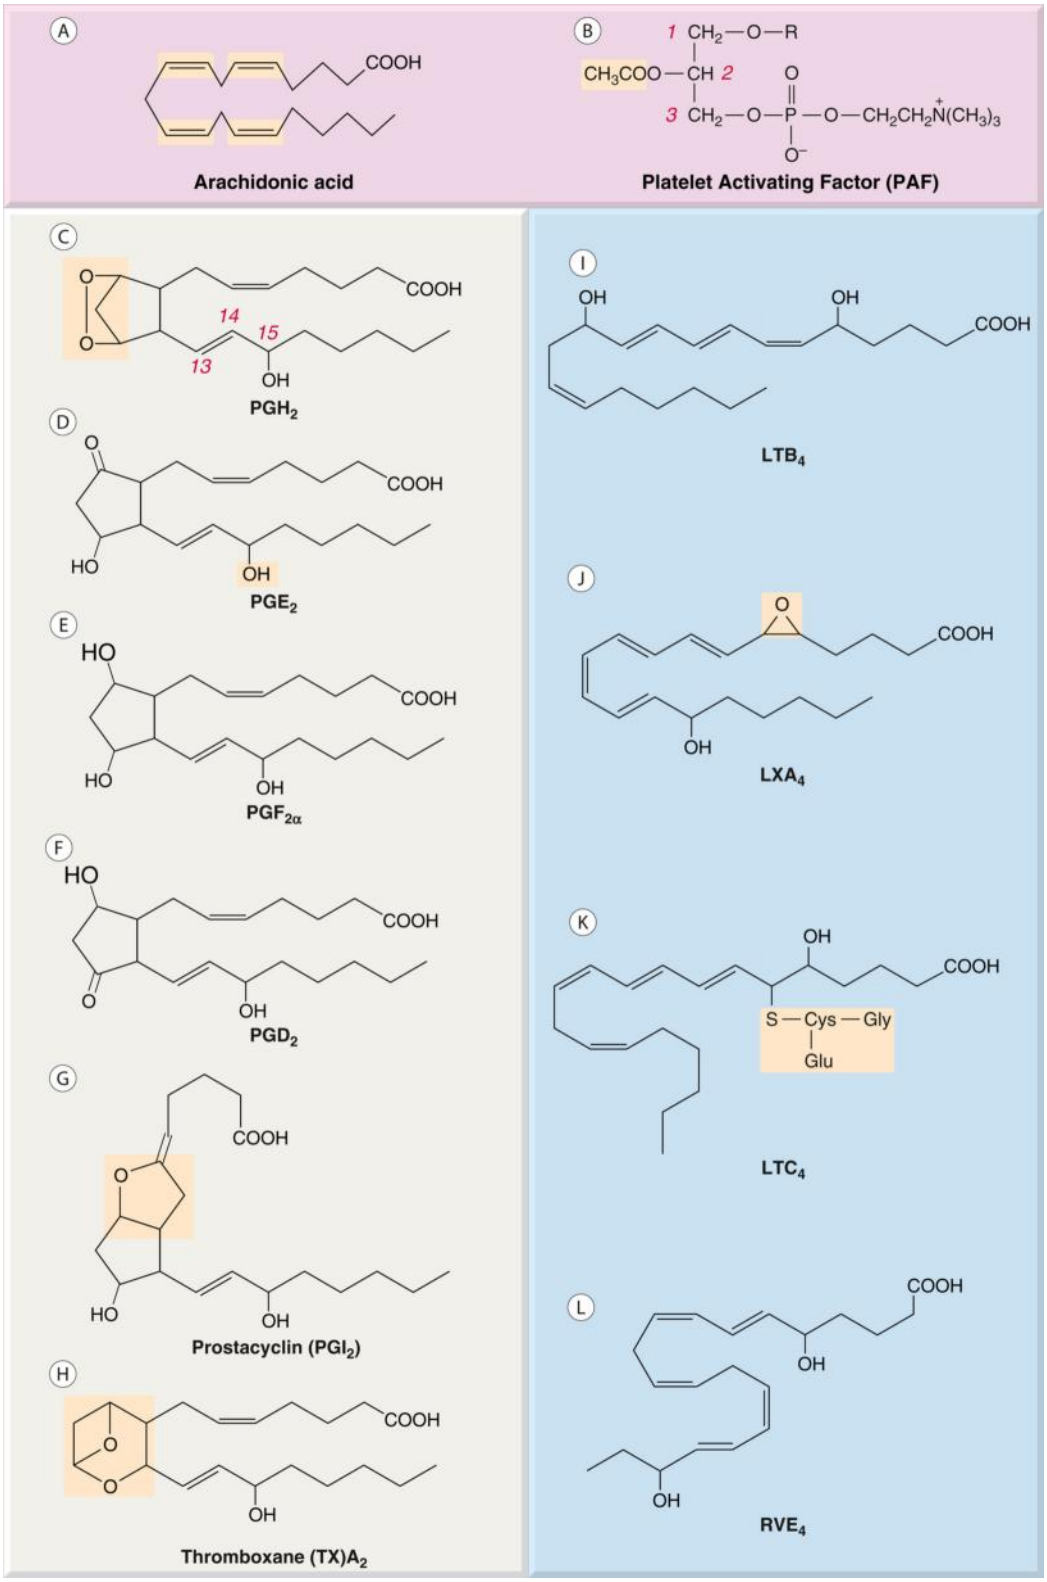

FIG. 17.2 Some key lipid mediators involved in the host defence response.(A) Arachidonic

acid, an important precursor of prostanoids, leukotrienes and (some) lipoxins and resolvins. Note the conjugated double bonds *(in shaded box)*. (B) Platelet-activating factor (PAF): the location of the acetyl group at C2 is shown in the *shaded box*. R is a 6- or 8-carbon saturated fatty acid attached by an ether linkage to the carbon backbone. (C) Prostaglandin (PG)H_2, one of the labile intermediates in the synthesis of prostaglandins; note unstable ring structure *(in shaded box)* which can spontaneously hydrolyse in biological fluids if not enzymatically changed. (D) PGE_2, the 15-hydroxyl group *(in shaded box)* is crucial for the biological activity of prostaglandins and its removal is the first step in their inactivation. (E) and (F) $PGF_{2\alpha}$ and PGD_2. (G) Prostacyclin (PGI_2); note unstable ring structure (in shaded box). (H) Thromboxane (TX)A_2; note unstable oxane structure *(in shaded box)*. (I) Leukotriene (LT)B_4. (J) Lipoxin (LX)A_4; note unstable and highly reactive oxygen bridge structure *(in shaded box)*. (K) Leukotriene (LT)C_4; note conjugated glutathione moiety *(in shaded box)*. (L) Resolvin (RV)E_4.

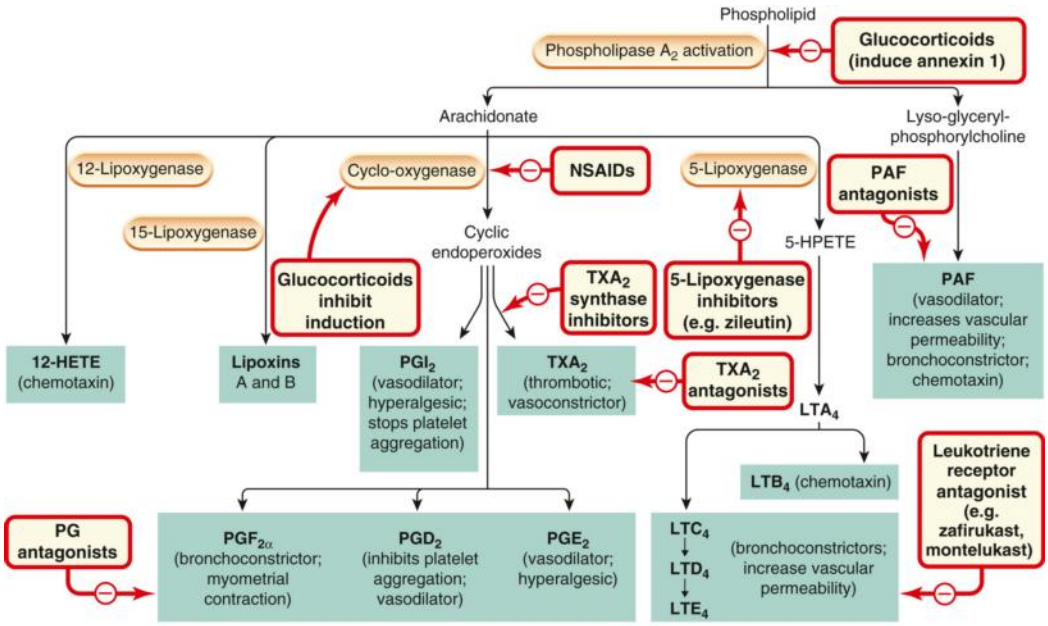

FIG. 17.3 Summary diagram of the inflammatory mediators derived from phospholipids, with an outline of their actions and the sites of action of anti-inflammatory drugs.Arachidonate metabolites are known as eicosanoids. The glucocorticoids inhibit transcription of the gene for cyclo-oxygenase (COX)-2, which is induced in cells by inflammatory mediators and induce and release annexin-A1 which down-regulates phospholipase A_2 activity, thereby limiting arachidonate release. The effects of prostaglandin (PG)E_2 depend on which of the four receptors it activates. *HETE,* Hydroxyeicosatetraenoic acid; *HPETE,* hydroperoxyeicosatetraenoic acid; *LT,* leukotriene; *NSAID,* non-steroidal anti-

inflammatory drug; *PAF,* platelet-activating factor; *PGI* $_2$ *,* prostacyclin; *TX,* thromboxane.

- *Fatty acid cyclo-oxygenase* (COX). Two main isoforms exist, COX-1 and COX-2. These are highly homologous enzymes but are regulated in different and tissue-specific ways. They enzymatically combine arachidonic (and some other unsaturated fatty acid) substrates with molecular oxygen to form *cyclic endoperoxides*, unstable intermediates which can subsequently be transformed by other enzymes to different prostanoids.
- *Lipoxygenases*. There are several subtypes, which often work sequentially, to synthesise leukotrienes, lipoxins and other compounds (Figs **17.2**–**17.4**).

Chapter 25 deals in detail with the way inhibitors of these pathways (including non-steroidal anti-inflammatory drugs (NSAIDs) and glucocorticoids) produce their anti-inflammatory effects.

Mediators derived from phospholipids

- The principal phospholipid-derived mediators are the eicosanoids (prostanoids and leukotrienes) and PAF.
- The eicosanoids are synthesised from arachidonic acid released directly from phospholipids by phospholipase A_2, or by a two-step process involving phospholipase C and diacylglycerol lipase.

- Arachidonate is metabolised by COX-1 or COX-2 to prostanoids, by 5-lipoxygenase to leukotrienes and, after further conversion, to lipoxins and other compounds.
- PAF is derived from phospholipid precursors by phospholipase A_2, giving rise to lyso-PAF, which is then acetylated to give PAF.

We will look at the different classes of these lipid mediators separately.

Prostanoids

COX-1 is present in most cells as a constitutive enzyme. It produces prostanoids that act mainly as homeostatic regulators (e.g. modulating vascular responses, regulating gastric acid secretion). COX-2 is not normally present (at least in most tissues – CNS and renal tissue are important exceptions) but it is strongly induced by inflammatory stimuli and therefore generally believed to be more relevant as a target for anti-inflammatory drugs. Both enzymes catalyse the incorporation of two molecules of oxygen into two of the unsaturated double bonds in each arachidonate molecule, forming the highly unstable endoperoxides prostaglandin (PG)G_2 and PGH_2 (see **Fig. 17.2**). The suffix '2' indicates that the product contains only two double bonds. PGG_2 and PGH_2 are rapidly transformed in a tissue-specific manner by endoperoxide *isomerase* or *synthase* enzymes to PGE_2, PGI_2 (prostacyclin), PGD_2, $PGF_{2\alpha}$ and thromboxane (TX)A_2, which are the principal bioactive end products of this reaction. The mix of eicosanoids thus produced varies between cell types and their current activation state, depending on

the particular endoperoxide isomerases or synthases present and active. In platelets, for example, TXA_2 predominates, whereas in vascular endothelium PGI_2 is the main product. Macrophages, neutrophils and mast cells synthesise a mixture of products upon stimulation. If *eicosatrienoic acid* (three double bonds) rather than arachidonic acid is the substrate for these enzymes, the resulting prostanoids have only a single double bond, for example PGE_1, while *eicosapentaenoic acid (EPA)*, which contains five double bonds, yields PGE_3. EPA, like other ω-3 PUFAs (including *docosahexaenoic acid, DHA*), is abundant in diets rich in oily fish and may, if present in sufficient amounts, represent a significant fraction of cellular fatty acids and thus constitute the major source of precursors for the COX enzyme. When this occurs, the production of the (broadly) pro-inflammatory PGE_2 and, more significantly, the generation of TXA_2 are diminished. This may partly underlie the beneficial anti-inflammatory, metabolic and cardiovascular actions that are ascribed to diets rich in this type of marine product (see also Resolvins, later, **Natto et al., 2019**, and **Khan et al., 2021**).

Another family of related compounds with a wide range of interesting biological activities has also been discovered, the *cyclopentenone prostanoids*. We do not cover these here but interested readers may refer to **Lee et al. (2021)** for a detailed account.

The endocannabinoid *anandamide* (see **Ch. 18**) is an ethanolamine derivative of arachidonic acid and, surprisingly, it can also be oxidised by COX-2 to form a range of *prostamides*. These substances are of increasing interest. They act at prostanoid

receptors but often exhibit a unique pharmacology (see **Urquhart et al., 2015**).

Catabolism of the Prostanoids

This is a multi-step process. After carrier-mediated uptake, most prostaglandins are rapidly inactivated by prostaglandin *dehydrogenase* and *reductase* enzymes. These enzymes oxidise the 15-hydroxyl group (see **Fig. 17.2**) and the 13–14 double bond, both of which are important for biological activity. The inactive products are further degraded by general fatty acid–oxidising enzymes and excreted in the urine. These dehydrogenase enzymes are present in high concentration in the lung, and 95% of infused PGE_2, PGE_1 or $PGF_{2\alpha}$ is inactivated after a single passage through the lungs, meaning that little normally reaches the arterial circulation and for this reason the half-life of most prostaglandins in the circulation is less than 1 minute.

TXA_2 and PGI_2 are slightly different. Both are inherently unstable and decay rapidly and spontaneously (within 30 s and 5 min, respectively) in biological fluids into inactive TXB_2 and 6-keto-$PGF_{1\alpha}$, respectively. Further metabolism then occurs, but this is less relevant to us here.

Prostanoid Receptors

There are five main classes of prostanoid receptor (see **Woodward et al., 2011**, and **Biringer 2021**), all of which are GPCRs (**Table 17.1**). Depending on whether their ligands are PGD, PGF, PGI, PGE or TXA species, they are termed DP, FP, IP, EP and TP receptors respectively. Some have further subtypes; for example, there are four EP receptors. Polymorphisms and other variants of these

enzymes have been implicated in the pathogenesis of various diseases (see **Cornejo-Garcia et al., 2016**).

Actions of the Prostanoids

The prostanoids can affect most tissues and exert a bewildering variety of site- and context-dependent biological effects.

- PGD_2 causes vasodilatation in many vascular beds, inhibition of platelet aggregation, relaxation of gastrointestinal and uterine muscle and modification of release of hypothalamic/pituitary hormones. It has a bronchoconstrictor effect through a secondary action on TP receptors. It may also activate chemoattractant receptors on some leukocytes.
- $PGF_{2\alpha}$ causes uterine contraction in humans (see **Ch. 35**), luteolysis in some species (e.g. cattle) and bronchoconstriction in others (e.g. cats and dogs).
- PGI_2 causes vasodilatation and inhibits platelet aggregation (see **Ch. 23**), renin release and natriuresis through effects on tubular reabsorption of Na^+.
- TXA_2 causes vasoconstriction, platelet aggregation and bronchoconstriction (more marked in guinea pig than in humans).
- PGE_2, the predominant 'inflammatory' prostanoid has the following actions:
  - *at EP_1 receptors*, it causes contraction of bronchial, gastrointestinal and uterine smooth muscle;
  - *at EP_2 receptors*, it causes bronchodilatation, vasodilatation, stimulation of intestinal fluid secretion

and relaxation of gastrointestinal smooth muscle;

- *at EP_3 receptors*, it causes contraction of intestinal smooth muscle, inhibition of gastric acid (see **Ch. 30**) with increased mucus secretion, inhibition of lipolysis, inhibition of autonomic neurotransmitter release and contraction of the pregnant human uterus (see **Ch. 35**);
- *at EP_4 receptors*, it causes similar effects to those of EP_2 stimulation (they were originally thought to be a single receptor). Vascular relaxation is one consequence of receptor activation, as is cervical 'ripening'. Some inhibitory effects of PGE_2 on leukocyte activation and function are probably mediated either through this receptor or EP_2.

Several clinically useful drugs act at prostanoid receptors.

These include the EP agonists **misoprostol** (EP_2/EP_3), that suppresses gastric acid secretion and also acts as a potent uterine stimulant, and **dinoprostone** which aids cervical ripening and can induce labour (including via the vaginal route); the FP agonists **bimatoprost**, [4] **latanoprost, tafluprost** and **travoprost** which are used for the treatment of glaucoma (see **Ch. 27**); and **iloprost** and **epoprostenol** which are IP agonists used for the treatment of pulmonary hypertension (see **Ch. 21**). Misoprostol is also used in both medical abortion and treating postpartum bleeding in women.

Clinical uses of prostanoids

- Gynaecological and obstetric (see **Ch. 35**):

  - termination of pregnancy: **gemeprost** or **misoprostol** (a metabolically stable prostaglandin [PG]E analogue)
  - induction of labour: **dinoprostone** or **misoprostol**
  - postpartum haemorrhage: **carboprost.**
- Gastrointestinal:
  - to prevent ulcers associated with NSAID use: **misoprostol** (see **Ch. 30**).
- Cardiovascular:
  - to maintain the patency of the ductus arteriosus until surgical correction of the defect in babies with certain congenital heart malformations: **alprostadil** (PGE_1);
  - to inhibit platelet aggregation (e.g. during haemodialysis): **epoprostenol** (PGI_2), especially if **heparin** is contraindicated;
  - primary pulmonary hypertension: **epoprostenol** or **treprostinil** (PGI_2) (see **Ch. 21**).
- Ophthalmic:
  - open-angle glaucoma: **latanoprost** eye drops (see **Ch. 27**).

The Role of Prostanoids in Inflammation

The inflammatory response is inevitably accompanied by the release of prostanoids. PGE_2 predominates, although PGI_2 is also important. In areas of acute inflammation, PGE_2 and PGI_2 are generated by the local tissues and blood vessels, while mast cells release mainly PGD_2. In chronic inflammation, cells of the monocyte/macrophage series also release PGE_2 and TXA_2. Together,

the prostanoids exert a sort of yin–yang effect in inflammation, stimulating some responses and decreasing others. Their effects are pleiotropic and context dependent and defy simple classification. For a more thorough coverage see **Dennis and Norris (2015)**. The most striking effects are as follows:-

- PGE_2, PGI_2 and PGD_2 are themselves powerful vasodilators but they also synergise with other inflammatory vasodilators, such as histamine and bradykinin. It is this combined dilator action on precapillary arterioles that contributes to the redness and increased blood flow in areas of acute inflammation. Prostanoids do not directly increase the permeability of the postcapillary venules but potentiate the effects on vascular leakage caused by histamine and bradykinin. Similarly, they do not themselves produce pain, but sensitise afferent C fibres (see **Ch. 42**) to the effects of bradykinin and other noxious stimuli. The anti-inflammatory and analgesic effects of NSAIDs stem largely from their ability to block these actions.
- Prostaglandins of the E series are also pyrogenic (i.e. they induce fever). High concentrations are found in cerebrospinal fluid during infection, and the increase in temperature (attributed to cytokines) is actually mediated by the release of PGE_2. NSAIDs exert antipyretic actions by inhibiting PGE_2 synthesis in the hypothalamus.
- Some prostaglandins have anti-inflammatory effects which are important during the resolution phase of inflammation. For example, PGE_2 decreases lysosomal enzyme release and the generation of toxic oxygen metabolites from

neutrophils, as well as the release of histamine from mast cells.

As in the case of all inflammatory mediators, eicosanoids possess the intrinsic potential to be harmful to the host if their synthesis or release is dysregulated. For those interested in such 'collateral damage' mechanisms see **Chapter 7** as well as articles by **Theken and FitzGerald (2021)** and **Hammock et al. (2020)** which exemplify this in the context of COVID-19.

Prostanoids

- The term *prostanoids* encompass prostaglandins and thromboxanes.
- Cyclo-oxygenases (COX) oxidise arachidonate, producing the unstable intermediates PGG_2 and PGH_2. These are enzymatically transformed to the different prostanoid species.
- There are two main COX isoforms: COX-1, a constitutive enzyme, and COX-2, which is often induced by inflammatory stimuli.
- The principal prostanoids are:
  - PGI_2 (prostacyclin), predominantly from vascular endothelium, acts on IP receptors, producing vasodilatation and inhibition of platelet aggregation.
  - Thromboxane $(TX)A_2$, predominantly from platelets, acts on TP receptors, causing platelet aggregation and vasoconstriction.

  - PGE_2 is an important mediator of inflammatory responses and also causes fever and pain.
- Other effects of PGE_2 include:
  - at EP_1 receptors: contraction of bronchial, gastrointestinal (GI) tract and uterine smooth muscle;
  - at EP_2 receptors: relaxation of bronchial, vascular and GI tract smooth muscle;
  - at EP_3 receptors: inhibition of gastric acid secretion, increased gastric mucus secretion, contraction of pregnant uterus and of gastrointestinal smooth muscle, inhibition of lipolysis and of autonomic neurotransmitter release.
  - at EP_4 receptors: similar to EP_2. May mediate some inhibitory or regulatory effects on the immune response.
- $PGF_{2\alpha}$ acts on FP receptors, found in uterine (and other) smooth muscle, and corpus luteum, producing contraction of the uterus and luteolysis (in some species).
- PGD_2 is abundant in activated mast cells. It acts on DP receptors, causing vasodilatation and inhibition of platelet aggregation.

Leukotrienes

Leukotrienes (*leuko-* because they are released by white cells, and *-trienes* because they contain a conjugated triene system of double bonds; see **Fig. 17.2**) comprise two main categories, chemoattractant (LTB_4) and cysteinyl (or *sufidopeptide*) leukotrienes (LTC_4, D_4, E_4 and F_4). Both types are synthesised from

arachidonic acid by lipoxygenases. These soluble cytosolic enzymes are mainly found in lung, platelets, mast cells and white blood cells. The principal enzyme of interest is *5-lipoxygenase*. On cell activation, this enzyme translocates to the nuclear membrane, where it associates with a crucial accessory protein, affectionately termed FLAP (Five-Lipoxygenase Activating Protein). The activated 5-lipoxygenase incorporates a hydroperoxy group at C5 in arachidonic acid to form *5-hydroperoxytetraenoic acid* (5-HPETE, see **Fig. 17.4**), which is further converted to the unstable leukotriene (LT)A_4. This may be converted enzymatically to LTB_4 or, utilising a separate pathway involving conjugation with glutathione, to the cysteinyl-containing leukotrienes LTC_4, LTD_4, LTE_4 and LTF_4. These cysteinyl leukotrienes are produced mainly by eosinophils, mast cells, basophils and macrophages. Mixtures of these substances constitute the biological activity historically ascribed to *slow-reacting substance of anaphylaxis* (SRS-A), an elusive bronchoconstrictor factor shown many years ago to be generated in guinea pig lung during anaphylaxis, and consequently predicted to be important in asthma.

LTB_4 is produced mainly by neutrophils. Lipoxins and other active products, some of which have anti-inflammatory properties, are also produced from arachidonate by this pathway.

LTB_4 is metabolised by a unique membrane-bound cytochrome P450 enzyme in neutrophils, and then further oxidised to 20-carboxy-LTB_4. LTC_4 and LTD_4 are metabolised to LTE_4, which is excreted in the urine.

Leukotriene Receptors

Leukotriene receptors are all GPCRs. They are termed *BLT* (two subtypes) if the ligand is LTB_4, and *CysLT* (two subtypes) for the cysteinyl leukotrienes (see **Table 17.1**). They are all of the G_q/G_{11} family which activate PLC signalling mechanisms, although there may be other receptors that also respond to these potent mediators. Genetic variations in the enzymes that synthesise leukotrienes or in their receptors may contribute to allergy and asthma, or to the failure of drug treatment in those disorders (**Thompson et al., 2016**). For those seeking further information, they have been the subject of recent review by **Biringer (2022)**.

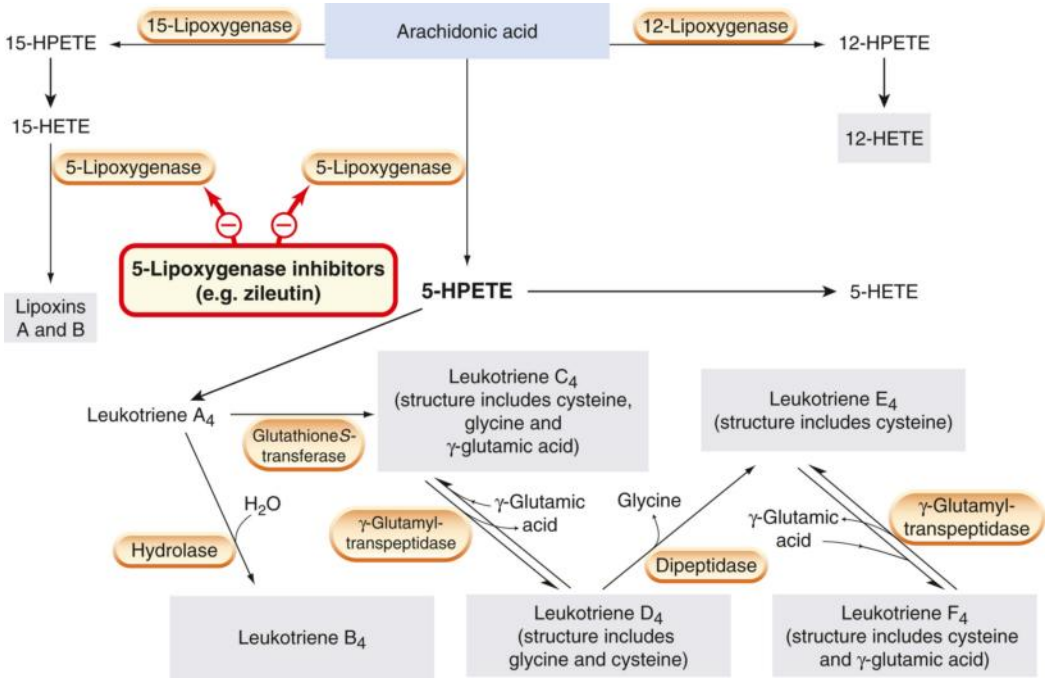

FIG. 17.4 The biosynthesis of leukotrienes from arachidonic acid.Compounds with biological action are shown in *grey boxes*. *HETE,* Hydroxyeicosatetraenoic acid; *HPETE,* hydroperoxyeicosatetraenoic acid.

Leukotriene Actions

Cysteinyl leukotrienes have important actions on the respiratory and cardiovascular systems, as well as a more general proinflammatory effect.

The respiratory system. Cysteinyl leukotrienes are potent spasmogens, causing a dose-related contraction of human bronchiolar muscle in vitro. LTE_4 is less potent than LTC_4 and LTD_4, but its effect is much longer lasting. All cause an increase in mucus secretion. Given by aerosol to human volunteers, they reduce specific airway conductance and maximum expiratory flow rate, the effect being more protracted than that produced by histamine (**Fig. 17.5**).

The cysteinyl leukotrienes are present in the sputum of chronic bronchitis patients in amounts that are biologically active. On antigen challenge, they are released from samples of human asthmatic lung in vitro, and into nasal lavage fluid in subjects with allergic rhinitis. There is evidence that they contribute to the

underlying bronchial hyper-reactivity in asthmatics, and it is thought that they are among the main mediators of both the early and late phases of asthma. **Yokomizo et al. (2018)** have reviewed the role of these mediators as therapeutic targets.

It is therefore not surprising that CysLT-receptor antagonists such as **zafirlukast** and **montelukast** are used in the treatment of asthma and allergic rhinitis, often in conjunction with a corticosteroid. Cysteinyl leukotrienes may mediate the cardiovascular changes of acute anaphylaxis. Agents that inhibit 5-lipoxygenase are therefore obvious candidates for antiasthmatic and anti-inflammatory agents. One such drug, **zileuton**, is available in some parts of the world for the treatment of asthma.

The cardiovascular system. Small amounts of LTC_4 or LTD_4 given intravenously cause a rapid, short-lived fall in blood pressure, and significant constriction of small coronary resistance vessels. Given subcutaneously, they are equipotent with histamine in causing weal and flare. Given topically in the nose, LTD_4 increases nasal blood flow and local vascular permeability.

The role of leukotrienes in inflammation. LTB_4 is a potent chemotactic agent for neutrophils and macrophages via the BLT_1 receptor (see **Ch. 7**). It up-regulates membrane adhesion molecule expression on neutrophils and increases the production of superoxide anions and the release of granule enzymes. On macrophages and lymphocytes, it stimulates proliferation and cytokine release. It is found in inflammatory exudates and tissues in many inflammatory conditions, including rheumatoid arthritis, psoriasis and ulcerative colitis. BLT_1 is additionally expressed on

vascular smooth muscle cells linking LTB_4 to atherogenesis and vascular injury.

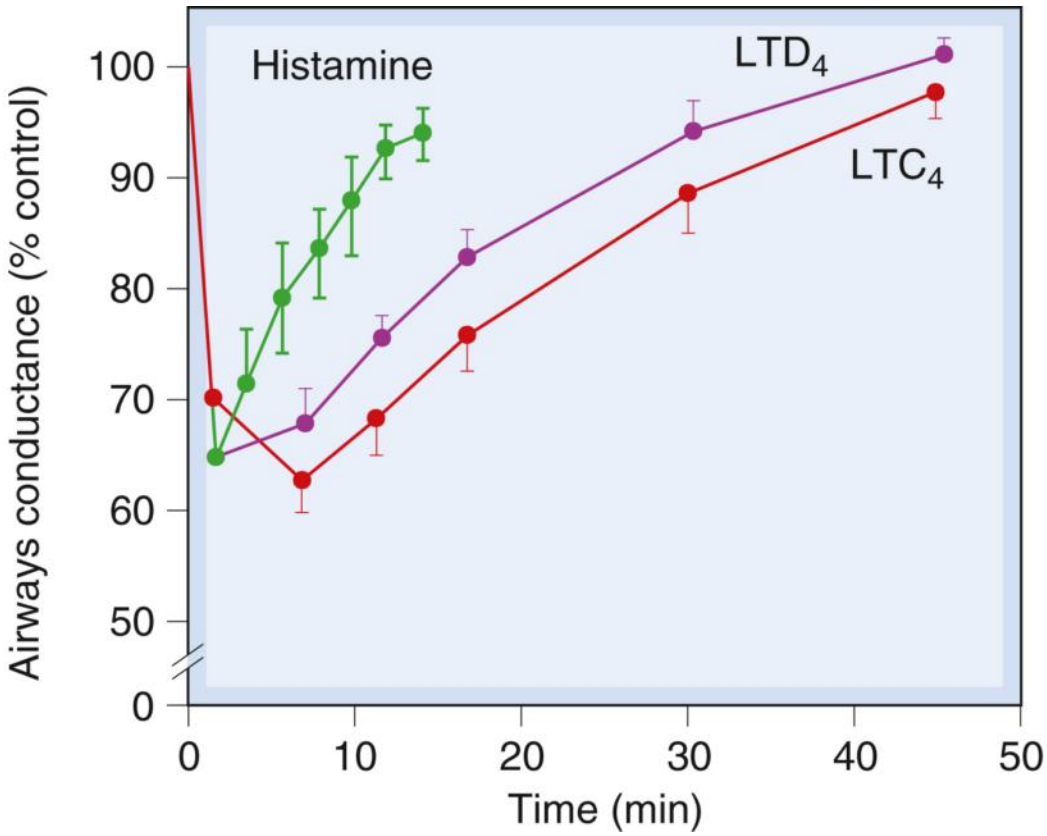

FIG. 17.5 The time course of action on specific airways conductance of the cysteinyl leukotrienes and histamine, in six normal subjects.Specific airways conductance was measured in a constant volume whole-body plethysmograph, and the drugs were given by inhalation. From Barnes, N.C., Piper, P.J., Costello, J.F., 1984. Comparative effects of inhaled leukotriene C_4, leukotriene D_4, and histamine in normal human subjects. Thorax 39, 500–504.

Leukotrienes

- 5-Lipoxygenase oxidises arachidonate to give 5-hydroperoxyeicosatetraenoic acid (5-HPETE), which is converted to leukotriene (LT)A_4. This, in turn, can be converted to either LTB_4 or to a series of glutathione adducts, the cysteinyl leukotrienes LTC_4, LTD_4 and LTE_4.
- LTB_4, acting on specific receptors, causes adherence, chemotaxis and activation of polymorphs and monocytes, and stimulates proliferation and cytokine production from macrophages and lymphocytes.
- The cysteinyl leukotrienes cause:
  - contraction of bronchial muscle
  - vasodilatation in most vessels, but coronary vasoconstriction
- LTB_4 is an important mediator in all types of inflammation; the cysteinyl leukotrienes are of importance in asthma and allergic rhinitis.

Other Important Fatty Acid Derivatives

In addition to the prostanoids and leukotrienes, PUFAs such as arachidonic acid, EPA and DHA can also be enzymatically transformed into other important lipid mediators. Trihydroxy arachidonate metabolites termed *lipoxins* (see Figs **17.2** and **17.4**) are formed by the concerted action of the 5- and the 12- or 15-lipoxygenase enzymes during inflammation. Lipoxins (abbreviation Lx) act on polymorphonuclear leukocytes, through GPCRs such as ALX, also known as *formyl peptide receptor 2* (FPR2), which is also targeted by other anti-inflammatory factors such as annexin-A1

(Anx-A1) and resolvins (see later), to oppose the action of pro-inflammatory stimuli, providing what might be called 'stop signals' to halt inflammation and promote its resolution (see **Jaen et al., 2021**). Aspirin may generate lipoxins via an alternate biosynthetic route because COX-2 can still produce hydroxy fatty acids even when inhibited by aspirin and thus unable to synthesise prostaglandins. The formation of these aspirin-triggered or 15-epi-lipoxins via acetylation probably contributes to aspirin's anti-inflammatory effects, some of which are not completely explained through inhibition of prostaglandin generation (see **Romano et al., 2015**; **Serhan et al., 2014**).

Resolvins (abbreviation Rv) represent one member of a broader family of specialised pro-resolving mediators, often referred to as SPM. As the name implies, they are a series of compounds that fulfil a similar function to lipoxins, but unlike lipoxins, their precursor fatty acid is EPA (RvE_{1-4}) or DHA acid (RvD_{1-4}). As aforementioned, fish oils are rich in these fatty acids and it is likely that at least some of their claimed multifaceted anti-inflammatory benefit is produced through conversion to these highly active species (see **Zhang and Spite, 2012**, for a review of this fascinating area). RvD_1 acts through the ALX/FPR2 and GPR32 receptor systems, whereas RvE_1 acts through a GPCR called *chemerin receptor 23 (ChemR23)* to lower cAMP and release intracellular calcium. Resolvins can counteract inflammatory pain (see **Oehler et al., 2017**) and analogues are undergoing trials for the treatment of a variety of inflammatory conditions (**Serhan and Levy, 2018**). *Maresins* (abbreviation Ma) and *protectins* are dihydroxy acids generated from DHA by the actions of

lipoxygenases. Maresins are predominately synthesised by macrophages and have a role in inflammatory resolution. Protectins (abbreviation P) are produced by lymphocytes and probably act to modulate the operation of the immune system among other functions. The area, which can be confusing until you come to terms with lipid structures, has been well reviewed by **Sansbury and Spite (2016)**, **Serhan and Levy (2018)** and **Serhan et al. (2015)**.

Platelet-Activating Factor

Platelet-activating factor (PAF), also variously termed *PAF-acether* and *AGEPC* (acetyl-glyceryl-ether-phosphorylcholine), is a biologically active lipid that can produce effects at astonishingly low concentrations (less than 10^{-10} mol/L) through its GPCR (G_q/G_{11}; stimulates cAMP production). Although accurate since the original observation was that it was released from basophils and caused platelets to aggregate, the name 'PAF' is somewhat misleading because it acts on many different target cells and, in particular, is believed to be an important mediator in both acute and chronic allergic and inflammatory phenomena.

Biosynthesis

PAF (see **Fig. 17.2**) is produced by platelets in response to thrombin, and also by activated inflammatory cells. It is enzymatically synthesised from phospholipids which have an ether-linked hexadecyl or octadecyl fatty acid at C1, an unsaturated fatty acid such as arachidonic acid ester-linked at C2 and a phosphoryl choline base at C3. The action of PLA_2 removes the arachidonic acid

yielding *lyso-PAF*, which is then acetylated by an *acetyltransferase* to yield the biologically active PAF. The reaction is reversible and PAF, in turn, can be inactivated by an *acetylhydrolase* yielding lyso-PAF ready for recycling. Of note, the PAF receptor is itself a potent stimulator for further PAF synthesis (indicating a feed-forward system) and PAF receptor agonists can be formed non-enzymatically by the action of free radicals on *glycerophosphocholines* (see **Lordan et al., 2019**).

Actions and Role in Inflammation

PAF can reproduce many of the signs and symptoms of inflammation. Injected locally, it produces vasodilatation (and thus erythema), increased vascular permeability and weal formation. Higher doses produce hyperalgesia. It is a potent chemoattractant for neutrophils and monocytes, and recruits eosinophils into the bronchial mucosa in the late phase of asthma (see **Ch. 28**). PAF also contracts both bronchial and ileal smooth muscle.

Acting predominantly in an autocrine or juxtacrine manner through its receptor, PAF activates $cPLA_2$ and stimulates arachidonate turnover in many cells. In platelets it increases TXA_2 generation, producing a shape change and the release of the granule contents. This is important in haemostasis and thrombosis (see **Ch. 23**).

Pathophysiologically, while elevated PAF concentrations are noted in multiple disease states, it seems directly responsible for none. Correspondingly, while several PAF antagonists (e.g. **lexipafant** and **modipafant**) exist they have not found a clear clinical niche. **Rupatadine** is a combined H_1 and PAF antagonist

that is available in some parts of the world for treating allergic symptoms, but it is not clear what (if anything) its anti-PAF action adds clinically to its effect. Of note, however, the anti-inflammatory actions of the glucocorticoids may be caused, at least in part, by inhibition of PAF synthesis and it may be that competitive antagonists of PAF and/or specific inhibitors of *lyso-PAF acetyltransferase* could yet become useful modulators of inflammation (**Travers et al., 2021**).

Platelet-activating factor (PAF)

- PAF precursors are released from activated inflammatory cells by phospholipase A_2. After acetylation, the resultant PAF is released and acts on specific receptors in target cells.
- Pharmacological actions include vasodilatation, increased vascular permeability, chemotaxis and activation of leukocytes (especially eosinophils), activation and aggregation of platelets, and smooth muscle contraction.
- PAF is implicated in multiple inflammatory diseases but directly responsible for none.

Sphingosine 1-Phosphate

Sphingolipids (and the related *glycosphingolipids* and *galactosphingolipids*) are a class of lipids defined by their 18-carbon amino-alcohol backbones. They play crucial roles in membrane structure and function as well as being the source of multiple bioactive metabolites (see **Gault et al., 2010**). *Sphingosine 1-*

phosphate (S1P) represents one of these, being formed by the metabolism of *sphingomyelin*.

S1P is found in high concentration in plasma (~0.75 nmol/mL), where it is 'chaperoned' by apolipoprotein M-containing high-density lipoprotein ($ApoM^+$ HDL) and albumin, and at low concentration in interstitial fluid. This gradient is crucial for its biological function. S1P acts through five specific GPCRs (S1P $receptors_{1-5}$; S1PRs) and has been implicated in multiple physiological and pathophysiological processes (see **Fig. 17.6**).

Biosynthesis and Metabolism

Sphingomyelinase initially generates *ceramide* from sphingomyelin which is further processed to *sphingosine* by *ceramidase*. The action of *sphingosine kinase (Sphk) isoenzymes* on this substrate results in the generation of S1P.

S1P is actively exported from cells by specific transporters (for instance *spinster 2* – don't ask!) which, supported by Sphk1 secretion to permit extracellular S1P synthesis, results in the aforementioned plasma-tissue gradient. Intracellular S1P concentrations are additionally regulated via the degradative *S1P phosphatases* and *S1P lyase*. *Lysophospholipid phosphatase* 3 acts on unbound extracellular SP1, converting it into sphingosine, which may then be taken up again by cells for further metabolism (**Mendelson et al., 2014**).

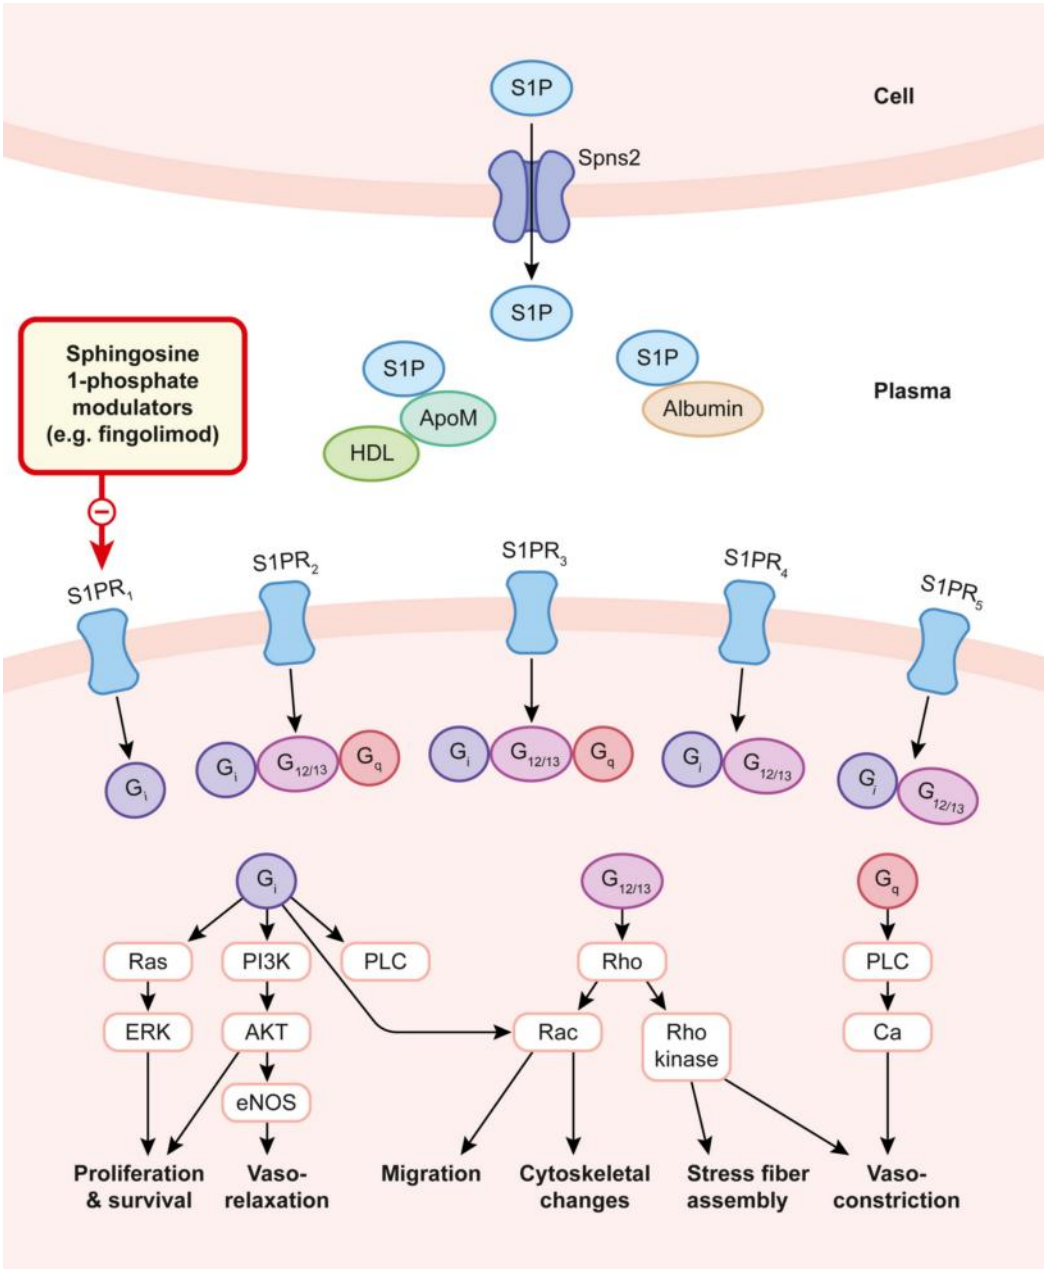

FIG. 17.6 Summary of sphingosine 1-phosphate (S1P) secretion, its cognate receptors (S1P receptors **(S1PR $_{1-5}$)**) and signalling pathways.S1P is produced intracellularly prior to export into the extracellular space via dedicated transporters (e.g. Spns2; Spinster-2) where it is bound by chaperones including albumin and

apolipoprotein M-containing high-density lipoprotein (ApoM$^+$ HDL). While acting on five separate GPCRs, S1P's binding to S1PR$_1$ and effect on chemotaxis have received the greatest attention to date. The S1PR modulators bind this receptor on lymphocytes leading to its internalisation and loss of response to the gradient that drives egress from lymph nodes. *AKT,* Protein kinase B; *eNOS,* endothelial nitric oxide synthase; *ERK,* extracellular signal-regulated kinase; *PI3K,* phosphoinositide-3-kinase; *PLC,* phospholipase C Based on Mendelson, K., Evans, T. & Hla, T. 2014. Sphingosine 1-phosphate signalling. Development. 141, 5–9.

Receptors and Actions

S1PRs are widely distributed cell-surface receptors. S1PR ($G_{i/o}$-coupled), the most studied and therapeutically important receptor, is found predominantly in the CNS, heart and vasculature, lung, kidney, liver and – significantly – primary and secondary lymphoid tissue including the thymus. S1PR$_{2–5}$ are found in many of the same tissues, but have more limited distribution. Signalling through S1PRs has been shown to play a key role in embryogenesis (notably neurogenesis and angiogenesis as well as pancreas and limb development), endothelial and blood–brain barrier function and the control of smooth muscle tone, both vascular and bronchial. It is

however their role in mediating lymphocyte cell-trafficking and activation that is, to date, their most clinically relevant function.

$S1PR_1$ signalling mediates responsiveness to the chemotactic gradient between secondary lymphoid tissues and the efferent lymphatics such that, when its function is blocked, lymphocytes (especially naïve and CCR7-expressing central memory T-cells) are sequestered in the lymph nodes. Antagonism additionally impairs B-cell trafficking, dendritic cell recruitment, vascular permeability and both mast cell and eosinophil degranulation and chemotaxis. $S1PR_{2-5}$ demonstrate overlapping but unique functions again broadly related to immune modulation and neural function.

S1PR modulators including **fingolimod**, **siponimod**, **ozanimod**, and **ponesimod** are consequently immunosuppressants that have found clinical utility in the treatment of multiple sclerosis (see **Ch. 40**). Principally exerting their action via $S1PR_1$ (but demonstrating variable selectivity for the other S1PRs which likely dictates their side effect profile), these agents are thought to exert their effect by reducing the number of circulating lymphocytes via preventing their egress from lymph nodes. They also appear to increase the proportion of T-reg (see **Ch. 7**) and naïve B cells, dampening inflammation. Secondary effects on the CNS including blood–brain barrier stabilisation, reduction in astrogliosis, axonal loss and demyelination may also contribute. S1PR modulators have additionally been trialled as immunosuppressants for the treatment of renal transplant, stroke, neuromuscular disorders, psoriasis and autoimmune disease (e.g. inflammatory bowel disease, systemic lupus erythematous), as well as in asthma (based on S1PR's effect on mast cells, eosinophils and

bronchial muscle tone). Results have been mixed and their use limited by side effects; however, several promising avenues warrant further exploration (see **McGinley and Cohen, 2021**).

Sphingosine-1 phosphate (S1P)

- S1P is a sphingolipid generated from sphingomyelin via several enzymatically catalysed steps. It is actively secreted to ensure a higher gradient in blood than in tissues, thus forming a chemotactic gradient for leukocytes.
- There are five S1P receptors (S1PR) with wide-ranging expression and both developmental and physiological roles. The actions of $S1PR_1$ include regulation of lymphocyte egress from secondary lymphatic organs, chemotaxis and activation of leukocytes (including dendritic cells and eosinophils), vascular permeability and smooth muscle tone as well as maintaining CNS integrity.
- S1PR modulators are immunosuppressants and have established clinical utility in the treatment of multiple sclerosis.

Protein and Peptide Mediators

General Principles

Structure

Peptide and protein mediators generally vary from 3 to about 200 amino acid residues in length, the arbitrary dividing line between

peptides and proteins being about 50 residues. An important difference is that proteins need to adopt a complex folded structure to exert their specific function, whereas short peptides are, in most cases, flexible. Specific residues in proteins and peptides often undergo post-translational modifications, such as *amidation*, *glycosylation*, *acetylation*, *carboxylation*, *sulfation* or *phosphorylation*.[5] They also may contain *intramolecular* disulfide bonds, such that the molecule adopts a partially cyclic conformation, or they may comprise two or more separate chains linked by *intermolecular* disulfide bonds.

Generally speaking, larger proteins adopt restricted conformations that expose functional groups in fixed locations on their surface, which interact with multiple sites on their receptors in a 'lock-and-key' mode. To envisage flexible peptides fitting into a receptor site this way is to imagine that you can unlock your front door with a length of cooked spaghetti. These features have greatly impeded the rational design of non-peptide analogues that mimic the action of proteins and peptides at their receptors (peptidomimetics). The use of random screening methods has (somewhat to the chagrin of the rationalists) nevertheless led in recent years to the discovery of many non-peptide *antagonists* – although few *agonists* – for peptide receptors.

Types of Protein and Peptide Mediator

Protein and peptide mediators that are secreted by cells and act on surface receptors of the same or other cells can be very broadly divided into four groups:

- neurotransmitters (e.g. endogenous opioid peptides, see **Ch. 42**) and neuroendocrine mediators (e.g. vasopressin, somatostatin, hypothalamic releasing hormones, adrenocorticotrophic hormone (ACTH), luteinising hormone (LH), follicle-stimulating hormone (FSH) and thyroid-stimulating hormone (TSH), see Chs **33**–**35**) (not discussed further in this chapter);
- hormones from non-neural sources: these comprise plasma-derived peptides, notably angiotensin (see **Ch. 21**) and bradykinin, as well as other hormones such as insulin (see **Ch. 31**), endothelin (see **Ch. 21**), atrial natriuretic peptide (see **Ch. 20**) and leptin (see **Ch. 32**);
- growth factors: produced by many different cells and tissues that control cell growth and differentiation (especially, in adults, in the haemopoietic system; see **Ch. 24**);
- mediators of the immune system (cytokines, see later).

Biosynthesis and Regulation of Peptides

Peptide structure is, of course, directly coded in the genome, in a manner that the structure of (say) acetylcholine is not, so intracellular manufacture is by conventional protein synthesis pathways. This often begins with the manufacture of a precursor protein in which the desired final peptide sequence is embedded. Specific proteolytic enzymes excise the mature active peptide from within this peptide sequence, a process of sculpture rather than synthesis. The precursor protein is packaged into vesicles at the point of synthesis, and the active peptide is formed in situ ready for release (**Fig. 17.7**). Thus, there is no need for specialised

biosynthetic pathways, or for the uptake or recapturing mechanisms, that are important for the synthesis and release of most non-peptide mediators (e.g. 5-hydroxytryptamine; see **Ch. 16**).

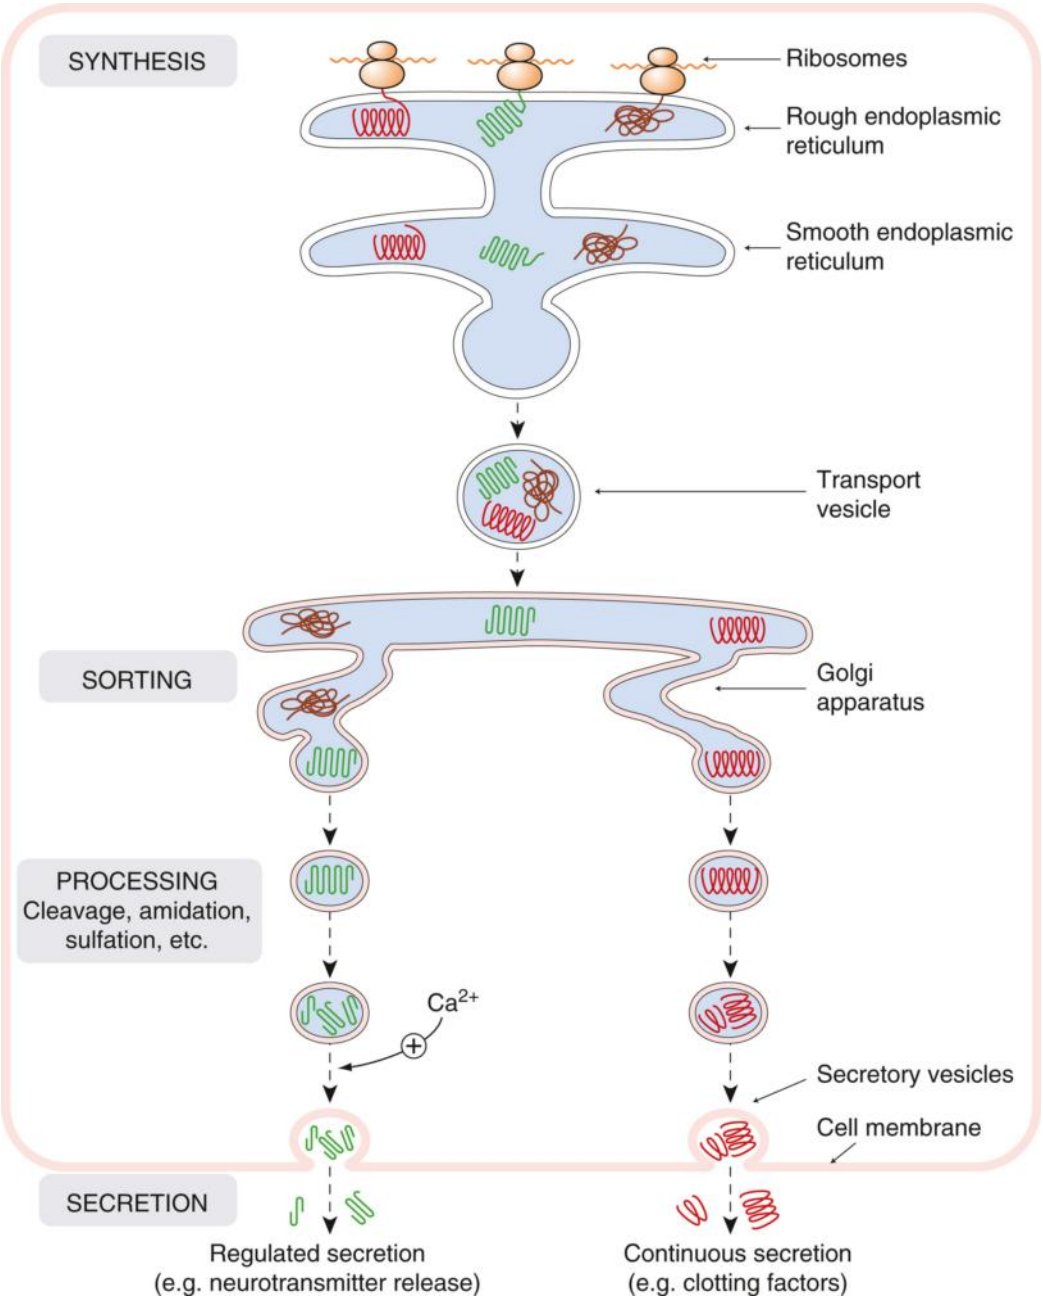

FIG. 17.7 Cellular mechanisms for peptide synthesis and release.Proteins synthesised by ribosomes are threaded through the membrane of the rough endoplasmic reticulum, from where they are conveyed in transport vesicles to the Golgi apparatus. Here, they are sorted and

packaged into secretory vesicles. Processing (cleavage, glycosylation, amidation, sulfation, etc.) occurs within the transport and secretory vesicles, and the products are released from the cell by exocytosis. Constitutive secretion (e.g. of plasma proteins and clotting factors by liver cells) occurs continuously, and little material is stored in secretory vesicles. Regulated secretion (e.g. of neuropeptides or cytokines) occurs in response to increased intracellular Ca^{2+} or other intracellular signals, and material is typically stored in significant amounts in secretory vesicles awaiting release.

Peptide Precursors

The precursor protein, or *pre-prohormone*, usually 100–250 residues in length, consists of an N-terminal *signal sequence* (peptide), followed by a variable stretch of unknown function, and a peptide-containing region that may contain several copies of active peptide fragments. Often, several different peptides are found within one precursor, but sometimes there are multiple copies of a single peptide. [6] The *signal sequence*, which is strongly hydrophobic, facilitates insertion of the protein into the endoplasmic reticulum and is then cleaved off at an early stage, yielding the *prohormone*.

The active peptides are usually demarcated within the prohormone sequence by pairs of basic amino acids (Lys-Lys or Lys-Arg), which are cleavage points for the trypsin-like proteases that

release the peptides. This *endoproteolytic cleavage* generally occurs in the Golgi apparatus or the secretory vesicles. The enzymes responsible are known as *prohormone convertases*. Scrutiny of the prohormone sequence often reveals likely cleavage points that distinguish previously unknown peptides. In some cases (e.g. *CGRP*; see later), new peptide mediators have been discovered in this way, but there are many examples where no function has yet been assigned. Whether these peptides are, like strangers at a funeral, waiting to declare their purpose or merely functionless mournful relics remains a mystery. There are also large stretches of the prohormone sequence of unknown function lying between the active peptide fragments. [7]

The abundance of mRNA coding for particular pre-prohormones, which reflects the level of gene expression, is very sensitive to physiological conditions. This type of *transcriptional control* is one of the main mechanisms by which peptide expression and release are regulated over the medium to long-term. Inflammation, for example, increases the expression, and hence the release, of various cytokines by immune cells. Sensory neurons respond to peripheral inflammation by increased expression of tachykinins (*substance P* and *neurokinins A and B*), which is important in the genesis of inflammatory pain (see **Ch. 43**).

Diversity within Peptide Families

Peptides commonly occur in families with similar or related sequences and actions. For example, the pro-opiomelanocortin (POMC) polypeptide, which has 241 amino acids, serves as a source of ACTH, melanocyte-stimulating hormones (MSHs) and β-

endorphin, all of which have a role in controlling the inflammatory response (as well as other processes). There are two main mechanisms which control peptide diversity.

Gene Splicing

Diversity of members of a peptide family can also arise by gene splicing or during post-translational processing of the prohormone. Genes contain coding regions (*exons*) interspersed with intervening non-coding (but potentially functional) regions (*introns*). When the gene is transcribed, the ensuing RNA (*heterologous nuclear RNA,* or alternatively *precursor mRNA*) is spliced to remove the introns and some of the exons, forming the final *mature mRNA* that is translated. Control of the splicing process allows a measure of cellular control over the peptides that are produced.

For example, the *calcitonin* gene codes for calcitonin itself, important in bone metabolism (see **Ch. 36**), and also for a completely dissimilar peptide (CGRP, involved in migraine pathogenesis, see **Ch. 43**). Alternative splicing allows cells to produce either pro-calcitonin (expressed in thyroid cells) or pro-CGRP (expressed in many neurons) from the same gene. Substance P and neurokinin A are two closely related tachykinins belonging to the same family and are also encoded on the same gene. Alternative splicing results in the production of two precursor proteins; one of these includes both peptides, the other includes only substance P. The ratio of the two varies widely between tissues, which correspondingly produce either one or both peptides.

Post-Translational Modifications

Many peptides, such as tachykinins and ACTH-related peptides (see **Ch. 34**), must undergo enzymatic *amidation* at the C-terminus to acquire full biological activity. Tissues may also generate peptides of varying length from the same primary sequence by the action of specific peptidases that cut the chain at different points. For example, *pro-cholecystokinin* (pro-CCK) contains the sequences of at least five CCK-like peptides ranging in length from 4 to 58 amino acid residues, all with the same C-terminal sequence. CCK itself (33 residues) is the main peptide produced by the intestine, whereas the brain produces mainly CCK-8. The opioid precursor *prodynorphin* similarly gives rise to several peptides with a common terminal sequence, the proportions of which vary in different tissues and in different neurons in the brain. In some cases (e.g. the inflammatory mediator bradykinin), peptide cleavage occurring after release generates a new active peptide (des-Arg^9-bradykinin), which acts on a different receptor, both peptides contributing differently to the combined inflammatory response.

Peptide Trafficking and Secretion

The basic mechanisms by which peptides are synthesised, packaged into vesicles, processed and secreted are summarised in **Fig. 17.7**. Two secretory pathways exist, for *constitutive* and *regulated* secretion, respectively. Constitutively secreted proteins (e.g. plasma proteins, some clotting factors) are not stored in appreciable amounts, and secretion is coupled to synthesis. Regulated secretion is, as with many hormones and transmitters, controlled by receptor-activated signals that lead to a rise in intracellular Ca^{2+}, and peptides awaiting release are stored in cytoplasmic vesicles. Specific

protein–protein interactions appear to be responsible for the sorting of different proteins and their routing into different vesicles, and for choreographing their selective release. Identification of the specific 'trafficking' proteins involved in particular secretory pathways may eventually yield novel drug targets for the selective control of secretion.

Having described the general mechanisms by which peptides are synthesised, processed and released, we now describe some significant mediators that fall into this category.

Bradykinin

Bradykinin and lysyl-bradykinin (*kallidin*) are active peptides formed by proteolytic cleavage of circulating proteins termed *kininogens* through a protease cascade pathway.

Source and Formation of Bradykinin

An outline of the formation of bradykinin from high-molecular-weight kininogen in plasma by the serine protease *kallikrein* is given in **Fig. 17.8**. *Kininogen* is a plasma α-globulin that exists in both high (Mr 110,000) and low (Mr 70,000) molecular-weight forms. Kallikrein itself is cleaved from the inactive precursor *prekallikrein* by the action of factor XII (Hageman factor; see Chs 7 and **23**). Factor XII is activated by contact with negatively charged surfaces such as collagen, basement membrane, bacterial lipopolysaccharides, urate crystals and so on. Factor XII, prekallikrein and the kininogens leak out of the vessels during inflammation because of increased vascular permeability, and exposure to negatively charged surfaces promotes the interaction of

factor XII with prekallikrein. The activated enzyme then 'clips' bradykinin from its kininogen precursor. Kallikrein can also activate the complement system and can convert plasminogen to plasmin.

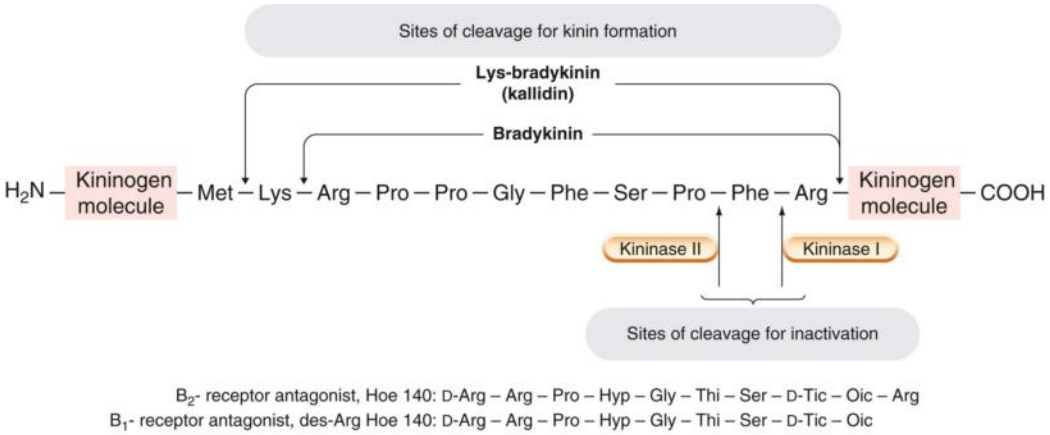

FIG. 17.8 The structure of bradykinin and some bradykinin antagonists.The sites of proteolytic cleavage of high-molecular-weight kininogen by kallikrein involved in the formation of bradykinin are shown in the upper half of the figure; the sites of cleavage associated with bradykinin and kallidin inactivation are shown in the lower half. The B_2-receptor antagonist icatibant (Hoe 140) has a pA_2 of 9, and the competitive B_1-receptor antagonist des-Arg Hoe 140 has a pA_2 of 8. The Hoe compounds contain unnatural amino acids: Thi, δ-Tic and Oic, which are analogues of phenylalanine and proline.

In addition to plasma kallikrein, there are other kinin-generating isoenzymes found in the pancreas, salivary glands, colon and skin. These *tissue kallikreins* act on both high- and low-molecular-weight

kininogens and generate mainly *kallidin*, a peptide with actions similar to those of bradykinin.

Metabolism and Inactivation of Bradykinin

Specific enzymes that inactivate bradykinin and related kinins are called *kininases* (see **Fig. 17.8**). One of these, *kininase II*, is a peptidyl dipeptidase that inactivates kinins by removing the two C-terminal amino acids. This enzyme, which is bound to the luminal surface of endothelial cells, is identical to *angiotensin-converting enzyme* (ACE; see **Ch. 21**), which cleaves the two C-terminal residues from the inactive peptide angiotensin I, converting it to the active vasoconstrictor peptide angiotensin II. Thus, kininase II inactivates a vasodilator and activates a vasoconstrictor. Potentiation of bradykinin actions by ACE inhibitors (e.g. **ramipril**) may contribute to some side effects of these drugs (e.g. cough and angioedema).

Kinins are also metabolised by various less specific peptidases, including a serum carboxypeptidase that removes the C-terminal arginine, generating *des-Arg^9-bradykinin*, a specific agonist at one of the two main classes of bradykinin receptor, and *neprilysin*. Neprilysin (also known as *neutral endopeptidase 24.11*, *common acute lymphoblastic leukaemia antigen* or CD10) is a predominantly membrane-bound member of the neprilysin (M13) family of metallopeptidases and is a key enzyme in the degradation of naturitic peptides. **Sacubitril**, a prodrug that is hydrolysed to form LBQ657 – a potent inhibitor of neprilysin – and licensed for the management of heart failure (see **Ch. 20**), also increases

bradykinin concentration: a feature which contributes to both its therapeutic effect and side effect profile (see **Campbell, 2018**).

Bradykinin Receptors

There are two bradykinin receptors, designated B_1 and B_2. Both are GPCRs and mediate very similar effects. B_1 receptors are normally expressed at very low levels but are strongly induced in inflamed or damaged tissues by cytokines such as IL-1. B_1 receptors respond to the carboxypeptidase N (kininase I) metabolite *des-Arg^9-bradykinin* but not to bradykinin itself. A number of selective peptide and non-peptide antagonists are known. It is likely that B_1 receptors play a significant role in inflammation and hyperalgesia (see **Ch. 42**), and antagonists could be useful in the treatment of cough, neurological disorders and osteoarthritis (**Whalley et al., 2012**).

B_2 receptors are constitutively present in many normal cells and are activated by bradykinin and kallidin, but not by des-Arg ^{9} -bradykinin. Peptide and non-peptide antagonists have been developed, the best known being the bradykinin analogue **icatibant**, used to treat acute attacks in patients with *hereditary angio-oedema* (an uncommon disorder caused by deficiency of C1-esterase inhibitor that normally restrains complement activation). Other small molecule B_2 receptor antagonists including **anatibant** and **fasitibant** have failed to demonstrate efficacy for alternate indications.

Actions and Role in Inflammation

Bradykinin causes vasodilatation and increased vascular permeability. Its vasodilator action is partly a result of generation of

PGI_2 and release of nitric oxide (NO). It causes pain by stimulating nociceptive nerve terminals, and its action here is potentiated by prostaglandins, which are released by bradykinin. Bradykinin also contracts intestinal, uterine and bronchial smooth muscle in some species. The contraction is slow and sustained in comparison with that produced by tachykinins such as substance P (*brady-* means slow; *tachy-* means rapid). Bradykinin may also increase cell proliferation promote leukocyte activation and migration.

Although bradykinin reproduces many inflammatory signs and symptoms, its role in inflammation and allergy is not clear, partly because its effects are often component parts of a complex cascade of events triggered by other mediators. However, excessive bradykinin production contributes to the diarrhoea of gastrointestinal disorders, and in allergic rhinitis it stimulates nasopharyngeal secretion. Bradykinin also contributes to the clinical picture in *pancreatitis*, [8] although, disappointingly, B_2 antagonists worsen rather than alleviate this disorder. Physiologically, the release of bradykinin by tissue kallikrein may regulate blood flow to certain exocrine glands, and influence secretions. Bradykinin also stimulates ion transport and fluid secretion by some epithelia, including intestine, airways and gall bladder.

Bradykinin

- Bradykinin (BK) is a nonapeptide ‘clipped’ from a plasma α-globulin, *kininogen*, by *kallikrein*.

- It is converted by *kininase I* to an active octapeptide, BK_{1-8} (des-Arg9-BK), and inactivated by the removal of an additional amino acid by *kininase II* (ACE) in the lung.
- Inhibition of bradykinin breakdown by angiotensin-converting enzyme or neprilysin inhibitors contributes to their side effect profile (e.g. cough and angioedema).
- Pharmacological actions:
  - vasodilatation (largely dependent on endothelial cell nitric oxide and PGI_2);
  - increased vascular permeability;
  - stimulation of pain nerve endings;
  - stimulation of epithelial ion transport and fluid secretion in airways and gastrointestinal tract;
  - contraction of intestinal and uterine smooth muscle;
  - cell proliferation, migration and activation.
- There are two main subtypes of BK receptors: B_2, which is constitutively present, and B_1, which is induced in inflammation.
- **Icatibant**, a peptide analogue of BK, is a selective competitive antagonist for B_2 receptors and is used to treat acute attacks of hereditary angioedema. Other, non-peptide antagonists for both B_1 and B_2 receptors are known and may be developed for treating inflammatory disorders.

Neuropeptides

Neuropeptides constitute a large (>100) and diverse family of small to medium-sized peptides. Many are found in the CNS, the autonomic nervous system, and peripheral sensory neurons, as well as in many peripheral tissues. They are often released as co-transmitters (see Chs **13** and **39**), along with non-peptide neurotransmitters.

When released from peripheral endings of nociceptive sensory neurons (see **Ch. 42**), neuropeptides in some species cause *neurogenic inflammation* (**Chiu et al., 2012**). The main peptides involved are substance P, neurokinin A and CGRP. Substance P and neurokinin A are small (about 1100 Da) members of the *tachykinin* family with partly homologous structures. They act on mast cells, releasing histamine and other mediators, and producing smooth muscle contraction, neural activation, mucus secretion and vasodilatation. CGRP, a member of the calcitonin family (37 amino acids in length), shares these properties and is a particularly potent vasodilator. Tachykinins released from the central endings of nociceptive neurons also modulate transmission in the dorsal horn of the spinal cord, affecting sensitivity to pain (see **Ji et al., 2018**). All these neuropeptides act through specific GPCRs to produce their effects.

Neurogenic inflammation is implicated in the pathogenesis of several inflammatory conditions, including the delayed phase of asthma, allergic rhinitis, inflammatory bowel disease, some types of arthritis and migraine. Antagonists at the neurokinin NK_1 receptor, such as **aprepitant**, **fosaprepitant and netupitant**, are used to treat emesis, particularly that associated with some forms of cancer chemotherapy (see **Ch. 57**). Other important members of the

neuropeptide family include *enkephalins/endorphins* (see **Ch. 42**) and *orexins* (see **Ch. 32**). The latter are the therapeutic target of **suvorexant** and **daridorexant** which, by inhibiting the binding of orexin-A and orexin-B to their OXR1 and OXR2 receptors, promote sleep (see **Ch. 45**).

Cytokines

'Cytokine' is an all-purpose functional term that is applied to protein or polypeptide mediators synthesised and released by cells of the immune system during inflammation. They are crucial for the overall coordination of the inflammatory response. Cytokines act locally by autocrine or paracrine mechanisms. Unlike conventional hormones such as insulin, concentrations in blood and tissues are almost undetectable under normal circumstances but are massively up-regulated (100–1000-fold) during inflammatory episodes. Cytokines are generally active at very low (sub-nanomolar) concentrations.

Cytokines bind to and activate specific, high-affinity receptors on target cells, that, in most cases, are also up-regulated during inflammation. Except for *chemokines*, which act on GPCRs, most cytokines act on kinase-linked receptors, regulating phosphorylation cascades that affect gene expression, such as the JAK-STAT pathway (see Ch. 25).

In addition to their own direct actions on cells, some cytokines amplify inflammation by inducing the formation of other inflammatory mediators. Others can induce receptors for other cytokines on their target cell or engage in synergistic or antagonistic interactions with other cytokines. Cytokines therefore constitute a

complex chemical signalling language, with the final response of a particular cell involved being determined by the strength and number of different messages received concurrently at the cell surface.

Systems for classifying cytokines abound in the literature, as do diagrams depicting their complex networks of interactions with each other and with their many target cells. However, no one system of classification does justice to the complexity of cytokine biology. The terminology and nomenclature are horrendous, and a comprehensive coverage of this area is beyond the scope of this book. **Table 17.2** lists some of the more significant cytokines and their biological actions. Aspiring cytokine aficionados will find further information in **Liu et al. (2021)**, the clinically focused but renally biased **Holdsworth and Gan (2015)** and the IUPHAR/BPS Guide to Pharmacology. To explore the interesting history of this field, including how an understanding of cytokine biology was harnessed for therapeutic benefit, see **Vilcek and Feldmann (2004)** and **Dinarello (2007)**.

More than 100 cytokines have been identified. These may be broadly categorised into four main functional groups, namely *interleukins*, *chemokines*, *interferons* and *colony-stimulating factors* (discussed separately in **Ch. 24**), but these demarcations are of limited use because many cytokines have multiple roles.

Using biopharmaceuticals (see **Chs 5 and 25**) to interfere with cytokine action has proved to be a particularly fertile area of drug development: several successful strategies have been adopted, including direct neutralisation of cytokines using antibodies and the

use of ‘decoy’ receptor proteins that remove the biologically active pool from the circulation.

Cytokines

- Cytokines are polypeptides that are rapidly induced and released during inflammation. They regulate the action of inflammatory and immune system cells.
- The cytokine superfamily includes the *interferons*, *interleukins*, *chemokines* and *colony-stimulating factors*.
- Utilising both autocrine or paracrine mechanisms, they exert complex effects on leukocytes, vascular endothelial cells, mast cells, fibroblasts, haemopoietic stem cells and osteoclasts, controlling proliferation, differentiation and/or activation.
- Interleukin 1 (IL-1) and tumour necrosis factor-α (TNF-α) are important primary inflammatory cytokines, inducing the formation of other cytokines.
- Chemokines, such as IL-8, are mainly involved in the regulation of cell trafficking.
- Interferons IFN-α and IFN-β have antiviral activity, and IFN-α is used as an adjunct in the treatment of viral infections. IFN-γ has significant immunoregulatory function and is used in the treatment of multiple sclerosis.

Interleukins and Related Compounds

The name was originally coined to describe mediators that signalled between leukocytes but, like so much else in the cytokine lexicography, it has become rather redundant, not to say misleading. The primary pro-inflammatory species are *tumour necrosis factor* (TNF)-α and *IL-1*. The principal members of the latter cytokine group consist of two agonists, IL-1α, IL-1β and, surprisingly, an endogenous soluble IL-1-receptor antagonist (IL-1ra). [9] Mixtures of these are released from macrophages and many other cells during inflammation and can initiate the synthesis and release of a cascade of secondary cytokines, among which are the chemokines. TNF and IL-1 are key regulators of almost all manifestations of the inflammatory response. A long-standing debate about which of the two is really the prime mover of inflammation ended when it was found that this varies according to the disease type. In auto-*immune* disease (e.g. rheumatoid arthritis, where the adaptive immune system is activated), TNF appears to be the predominant influence and blocking its action is therapeutically effective. In auto-*inflammatory* diseases (e.g. gout, where only the innate system is involved), IL-1 seems to be the key mediator (**Dinarello et al., 2012**). Both TNF-α and IL-1 are important targets for anti-inflammatory biopharmaceuticals.

Not all interleukins are pro-inflammatory: some, including transforming growth factor (TGF)-β, IL-4, IL-10 and IL-13 are potent anti-inflammatory substances. They inhibit chemokine production, and the responses driven by T-helper (Th) 1 cells, whose inappropriate activation is involved in the pathogenesis of several diseases.

Chemokines

Chemokines are defined as *chemo*attractant cyto*kines* that control the migration of leukocytes, functioning as traffic coordinators during immune and inflammatory reactions. Again, the nomenclature (and the classification) is confusing because some non-cytokine mediators also control leukocyte movement (e.g. C5a, LTB_4, fMet-Leu-Phe, etc.; see **Ch. 7**) and many chemokines have more than one name. Furthermore, many chemokines have other actions, causing mast cell degranulation or promoting angiogenesis, for example.

More than 40 chemokines have been identified. They are all highly homologous peptides of 8–10 kDa, which are usually grouped according to the configuration of key cysteine residues in their polypeptide chain. Chemokines with one cysteine are known as *C chemokines*. If there are two adjacent cysteine residues they are termed *C–C chemokines*. Other members have cysteines separated by one (*C–X–C chemokines*) or three (*C–XXX–C chemokines*) other residues. The C–X–C chemokines (main example IL-8) act on neutrophils and are predominantly involved in acute inflammatory responses. The C–C chemokines (main examples *eotaxin*, *MCP-1* and *RANTES*) act on monocytes, eosinophils and other cells, and are involved predominantly in chronic inflammatory responses.

Chemokines generally act through GPCRs, and alteration or inappropriate expression of these is implicated in multiple sclerosis, cancer (tumorigenesis and metastasis), autoimmune and cardiovascular diseases (**Raman et al., 2011**). Several types of viruses (herpes virus, cytomegalovirus, pox virus and members of the retrovirus family) can manipulate the chemokine system to

subvert the host's defences (**Murphy, 2001**). Some produce proteins that mimic host chemokines or chemokine receptors, some act as antagonists at chemokine receptors and some masquerade as growth or angiogenic factors. HIV is responsible for the most audacious exploitation: it has a protein (gp120) in its envelope that recognises and binds T-cell receptors for CD4 and the chemokine co-receptors CCR5 (blocked by the HIV drug **maraviroc**) and CXCR4 to hijack its way into the cell (see **Ch. 53**).

Table 17.2

GM–CSF, Granulocyte-macrophage colony-stimulating factor; *IFN,* interferon; *Ig,* immunoglobulin; *IL,* interleukin; *MCP,* monocyte chemoattractant protein; *MIP,* macrophage inflammatory protein; *NK,* natural killer (cell); *RANTES,* regulated on activation normal T cell expressed and secreted; *TGF,* transforming growth factor; *Th,* T-helper (cell); *TNF,* tumour necrosis factor.

Interferons

So called because they interfere with viral replication, there are three main types of interferon, termed IFN-α, IFN-β and IFN-γ. 'IFN-α' is not a single substance but a family of approximately 20 proteins with similar activities. IFN-α and IFN-β have antiviral activity whereas IFN-α also has some antitumour action. Both are released from virus-infected cells and activate antiviral mechanisms in neighbouring cells. IFN-γ also induces Th1 responses (see **Ch. 7**). Confusingly, interferons are also grouped into three families based on their interactions with the IFN receptor subunits, peptide mapping, and sequencing homology. These consist of the *type 1 IFN*

family (comprising 13 partially homologous IFN-α subtypes and a single IFN-β among others; these signal through the IFN-α receptor 1 and 2), *type II IFN family* (IFN-γ, acting on the IFN-γ receptor) and the *type III family* (IFN-λ1–3, also known as IL-29, IL-28A and IL28B). See **McNab et al. (2015)** and **López de Padilla and Niewold (2016)** for further details.

Clinical Use of Interferons

IFN-α is used in the treatment of chronic hepatitis B and C (although note recent advances in this field: see **Ch. 53**) and has some action against herpes zoster and in the prevention of the common cold. Antitumour action against some lymphomas and solid tumours has also been reported. Dose-related side effects, including influenza-like symptoms, may occur. IFN-β is used in patients with the relapsing–remitting form of multiple sclerosis, and *chronic granulomatous disease*, an uncommon chronic disease of childhood in which neutrophil function is impaired, can be treated with IFN-γ in conjunction with antibacterial drugs.

Clinical uses of interferons

- α: chronic hepatitis B or C (in combination with **ribavirin**, however direct-acting oral antivirals e.g. **tenofovir** or **sofosbuvir** now preferred).
  - Malignant disease (alone or in combination with other drugs, e.g. **cytarabine**): chronic myelogenous leukaemia (CML), hairy cell leukaemia, follicular lymphoma, metastatic carcinoid, multiple myeloma, malignant

melanoma (as an adjunct to surgery), myelodysplastic syndrome.
  - Conjugation with polyethylene glycol ('pegylation') results in preparations that are more slowly eliminated and are administered intermittently subcutaneously.
- β: multiple sclerosis (especially the relapsing–remitting form of this disease).
- γ: to reduce infection in children with chronic granulomatous disease.
- Inhibition of IFN action may also have therapeutic benefit, the anti-type 1 interferon receptor subunit 1 drug **anifrolumab** having efficacy in systemic lupus erythematosus.

The 'Cytokine Storm'

Many cytokines release further cytokines in what is essentially a positive feedback loop. There are times when this feedback system becomes unstable, perhaps as a result of the absence of balancing anti-inflammatory factors. The result can be a massive overproduction of cytokines in response to infection or other injury. This is known as a *cytokine storm* (also called *hypercytokinemia*) and can pose a significant threat to the host. Cytokine storms may be responsible for deaths in septic shock as well as in some pandemic diseases including COVID-19 (see **Fajgenbaum and June, 2020**). A tragic case of volunteers suffering cytokine storms after receiving an experimental drug is related in **Chapter 5**.

Proteins and Peptides that Down-Regulate Inflammation

Inflammation is not regulated solely by factors that provoke or enhance it: it has become increasingly evident that there is another panel of mediators that function at every step to down-regulate inflammation, to check its progress and limit its duration and scope. It is the dynamic balance between these two systems that regulates the onset and resolution of inflammatory episodes, and when this breaks down, may lead also to inflammatory disease or, in extreme cases, to the cytokine storm phenomenon. Some of these counter-regulatory controllers are peptidic in nature and we have already encountered IL-1ra, TGF-β and IL-10, which are important negative regulators of inflammation. There are two other systems that are significant here because common anti-inflammatory drugs exploit their action.

Anx-A1 is a 37-kDa protein produced by many cells and especially abundant in cells of the myeloid lineage. When released, it exerts potent anti-inflammatory actions, down-regulating cell activation, cell transmigration and mediator release. It does this by acting through the GPCR ALX/FPR2, a member of the formyl peptide receptor family already discussed in the context of the anti-inflammatory lipoxins.

The significance of the Anx-A1 system is that it is activated by anti-inflammatory glucocorticoids (see **Ch. 25**), which increase Anx-A1 gene transcription and promote its release from cells. Interestingly, the anti-allergic cromones (**cromoglicate**, etc.; see **Ch. 27**) also promote the release of this protein from cells. Anx-A1 gene 'knock-out' studies have shown that this protein is important

for restraining the inflammatory response, including a laboratory model of septic shock, and for its timely resolution. The anti-inflammatory glucocorticoids cannot develop their full inhibitory actions without it. A recent review of Anx-A1 biology, including its role outside of inflammation, is given by **Sheikh and Solito (2018)**.

The *melanocortin system* also plays an important part in regulating inflammation. There are five G protein–coupled melanocortin receptors, MC_{1-5}. Endogenous ligands for these receptors, such as MSH (three types), are derived from the POMC gene, and serve a number of purposes, including regulating the development of a suntan, penile erection and the control of appetite through an action on various MC receptors.

From the point of view of host defence, the MC_3 receptor is the most important. Again, gene deletion studies have highlighted the importance of this receptor in a variety of inflammatory conditions. Interestingly, another product of the POMC gene, ACTH, was formerly used as an anti-inflammatory agent, but it was thought that its action was secondary to its ability to release endogenous cortisol from the adrenals (an MC_2 action, see **Ch. 33**). It is now known that it is a ligand at the MC_3 receptor, and it is likely that it owes some of its activity to this action.

An account of the importance of this field is given by **Wang et al. (2019)**.

Concluding Remarks

In this chapter we have tried to provide an introduction to some of the key families of mediator that regulate human physiology and, in

particular, contribute to host defence. Other relevant low-molecular-weight factors include the purines (see **Ch. 16**) and nitric oxide (see **Ch. 19**) which are covered elsewhere. Even from the superficial sketch presented here (and in other related parts of this book such as **Ch. 7**), it must be evident that the host defence response is among the most intricate of all physiological responses. Perhaps that is not surprising, given its central importance to survival.

For the same reason, it is also understandable that so many different mediators orchestrate its operation. That the activity of many of these can be blocked in experimental models with little or no obvious effect on the initiation and outcome of inflammation points to redundancy among the many component systems and goes some way to explaining why, until the advent of highly specific antibody-based therapies for inflammatory conditions, our ability to curb the worst ravages of chronic inflammatory disease was so limited.

A crucial development over recent years is the advancement of analytical techniques and their computational processing. This has allowed both the identification of new mediators (and indeed families of mediators) as well as the interrogation of human biology in health and disease at both the systems and single cell level. It is hoped that application of these techniques, allied to improved drug design and development, will continue to yield novel therapeutic leads.

QUESTIONS

QUESTION 17.1

Histamine, originally identified during anaphylaxis, has been shown to be a key mediator of allergic and inflammatory reactions.

Which of the following would not enhance histamine release?

OPTIONS:

A. C5a

B. Beta adrenoceptor agonists

C. Antigen bound immunoglobulin E (IgE)

D. Increase in cytosolic [Ca^{2+}]

E. Morphine

QUESTION 17.2

The eicosanoids are a group of mediators generated from common 20-carbon fatty acid precursors, implicated in the control of many physiological processes, and modulators of the inflammatory reaction.

Which of the following statements about the eicosanoids is correct?

OPTIONS:

A. PGI_2 is rapidly inactivated by dehydrogenase and reductase enzymes in the lung.

B. Metabolism of eicosapentaenoic acid (EPA) by cyclo-oxygenase (COX) enzymes generates proinflammatory PGE_2 and TxA_2.

C. Misoprostol can be used in the induction of labour.

D. Prostanoids induce pain through the activation of afferent C fibres.

E. Leukotrienes are synthesised from the cyclic endoperoxides PGG_2 and PGH_2, by the action of lipoxygenases.

QUESTION 17.3

Asthma is characterised by bronchoconstriction and cellular infiltration exacerbated by a range of inflammatory mediators.

Which of the following have shown potential as therapeutic agents for the treatment of asthma?

OPTIONS:

A. Cetirizine

B. Fingolimod

C. Montelukast

D. Icatibant

E. Aspirin

ANSWERS

ANSWER 17.1

RATIONALE:

A. Complement components C3a and C5a interact with specific surface receptors on mast cells to mediate degranulation and histamine release.

B.

C. Antigen recognition by cell-fixed IgE antibodies on mast cells mediates degranulation and histamine release.

D. Histamine release is initiated by a rise in cytosolic [Ca^{2+}].

E. Basic drugs such as morphine stimulate histamine release.

CORRECT ANSWER WITH EXPLANATION:

B. Beta adrenoceptor agonists

Agents which increase cAMP decrease histamine release.

ANSWER 17.2

RATIONALE:

A. PGI_2 is inherently unstable and decays rapidly and spontaneously in biological fluids into inactive 6-keto-$PGF_{1\alpha}$.

B. EPA, found in oily fish, when used as a substitute substrate for COX enzymes results in the generation of PGE_3 and reduces the production of the pro-inflammatory PGE_2 and TXA_2. This may partly underlie the beneficial anti-inflammatory, metabolic and cardiovascular actions that are ascribed to diets rich in this type of marine product.

C.

D. Prostanoids do not themselves produce pain but sensitise afferent C fibres to the effects of bradykinin and other noxious stimuli.

E. Leukotrienes are synthesised from arachidonic acid by lipoxygenases.

CORRECT ANSWER WITH EXPLANATION:

C. Misoprostol can be used in the induction of labour.

Misoprostol is an agonist at $EP_{2/3}$ receptors and causes uterine contraction.

ANSWER 17.3

RATIONALE:

A. Cetirizine (H1 antagonist – little effect in human asthma).

B. Fingolimod – trialled in asthma (based on S1PRs' effect on mast cells, eosinophils and bronchial muscle tone); however, results have been mixed and its use is limited by side effects.

C.

D. Icatibant – although bradykinin reproduces many inflammatory signs and symptoms, its role in inflammation and allergy is not clear, partly because its effects are often component parts of a complex cascade of events triggered by other mediators.

E. Aspirin – although prostaglandins (PGs) are implicated in bronchial constriction, inhibition of PG synthesis has not been shown to have a significant impact in asthma.

CORRECT ANSWER WITH EXPLANATION:

C. Montelukast – leukotriene receptor antagonist

Agents which reduce leukotrienes have potential in the treatment of asthma.

[1] The term *autocrine* is sometimes used to denote a local mediator that acts on the cell from which it is released, whereas a *paracrine*

mediator acts on other neighbouring cells.

[2] To add to the lexicographical confusion, the term *bioregulator* has recently crept into use. As this portmanteau word could cover just about any biologically active substance, it is not much use for our purposes.

[3] Reasonable or not, it is a misnomer which arose through an anatomical error. In some species it is difficult to differentiate the prostaglandin-rich seminal vesicles from the prostate gland which (ironically, as we now know) contains relatively little. Nevertheless, the name stuck, outlasting the far more appropriate term *vesiglandin,* which was suggested later.

[4] Women being treated with **bimatoprost** eye drops for glaucoma were delighted with a side effect of this drug – stimulation of eyelash growth. It wasn't long before a thriving 'off-label' market had been established for its use in beauty spas. Eventually, the FDA gave in to popular lobbying and licensed a preparation specifically for this cosmetic indication.

[5] Bacteria are poor at post-translational modifications, hence over half of all protein drugs (biopharmaceuticals) are generated using mammalian cell cultures (see Ch. 5).

[6] In the case of the invertebrate *Aplysia*, one protein precursor contains no fewer than 28 copies of the same short peptide.

[7] When these large sequences of unknown function were discovered in our DNA, they were rather arrogantly termed 'junk DNA', not because they were rubbish, but because we didn't understand their function. It turns out 'junk DNA' is actually very

important, controlling gene expression and hence cell function. It is also a significant factor in some diseases. ‘Junk peptide’ may yet be ascribed similar or alternate biological roles.

8 A serious and painful condition in which proteolytic enzymes are released from damaged pancreatic cells, initiating proteolytic cascades that release, among other things, bradykinin.

8 A serious and painful condition in which proteolytic enzymes are released from damaged pancreatic cells, initiating proteolytic cascades that release, among other things, bradykinin.

9 One might have expected evolution to generate more examples of endogenous receptor antagonists as physiological regulators, but apart from IL-1ra, they are only exploited as toxins directed against other species.

18: Cannabinoids

OVERVIEW

Modern pharmacological interest in cannabinoids dates from the discovery that Δ^9-tetrahydrocannabinol (THC) is the main psychoactive component of cannabis, and took off with the discovery of specific cannabinoid receptors – termed *CB receptors* – and endogenous ligands (endocannabinoids), together with mechanisms for their synthesis and elimination. There has been a recent surge of interest in the therapeutic potential of other cannabinoids, especially cannabidiol (CBD), which lacks the psychoactive properties of THC. Here we consider plant-derived cannabinoids, cannabinoid receptors, endocannabinoids, physiological functions, pathological mechanisms, synthetic ligands and potential clinical applications. More detailed information is given by **Ligresti et al. (2016)** and by **Pertwee (2014, 2015)**. The pharmacology of cannabinoids in the central nervous system (CNS) is discussed in **Chapters 39**, **43**, **46**, **49** and **50**.

Plant-Derived Cannabinoids ('Phytocannabinoids') And Their Pharmacological Effects

Cannabis sativa, the hemp plant, has been used for its psychoactive properties for thousands of years (see **Ch. 49**). Its medicinal use was advocated in antiquity, but serious interest resurfaced only in 1964 with the identification of *Δ^9-tetrahydrocannabinol* (THC; **Fig. 18.1**) as the main psychoactive component. Cannabis extracts contain numerous related compounds, called phytocannabinoids, most of which are insoluble in water. The most abundant phytocannabinoids are THC, *cannabidiol* (CBD) and *cannabinol*, a breakdown product formed spontaneously from THC. CBD is said to lack the psychoactive properties of THC but CBD has anticonvulsant activity in preclinical models and has been licensed for some rare but serious forms of childhood epilepsy (see **Ch. 46**).

CBD and THC are synthesised by distinct biochemical pathways, but CBD can be converted to THC by cyclisation by artificially smoking cigarettes impregnated with CBD (**Mikeš and Waser, 1971**). It has recently been suggested that CBD can be converted to THC at temperatures occurring during vaping but this still needs to be verified and any in vivo consequences investigated.

A therapeutic effect of CBD has been claimed in a remarkably wide range of preclinical models of disease states outside its licensed indications ranging from cardiovascular disease, inflammation and autoimmunity to neurodegenerative disease, renal disease and malignancy, leading unfortunately to many poorly founded claims for efficacy in human disease (see **Pacher et al., 2020**, for a review). Rigorous controlled clinical trials are in short supply.

Pharmacological Effects

THC acts mainly on the CNS, producing a mixture of psychotomimetic and depressant effects, together with various centrally mediated autonomic effects. The main subjective effects in humans consist of:

- Sensations of relaxation and well-being without the accompanying recklessness and aggression sometimes caused by excessive ethanol consumption: insensitivity to risk is an important feature of alcohol intoxication and is often a factor in road accidents. Cannabis users are less accident prone in general – although acute cannabis use impairs specific driving skills, and meta-analyses show that the risks for cannabis users of car crashes are slightly, but significantly, increased (reviewed by **Preuss et al., 2021**).
- Feelings of sharpened sensory awareness, with sounds and sights seeming more intense and fantastic.
- These effects are similar to, but usually less pronounced than, those produced by psychotomimetic drugs such as lysergic acid diethylamide (LSD; see **Ch. 49**). Subjects report that time passes extremely slowly. Acute effects include feelings of paranoia especially with higher doses, although less marked than with LSD. Epidemiological studies support a connection between heavy cannabis use in adolescence and subsequent psychiatric disorder (**Rubino et al., 2012**). It is difficult to distinguish whether this is due to an effect common to individuals in this age group rather than an effect that is specific for susceptible individuals.

Central effects that can be directly measured in human and animal studies include:

- impairment of short-term memory and simple learning tasks – subjective feelings of confidence and heightened creativity are not reflected in actual performance;
- impairment of motor coordination (e.g. driving performance);
- catalepsy – the adoption of fixed unnatural postures;
- hypothermia;
- analgesia;
- antiemetic action (see **Ch. 30**);
- increased appetite.

The main peripheral effects of cannabis are:

- tachycardia, which can be prevented by drugs that block sympathetic transmission;
- vasodilatation, which is particularly marked in superficial blood vessels of the eye (scleral and conjunctival vessels), producing a bloodshot appearance which is characteristic of cannabis smokers;
- reduction of intraocular pressure;
- bronchodilatation.

Cannabis

- The main psychoactive constituent is **Δ^9-tetrahydrocannabinol (THC)** which generates a

pharmacologically active 11-hydroxy metabolite.

- Actions on the CNS include both depressant and psychotomimetic effects.
- Subjective experiences include euphoria and a feeling of relaxation, with sharpened sensory awareness.
- Objective tests show impairment of learning, memory and motor performance, including impaired driving ability.
- THC also shows analgesic and antiemetic activity, as well as causing catalepsy and hypothermia in animal tests.
- Peripheral actions include vasodilatation, reduction of intraocular pressure and bronchodilatation.
- Cannabinoids are less liable than opioids, **nicotine** or **alcohol** to cause dependence but may have long-term psychological effects.
- **CBD** lacks the psychoactive effects of THC but is therapeutic in some rare forms of childhood epilepsy and in a wide range of preclinical models of other diseases.

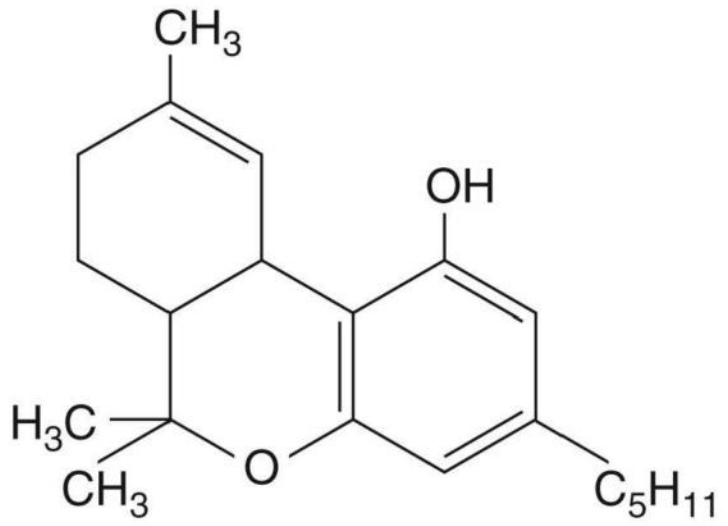
Pharmacokinetic Aspects

The effect of cannabis, taken by smoking, takes about 1 h to develop fully and lasts for 2–3 h. A small fraction of THC is converted to 11-hydroxy-THC, which is more active than THC itself and probably contributes to the pharmacological effect of smoking cannabis, but most is converted to inactive metabolites that are subject to conjugation and enterohepatic recirculation. Being highly lipophilic,

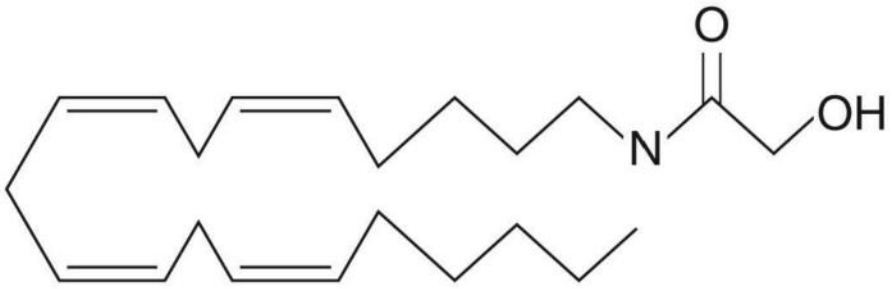
THC and its metabolites are sequestered in body fat, and detectable urinary excretion continues for several weeks after a single dose.

Adverse Effects

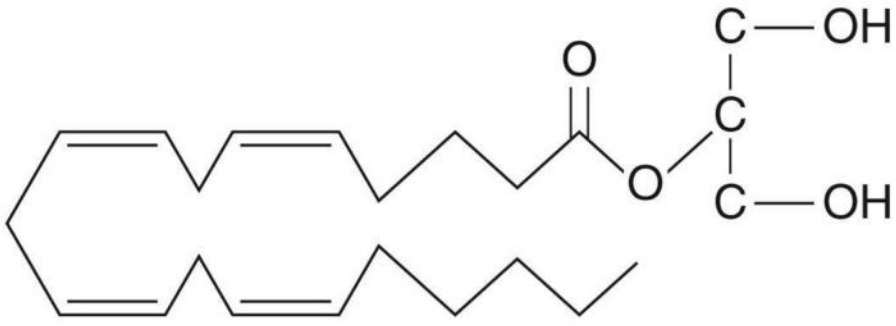
In acute overdose, THC is less dangerous than alcohol or opioids, producing drowsiness and confusion but not life-threatening respiratory or cardiovascular depression. Even in low doses, THC and synthetic derivatives such as **nabilone** (licensed for nausea and vomiting caused by cytotoxic chemotherapy, see later) produce euphoria and drowsiness, sometimes accompanied by sensory distortion and hallucinations. These effects, together with legal restrictions on the use of cannabis, [1] have limited the widespread therapeutic use of cannabinoids, although a cannabis extract administered by buccal spray has achieved regulatory approval in several countries as an adjunct in treating spasticity in multiple sclerosis.



Δ^9-Tetrahydrocannabinol (THC)



Anandamide



2-Arachidonoyl glycerol (2-AG)

FIG. 18.1 Structures of Δ^9-tetrahydrocannabinol and two endocannabinoids.

In rodents, THC produces teratogenic and mutagenic effects, and an increased incidence of chromosome breaks in circulating white cells has been reported in humans. Such breaks are, however, by no means unique to cannabis, and epidemiological studies have not shown an increased risk of fetal malformation or cancer among cannabis users.

Tolerance and Dependence

Tolerance to cannabis, and physical dependence, occurs only to a minor degree and mainly in heavy users. Abstinence symptoms that develop on cessation of cannabis use include nausea, agitation, irritability, confusion, tachycardia and sweating, but are relatively mild and do not result in a compulsive urge to take the drug. Psychological dependence does occur with cannabis, but it is less compelling than with the major drugs of abuse (see **Ch. 50**), although dependence is increasing in parallel with use of higher THC content material (**Maldonado et al., 2011**).

Cannabinoid Receptors

Cannabinoids, being highly lipid-soluble, were originally thought to act through their physical properties when partitioned into lipid-rich neuronal membranes rather than by interaction with specific receptors. However, in 1988, saturable high-affinity binding of a tritiated cannabinoid was demonstrated in membranes prepared

from homogenised rat brain. This led to the identification of specific cannabinoid receptors in the brain. These are now termed *CB_1 receptors* to distinguish them from the *CB_2 receptors* subsequently identified in peripheral tissues. Cannabinoid receptors are typical members of the family of G protein–coupled receptors (see **Ch. 3**). CB_1 receptors are linked via $G_{i/o}$ to inhibition of adenylyl cyclase and of voltage-operated calcium channels, and to activation of G protein–sensitive inwardly rectifying potassium (GIRK) channels, causing membrane hyperpolarisation (**Fig. 18.2**), effects similar to those mediated by opioid receptors (see **Ch. 43**), but with different anatomical distributions of CB_1 versus opioid receptors. CB_1 receptors are located in the plasma membrane of nerve endings and inhibit transmitter release from presynaptic terminals, which is triggered by depolarisation and Ca^{2+} entry (see **Ch. 4**). CB_1 receptors also influence gene expression, both directly by activating mitogen-activated protein kinase and indirectly by reducing the activity of protein kinase A as a result of reduced adenylyl cyclase activity (see **Ch. 3**).

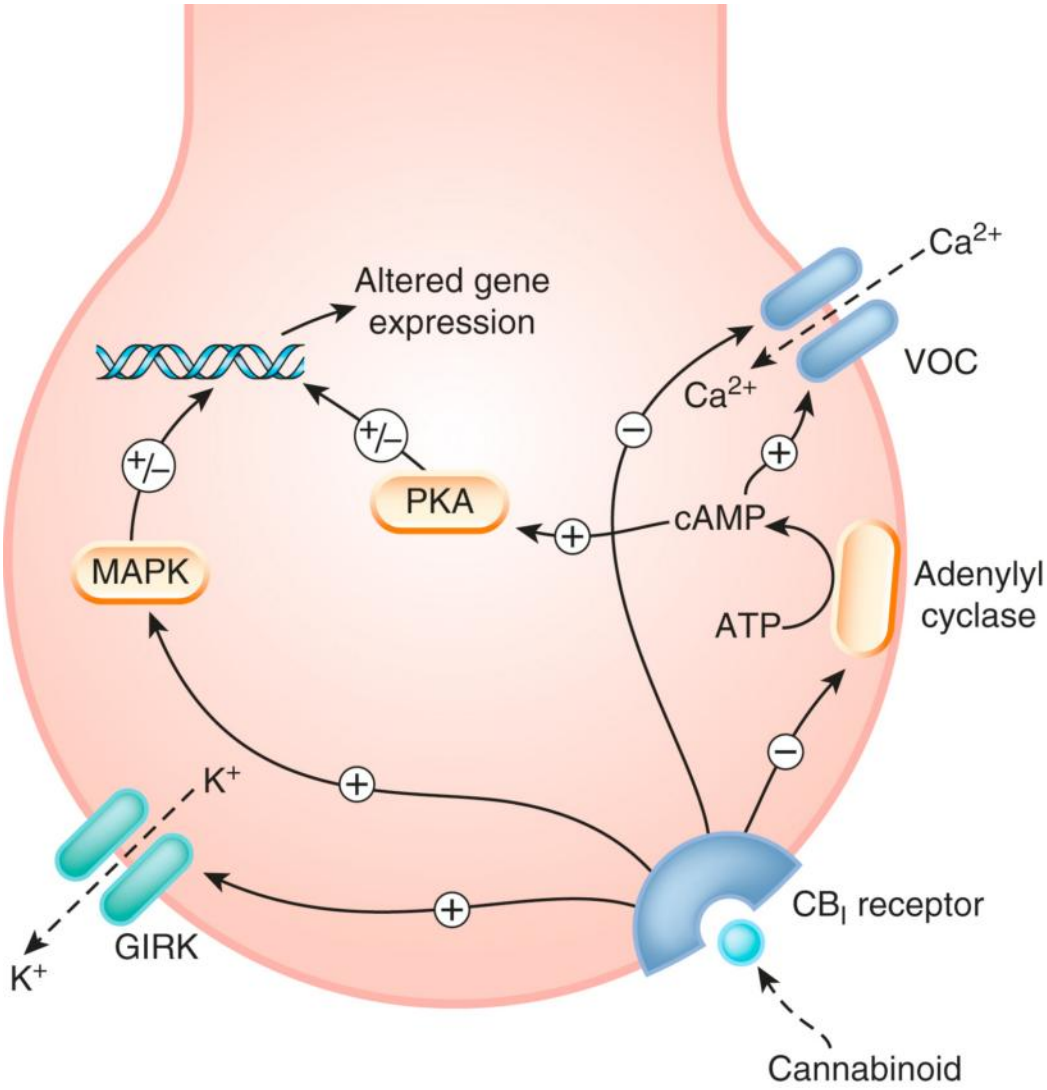


FIG. 18.2 Cellular actions of cannabinoids.CB_1 receptor activation inhibits neurotransmitter release via inhibition of Ca^{2+} entry and hyperpolarisation due to activation of potassium channels. It also alters gene expression. *GIRK,* G protein–sensitive inward-rectifying potassium channel; *MAPK,* mitogen-activated protein kinase; *PKA,* protein kinase A; *VOC,* voltage-operated calcium channel. Redrawn from **Devane, W.A., Hanu, L., Breurer, A., et al.,**

1992. Isolation and structure of a brain constituent that binds to the cannabinoid receptor. Science 258, 1946–1949.

CB_1 receptors are abundant in the brain, with numbers similar to those of receptors for glutamate and GABA – the main central excitatory and inhibitory neurotransmitters (see **Ch. 38**). They are not homogeneously distributed, being concentrated in the hippocampus (relevant to the effects of cannabinoids on memory), cerebellum (relevant to loss of coordination), hypothalamus (important in control of appetite and body temperature; see **Ch. 32** and later), substantia nigra, mesolimbic dopamine pathways that have been implicated in psychological 'reward' (see **Ch. 50**) and in association areas of the cerebral cortex. There is a relative paucity of CB_1 receptors in the brain stem, consistent with the lack of serious depression of respiratory or cardiovascular function by cannabinoids. At a cellular level, CB_1 receptors are mainly localised presynaptically, and inhibit transmitter release, as depicted in **Fig. 18.2**. Like opioids, they can, however, increase the activity of some neuronal pathways by disinhibition (see Chs 37 and 43), that is by inhibiting inhibitory connections, including GABA-ergic interneurons in the hippocampus and amygdala.

Table 18.1

In addition to their well-recognised location in the CNS, CB_1 receptors are also expressed in peripheral tissues, for example on endothelial cells, adipocytes and peripheral nerves. Cannabinoids promote lipogenesis through activation of CB_1 receptors, an action

that could contribute to their effect on body weight (see **DiPatrizio and Piomele, 2012**).

The CB_2 receptor has only approximately 45% amino acid homology with CB_1 and is located mainly in lymphoid tissue (spleen, tonsils and thymus as well as circulating lymphocytes, monocytes and tissue mast cells). CB_2 receptors are also present on microglia – immune cells in the CNS which, when activated, contribute to chronic pain (see **Ch. 43**). The localisation of CB_2 receptors on cells of the immune system was unexpected but may account for inhibitory effects of cannabis on immune function. CB_2 receptors differ from CB_1 receptors in their responsiveness to cannabinoid ligands (see **Table 18.1**). They are linked via $G_{i/o}$ to adenylyl cyclase, GIRK channels and mitogen-activated protein kinase similarly to CB_1, but not to voltage-operated calcium channels (which are not expressed in immune cells). So far, rather little is known about their function. They are present in atherosclerotic lesions (see **Ch. 22**), and CB_2 agonists have potentially anti-atherosclerotic effects on macrophages and foam cells (**Chiurchiu et al., 2014**). The contrasting cardiovascular effects of CB_1 and CB_2 pathways are reviewed by **Pacher et al. (2018)**.

Some endocannabinoids turned out, surprisingly, [2] to bind to sites on the cytoplasmic side of transient receptor potential channels (TRP channels), activating these ionotropic receptors and thereby stimulating nociceptive nerve endings (see **Ch. 43**). Other as-yet-unidentified G protein–coupled receptors are also implicated, because cannabinoids exhibit analgesic actions and activate G

proteins in the brain of CB_1 knock-out mice, despite the absence of CB_1 receptors.

Endocannabinoids

The discovery of specific cannabinoid receptors led to a search for endogenous mediators. The first success was chalked up by a team that screened fractions of extracted pig brain for ability to compete with a radiolabelled cannabinoid receptor ligand (**Devane et al., 1992**). This led to the purification of N-*arachidonylethanolamide*, an eicosanoid mediator (see **Ch. 17**), the structure of which is shown in **Fig. 18.1**. This was christened *anandamide*. [3] Anandamide not only displaced labelled cannabinoid from synaptosomal membranes in the binding assay, but also inhibited nerve evoked twitches of mouse vas deferens, a bioassay for CB_1 receptor ligands (**Fig. 18.3**). A few years later, a second endocannabinoid, *2-arachidonoyl glycerol* (2-AG, see **Fig. 18.1**), was identified, and more recently at least three further endocannabinoid candidates – all arachidonic acid derivatives – with distinct CB_1/CB_2 receptor selectivities have been added to the list (see **Table 18.1**). Endocannabinoids are made 'on demand', like other eicosanoids (see **Ch. 17**), rather than being presynthesised and stored for release when needed.

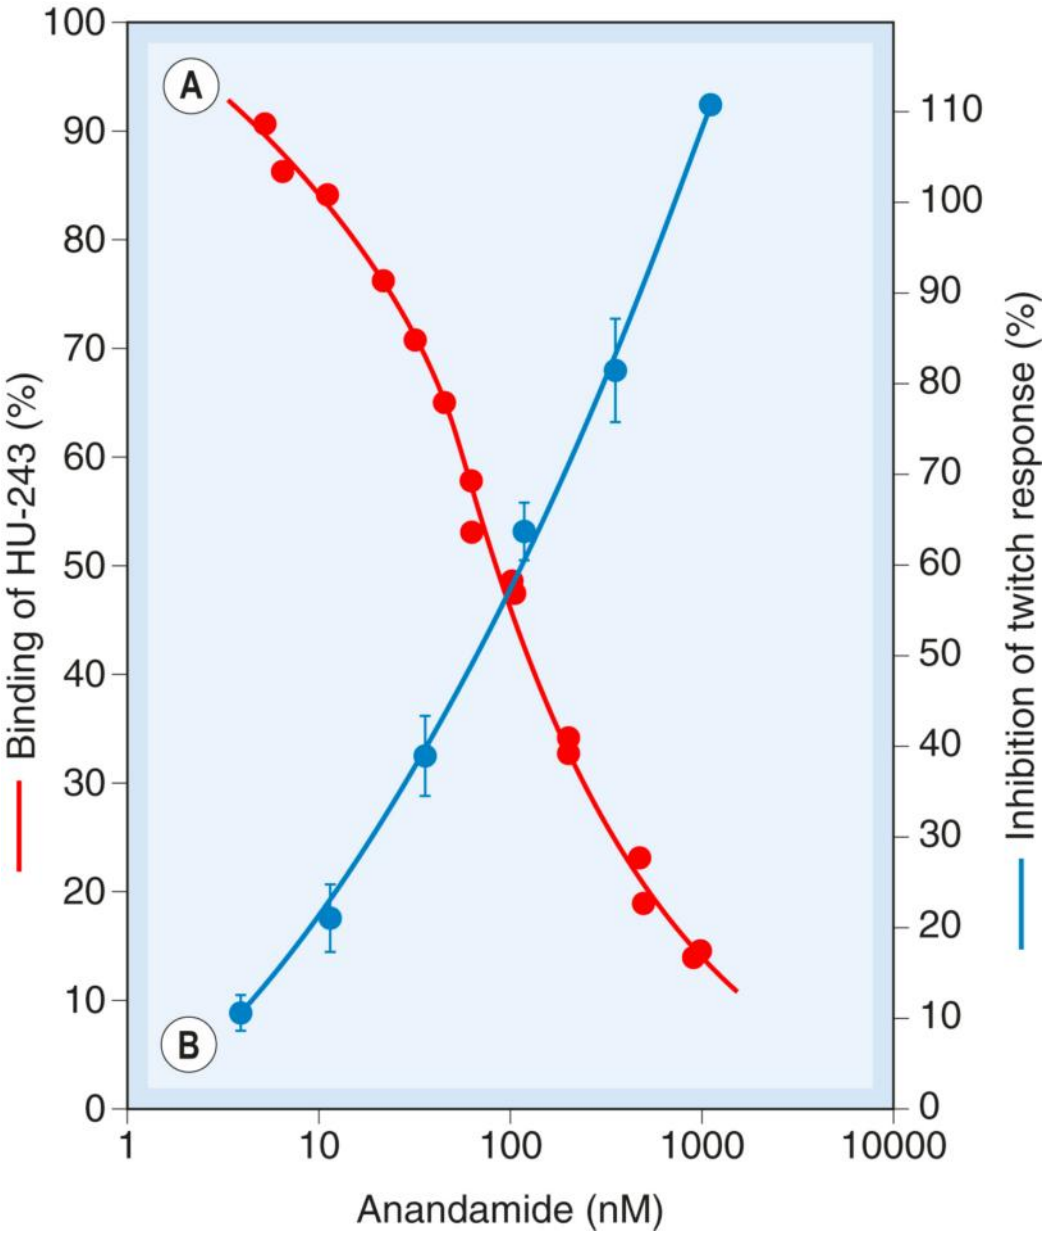

FIG. 18.3 Anandamide as an endocannabinoid.Anandamide is an endogenous cannabinoid. (A) Competitive inhibition of tritiated HU-243 (a cannabinoid receptor ligand) binding to synaptosomal membranes from rat brain by natural anandamide *(red circles, left-hand ordinate axis)*. (B) Inhibition of vas

deferens twitch response (a bioassay for cannabinoids) by natural anandamide *(blue symbols, right-hand ordinate)*. Note the concordance between the binding and bioactivity. Redrawn from **Devane, W.A., Hanu, L., Breurer, A., et al., 1992**. Isolation and structure of a brain constituent that binds to the cannabinoid receptor. Science 258, 1946–1949.

Biosynthesis of Endocannabinoids

The biosynthesis of anandamide and of 2-AG is summarised in **Fig. 18.4**. A fuller account of biosynthesis and degradation is given by **Di Marzo (2008)**.

Anandamide is formed by a distinct phospholipase D (PLD) selective for *N*-acyl-phosphatidylethanolamine (NAPE) but with low affinity for other membrane phospholipids, and is known as NAPE-PLD. NAPE-PLD is a zinc metallohydrolase that is stimulated by Ca^{2+} and also by polyamines. Selective inhibitors for NAPE-PLD are being sought. The precursors are produced by an as-yet-uncharacterised but Ca^{2+}-sensitive transacylase that transfers an acyl group from the *sn*-1 position of phospholipids to the nitrogen atom of phosphatidylethanolamine.

2-AG is also produced by hydrolysis of precursors derived from phospholipid metabolism. The key enzymes are two *sn*-1-selective diacylglycerol lipases (DAGL-α and DAGL-β), which belong to the family of serine lipases. Both these enzymes, like NAPE-PLD, are Ca^{2+} sensitive, consistent with intracellular Ca^{2+} acting as the

physiological stimulus to endocannabinoid synthesis. The DAGLs are located presynaptically in axons during fetal development, but postsynaptically in dendrites and neuron cell bodies in adult brain. This is consistent with a role for 2-AG in neurite growth, and with a role as a retrograde mediator (see later) in adults.

Little is known about the biosynthesis of the more recent endocannabinoid candidates noladin, virodhamine and *N*-arachidonoyl dopamine. pH-dependent non-enzymatic interconversion of virodhamine and anandamide is one possibility and could result in a switch between CB_2- and CB_1-mediated responses (see **Table 18.1**).

Termination of the Endocannabinoid Signal

Endocannabinoids are rapidly taken up from the extracellular space. Being lipid-soluble, they diffuse through plasma membranes down a concentration gradient. There is also evidence for a saturable, temperature-dependent, facilitated transport mechanism for anandamide and 2-AG, dubbed the 'endocannabinoid membrane transporter', for which selective uptake inhibitors (e.g. UCM-707) have been developed. Pathways of endocannabinoid metabolism are summarised in **Fig. 18.4**. The key enzyme for anandamide metabolism is a microsomal serine hydrolase known as fatty acid amide hydrolase (FAAH). FAAH converts anandamide to arachidonic acid plus ethanolamine and also hydrolyses 2-AG, yielding arachidonic acid and glycerol.

The phenotype of FAAH 'knock-out' mice gives some clues to endocannabinoid physiology; such mice have an increased brain content of anandamide and an increased pain threshold. Selective

inhibitors of FAAH [4] have analgesic and anxiolytic properties in mice (see **Ch. 45** for an explanation of how drugs are tested for anxiolytic properties in rodents). In contrast to anandamide, brain content of 2-AG is not increased in FAAH knock-out animals, indicating that another route of metabolism of 2-AG such as via monoacylglycerol lipase (MAGL; **Fig 18.4**) is likely to be important. Endocannabinoid pharmacology suggests that inhibitors of FAAH and/or of MAGL might have therapeutically useful effects in a wide range of disease states and several have been investigated in humans but thus far without positive outcomes (reviewed by **van Egmond et al., 2021**). Other possible routes of metabolism include esterification, acylation and oxidation by cyclo-oxygenase-2 to prostaglandin ethanolamides ('prostamides'), or by 12- or 15-lipoxygenase (see **Ch. 17**).

Physiological Mechanisms

Stimuli that release endocannabinoids, leading to activation of CB_1 receptors and the linkage to downstream events including behavioural or psychological effects, are incompletely defined. Increased intracellular Ca^{2+} concentration is probably an important cellular trigger because, as mentioned earlier, Ca^{2+} activates NAPE-PLD and other enzymes involved in endocannabinoid biosynthesis.

Activation of CB_1 receptors is implicated in a phenomenon known as *depolarisation-induced suppression of inhibition* (DSI). DSI occurs in hippocampal pyramidal cells; when these are depolarised by an excitatory input, this suppresses the GABA-mediated inhibitory input to the pyramidal cells, implying a retrograde flow of information from the depolarised pyramidal cell to inhibitory axons

terminating on it. Such a reverse flow of information from post- to presynaptic cell is a feature of other instances of neuronal plasticity, such as 'wind-up' in nociceptive pathways (see **Fig. 43.2**) and long-term potentiation in the hippocampus (see Figs 38.3 and 38.6). DSI is blocked by the CB_1 antagonist **rimonabant.** The presynaptic location of CB_1 receptors and cellular distributions of the DAGL and monoacyl glycerol lipase (MAGL) enzymes mentioned earlier (and see **Fig. 18.4**) fit nicely with the idea that the endocannabinoid 2-AG is a 'retrograde' messenger in DSI.

The neuromodulatory actions of endocannabinoids could influence a wide range of physiological activities, including nociception, cardiovascular, respiratory and gastrointestinal function. Interactions of endocannabinoids with hypothalamic hormones are believed to influence food intake and reproductive function. Mouse models lacking CB receptor subtypes (CB_1 or CB_2) support important and balanced roles of endocannabinoid signalling in male and female fertility. Such signalling is implicated in spermatogenesis, fertilisation, preimplantation development of the early embryo, implantation and postimplantation growth of the embryo (each receptor subtype is involved in specific aspects, see **Battista et al., 2012**). The effects of endocannabinoids on food intake (and phytocannabinoids: a strong desire for food following cannabis consumption is known colloquially as the 'munchies') are of particular interest, because of the importance of obesity (see **Ch. 32**).

Pathological Involvement

There is evidence, both from experimental animals and from human tissue, that endocannabinoid signalling is abnormal in multiple sclerosis (see **Ch. 40**) and other neurodegenerative diseases. Other diseases where abnormalities of cannabinoid signalling are implicated include haemorrhagic and septic forms of hypotensive shock (see **Ch. 21**), advanced cirrhosis of the liver (where there is evidence that vasodilatation is mediated by endocannabinoids acting on vascular CB_1 receptors – see **Bátkai et al., 2001**), miscarriage (see **Battista et al., 2012**) and

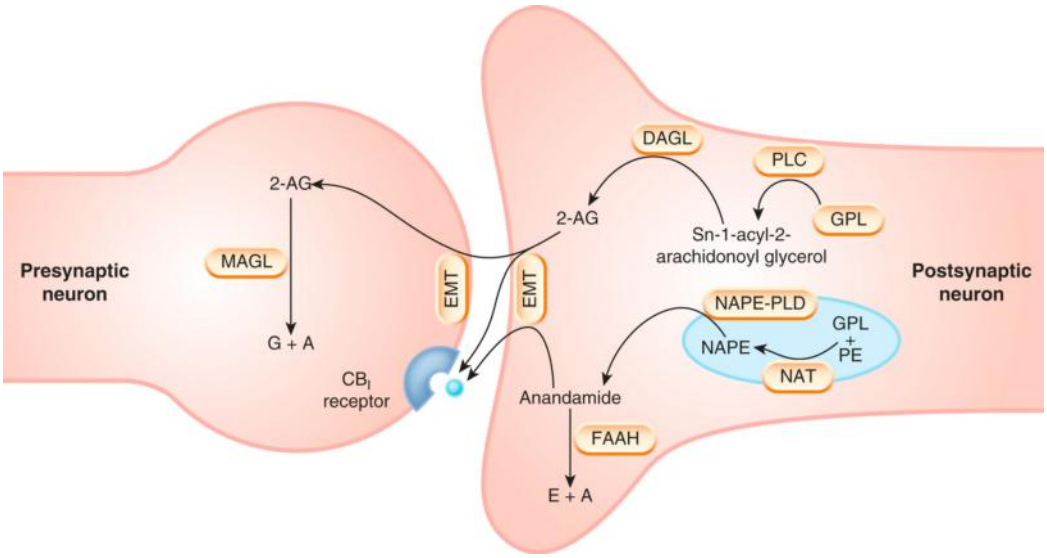

FIG. 18.4 Biosynthesis and inactivation of endocannabinoids. *2-AG,* 2-arachidonoyl glycerol; *A,* arachidonic acid; *DAGL,* diacylglycerol lipase; *E,* ethanolamine; *EMT,* endocannabinoid membrane transporter; *FAAH,* fatty acid amide hydrolase; *G,* glycerol; *GPL,* glycerophospholipid; *MAGL,* monoacyl glycerol lipase; *NAPE, N*-acyl-phosphatidylethanolamine; *NAPE-PLD, N*-acyl phosphatidylethanolamine-specific phospholipase D; *NAT*, *N*-acyl-transferase; *PE,* phosphatidylethanolamine; *PLC,* phospholipase C.

The endocannabinoid system

- Cannabinoid receptors (CB_1, CB_2) are G protein–coupled ($G_{i/o}$) receptors.

- CB_1 receptors are located especially on presynaptic nerve terminals. They are abundant in the CNS but not in the brainstem.
- Activation of CB_1 inhibits adenylyl cyclase and plasma membrane calcium channels, and activates potassium channels, inhibiting synaptic transmission.
- The CB_2 receptor is expressed in cells of the immune system, and its expression is also upregulated in the CNS in some pathological conditions.
- Selective agonists and antagonists have been developed for both CB_1 and CB_2 receptors.
- Endogenous ligands for CB receptors are known as endocannabinoids. They are eicosanoid mediators (see **Ch. 17**).
- The best-established endocannabinoids are anandamide and 2-arachidonoyl glycerol (2-AG), which have many roles and can function as 'retrograde' mediators passing information from postsynaptic to presynaptic neurons for example in DSI in hippocampal pyramidal neurons.
- The main enzyme that inactivates anandamide is FAAH.
- An 'endocannabinoid membrane transporter' transports cannabinoids from postsynaptic neurons, where they are synthesised, to the synaptic cleft, where they access presynaptic CB_1 receptors, and into presynaptic terminals, where 2-AG is metabolised.
- FAAH 'knock-out' mice have an increased brain content of anandamide and an increased pain threshold; selective

inhibitors of FAAH have analgesic and anxiolytic properties, implicating endocannabinoids in nociception and anxiety.

malignant disease. It seems likely that endocannabinoid activation evolved as a protective mechanism but can become 'too much of a good thing' and actually contribute to disease progression. Consequently, there may be a place in therapeutics for drugs that potentiate or inhibit the cannabinoid system (see **Pertwee, 2015**, for a fuller discussion).

Synthetic Cannabinoids

Cannabinoid receptor agonists were developed in the 1970s in the hope that they would prove useful non-opioid/non-NSAID (non-steroidal anti-inflammatory drug) analgesics (cf. Chs **43** and **25**, respectively, for limitations of opioids and NSAIDs), but adverse effects, particularly sedation and memory impairment, were problematic. Nevertheless, one such drug, **nabilone**, is sometimes used clinically to reduce nausea and vomiting caused by cytotoxic chemotherapy if this is unresponsive to conventional antiemetics (see **Ch. 30**). Furthermore, synthetic cannabinoid receptor agonists (SCRAs; sometimes referred to as 'spice') have become major drugs of abuse especially amongst the homeless population and those in prison (see **Ch. 49**). The cloning of CB_2 receptors, and their absence from healthy neuronal brain cells, led to the synthesis of CB_2-selective agonists in the hope that these would lack the CNS-related adverse effects of plant cannabinoids. Several such drugs are being investigated for possible use in inflammatory and neuropathic pain.

The first selective CB_1 receptor antagonist, **rimonabant**, also has inverse agonist properties in some systems. It was licensed in Europe for treating obesity, and there were hopes that it would help promote abstinence from tobacco, but it was withdrawn because it caused psychiatric problems including depression. Synthetic inhibitors of endocannabinoid uptake and/or metabolism have shown potentially useful effects in animal models of pain, epilepsy, multiple sclerosis, Parkinson's disease, anxiety and diarrhoea.

In addition to central CB_1 receptors, hepatocyte CB_1 receptors are also implicated in obesity and in non-alcoholic fatty liver disease, and research on selective peripheral antagonists and allosteric modulators is encouraging (**Nguyen et al., 2019**; **Rohbeck et al., 2021**).

Clinical Applications

Clinical uses of drugs that act on the cannabinoid system remain controversial, but in both the United Kingdom and the United States, cannabinoids have been used as antiemetics and to encourage weight gain in patients with chronic disease such as HIV/AIDS and malignancy. Cannabis extract (**nabiximols** – which contains similar amounts of THC and CBD) is used to treat spasticity, neuropathic pain and other symptoms in patients with multiple sclerosis (see **Borgelt et al., 2013**). Adverse events are generally mild at the doses used. Endocannabinoids have been implicated in shock and hypotension in liver disease (**Malinowska et al., 2008**), and modulation of this system is a potential therapeutic target. Prescription formulations of CBD are now licensed for treatment of Dravet's syndrome, Lennox-Gastaut

syndrome and seizures caused by tuberous sclerosis, rare and horrible diseases of infants where uncontrollable seizures are both a symptom of disease and, via the phenomenon of excitotoxicity (see **Ch. 40**), causes of disease progression. A study from the group of Julius Axelrod in 1998 showed that both CBD and THC possessed neuroprotective antioxidant properties (**Hampson et al., 1998**), so there is enormous general interest in the long-term outcome of such treatment. Other potential clinical uses are given in the following 'Potential and actual clinical uses of cannabinoids' box.

Potential and actual clinical uses of cannabinoids

Cannabis extract (nabiximols, containing CBD and THC) is licensed as an adjunct for experts treating spasticity in multiple sclerosis.

CBD is licensed for treatment of Dravet's syndrome, Lennox-Gastaut syndrome and tuberous sclerosis complex – rare neurological diseases of infants associated with intractable seizures.

Nabilone, a synthetic cannabinoid agonist is licensed for nausea/vomiting associated with cancer chemotherapy

Cannabinoid-related drugs are undergoing evaluation for a wide range of possible indications, including:

- Agonists:
  - cancer and AIDS (to reduce weight loss)
  - neuropathic pain
  - head injury

  - glaucoma
  - Tourette syndrome (to reduce tics – rapid involuntary movements that are a feature of this disorder)
  - Parkinson's disease (to reduce involuntary movements caused as an adverse effect of **levodopa**; see **Ch. 40**)
- CBD
  - seizure disorders
  - anxiety
  - drug and alcohol dependence
- Antagonists:
  - obesity
  - tobacco dependence
  - drug addiction
  - alcoholism.

QUESTIONS

QUESTION 18.1

Cannabinoid CB_1 receptors found in the central nervous system (CNS) and CB_2 receptors in the periphery are typical members of the family of G protein–coupled receptors.

Which of the following mechanisms is not mediated by CB_1 receptors?

OPTIONS:

A. Inhibition of transmitter release from presynaptic terminals

B. Activation of mitogen activated protein kinases

C. Activation of adenylyl cyclase

D. Activation of G protein–sensitive inwardly rectifying potassium (GIRK) channels

E. Inhibition of voltage-operated calcium channels

QUESTION 18.2

THC, the main active component of cannabis, acts mainly on the CNS, producing a mixture of psychotomimetic and depressant

effects, together with various centrally mediated autonomic effects.

Which of the following is not a major side effect of cannabis use?

OPTIONS:

A. Dependence

B. Drowsiness

C. Memory impairment

D. Catalepsy

E. Hypothermia

ANSWERS

ANSWER 18.1

RATIONALE:

A. In the brain CB_1 receptors are mainly localised presynaptically, and inhibit transmitter release.

B. CB_1 receptors influence gene expression by activating mitogen-activated protein kinase and inhibiting protein kinase A (PKA) via a decrease in cAMP.

C.

D. CB_1 receptor activation results in activation of G protein–sensitive inwardly rectifying potassium (GIRK) channels, causing membrane hyperpolarisation.

E. CB_1 receptor activation results in inhibition of voltage-operated calcium channels inhibiting transmitter release.

Correct answer with explanation:

C. Activation of adenylyl cyclase

CB_1 receptors are linked via $G_{i/o}$ to inhibition of adenylyl cyclase.

ANSWER 18.2

RATIONALE:

A.

B. In acute overdose, THC can produce drowsiness and confusion but not life-threatening respiratory or cardiovascular depression.

C. Memory impairment – objective tests show impairment of learning, memory and motor performance, including impaired driving ability.

D. Catalepsy – the adoption of fixed unnatural postures.

E. Hypothermia – shown in animal models and partly due to vasodilatation.

CORRECT ANSWER WITH EXPLANATION:

A. Dependence

Psychological dependence does occur to a minor degree with cannabis, but it is less compelling than with the major drugs of abuse, although dependence is increasing in parallel with use of higher THC content material.

---

[1] Cannabis is now legal in Canada, Mexico, South Africa and Uruguay as well as in 18 states in the United States. Its use has been decriminalized in many countries (see https://en.wikipedia.org/wiki/Legality_of_cannabis#A), but not in some mid-Eastern and E Asian countries where long prison terms are imposed for possession of cannabis and related products.

[2] Surprising, because capsaicin, the active principle of chili peppers, causes intense burning pain via activation of these receptors, whereas the endocannabinoid anandamide is associated with pleasure, or even bliss…so perhaps not so surprising after all!

[3] From a Sanskrit word meaning ‘bliss’ + amide.

[4] Several such drugs have been administered to humans (van Egmond et al., 2021). One drug, BIA 10-2474, caused severe CNS damage during a trial involving repeated dosing of healthy volunteers in Rennes, France. BIA 10-2474 is less selective than another FAAH inhibitor which was innocuous in earlier trials, inhibiting several lipases that are not targeted by the more selective drug. This suggests that promiscuous lipase inhibitors can cause metabolic dysregulation in the nervous system due to off-target toxicity (see van Esbroeck et al., 2017).

19: Nitric oxide and related mediators

OVERVIEW

Nitric oxide (NO) is a ubiquitous mediator with diverse functions. It is generated from L-arginine by NO synthase (NOS), an enzyme that occurs in endothelial, neuronal and inducible isoforms. In this chapter, we concentrate on general aspects of NO, especially its biosynthesis, degradation and effects. We touch on evidence that it can act as a circulating as well as local mediator and conclude with a brief consideration of the therapeutic potential of drugs that act on the L-arginine/NO pathway. Other gaseous mediators (carbon monoxide, hydrogen sulfide) [1] are described briefly: while they have yet to yield therapeutic drugs, their pathways are possible drug targets.

Introduction

NO, a free radical gas, is formed in the atmosphere during lightning storms. Less dramatically, but with far-reaching biological consequences, it is also formed in an enzyme-catalysed reaction between molecular oxygen and L-arginine. The convergence of several lines of research led to the realisation that NO is a key

signalling molecule in the cardiovascular and nervous systems, and that it has a role in host defence.

A physiological function of NO emerged when biosynthesis of this gas was shown to account for the *endothelium-derived relaxing factor* described by **Furchgott and Zawadzki (1980)** (**Figs 19.1** and **19.2**). NO is the endogenous activator of soluble guanylyl cyclase, leading to the formation of cyclic guanosine monophosphate (cGMP), an important 'second messenger' (see **Ch. 3**) in many cells, including neurons, smooth muscle, monocytes and platelets. Nitrogen and oxygen are neighbours in the periodic table, and NO shares several properties with O_2, in particular a high affinity for haem and other iron–sulfur groups. This is important for activation of guanylyl cyclase, which contains a haem group, for the inactivation of NO by haemoglobin and for the regulation of diffusion of NO from endothelial cells (which express the alpha chain of haemoglobin) to vascular smooth muscle.

The role of NO in specific settings is described in other chapters: the endothelium in **Chapter 21**, the autonomic nervous system (see **Ch. 13**) and as a chemical transmitter and mediator of excitotoxicity in the central nervous system (CNS) in **Chapters 37–39**. Therapeutic uses of organic nitrates and of nitroprusside (NO donors) are described in **Chapters 20** and **21**.

Biosynthesis of Nitric Oxide and its Control

NOS enzymes are central to the control of NO biosynthesis. There are three isoforms: an *inducible* form (iNOS or NOS2) which is expressed in macrophages and Kupffer cells, neutrophils,

fibroblasts, vascular smooth muscle and endothelial cells in response to pathological stimuli such as invading microorganisms (e.g. during sepsis, severe organ dysfunction leading to circulatory shock – see **Ch. 21** – due to a dysregulated host response to infection); and two *constitutive* forms, which are present under physiological conditions in endothelium (eNOS or NOS3) [2] and in neurons (nNOS or NOS1). [3] The constitutive enzymes generate small amounts of NO, whereas NOS2 produces much greater amounts, both because of its high activity and because of its abundance in pathological states associated with cytokine release. All three NOS isoenzymes are dimeric flavoproteins, contain tetrahydrobiopterin and have homology with cytochrome P450.

The activity of constitutive isoforms of NOS is controlled by intracellular calcium–calmodulin (**Fig. 19.3**). L-Arginine, the substrate of NOS, is usually present in excess in endothelial cell cytoplasm, so the rate of production of NO is determined by the activity of the enzyme rather than by substrate availability. Nevertheless, very high doses of L-arginine can restore endothelial NO biosynthesis in some pathological states (e.g. hypercholesterolaemia) in which endothelial function is impaired. Possible explanations for this paradox include:

- compartmentation: i.e. existence of a distinct pool of substrate in a cell compartment with access to NOS, which can become depleted despite apparently plentiful total cytoplasmic arginine concentrations;
- competition by high concentrations of L-arginine with endogenous competitive inhibitors of NOS such as *asymmetric dimethylarginine* (ADMA; see later and **Fig.**

19.4), which is elevated in plasma from patients with hypercholesterolaemia;
- recoupling of electron transfer to L-arginine.

Control of constitutive NOS activity by calcium–calmodulin is exerted in two ways:

1. Many endothelium-dependent agonists (e.g. acetylcholine, bradykinin, substance P) increase the cytoplasmic concentration of calcium ions $[Ca^{2+}]_i$; the consequent increase in calcium–calmodulin activates NOS1 and NOS3.

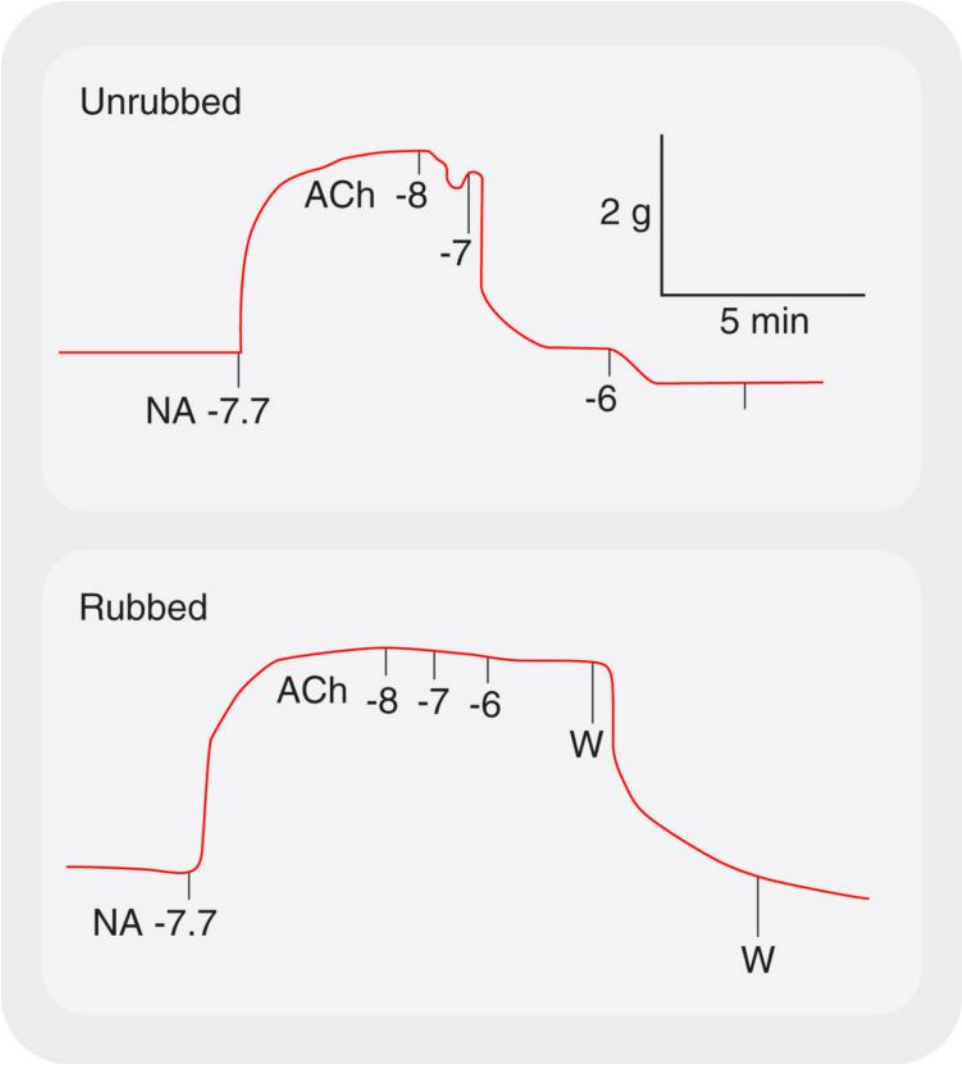

FIG. 19.1 Endothelium-derived relaxing factor.Acetylcholine (ACh) relaxes a strip of rabbit aorta precontracted with noradrenaline (NA) if the endothelium is intact *('unrubbed': upper panel)*, but not if it has been removed by gentle rubbing *('rubbed': lower panel)*. The numbers are logarithms of molar concentrations of drugs. From Furchgott, R.F., Zawadzki, J.V., 1980. The obligatory role of endothelial cells

in the relaxation of arterial smooth muscle by acetylcholine. Nature 288, 3734.

2. Phosphorylation of specific residues on NOS3 controls its sensitivity to calcium–calmodulin; this can alter NO synthesis in the absence of any change in $[Ca^{2+}]_i$.

Shear stress is an important physiological stimulus to endothelial NO synthesis in resistance vessels. This is sensed by endothelial mechanoreceptors and transduced via a serine–threonine protein kinase called Akt (see **Ch. 3**) which is also known as protein kinase B. Agonists that increase cAMP in endothelial cells (e.g. β_2-adrenoceptor agonists) increase NOS3 activity, via protein kinase A–mediated phosphorylation [4] whereas protein kinase C *reduces* NOS3 activity by phosphorylating residues in the calmodulin-binding domain, thereby reducing the binding of calmodulin. Insulin increases NOS3 activity via tyrosine kinase activation (and also increases the expression of NOS1 in diabetic mice).

In contrast to constitutive NOS isoforms, the activity of NOS2 is effectively independent of $[Ca^{2+}]_i$, being fully activated even at the low values of $[Ca^{2+}]_i$ present under resting conditions. The enzyme is induced by bacterial lipopolysaccharide and inflammatory cytokines, notably interferon-γ, the antiviral effect of which is due to this. Tumour necrosis factor-α and interleukin-1 do not alone induce NOS2, but they each synergise with interferon-γ in this regard (see **Ch. 17**). Induction of NOS2 is inhibited by glucocorticoids and by several cytokines, including transforming growth factor-β. There are important species differences in the

inducibility of NOS2, which is less readily induced in human than in mouse cells.

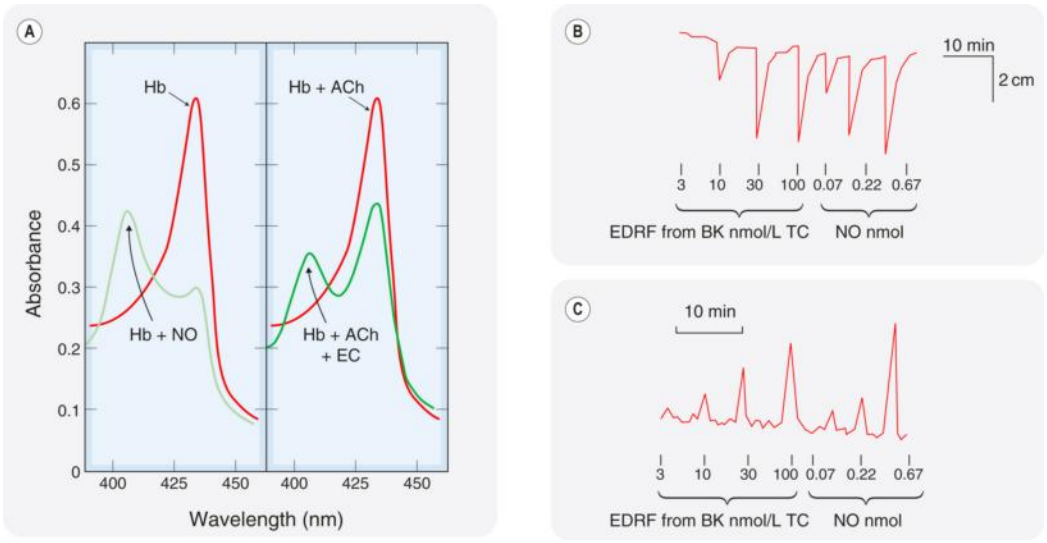

FIG. 19.2 Endothelium-derived relaxing factor (EDRF) is closely related to nitric oxide (NO).(A) EDRF released from aortic endothelial cells (EC) by acetylcholine (ACh) *(right panel)* has the same effect on the absorption spectrum of deoxyhaemoglobin (Hb) as does authentic NO *(left panel)*. (B) EDRF is released from a column of cultured ECs by bradykinin (BK; 3–100 nmol) applied through the column of cells (TC) and relaxes a de-endothelialised precontracted bioassay strip, as does authentic NO (upper trace). (C) A chemical assay of NO based on chemiluminescence shows that similar concentrations of NO are present in the EDRF released from the column of cells as in equiactive authentic NO solutions. From Ignarro, L.J., Byrns, R.E., Buga, G.M., et al., 1987. Circ. Res. 61, 866–879; and Palmer, R.M.J., Ferrige,

A.G., Moncada, S., et al., 1987. Nature 327, 524–526.

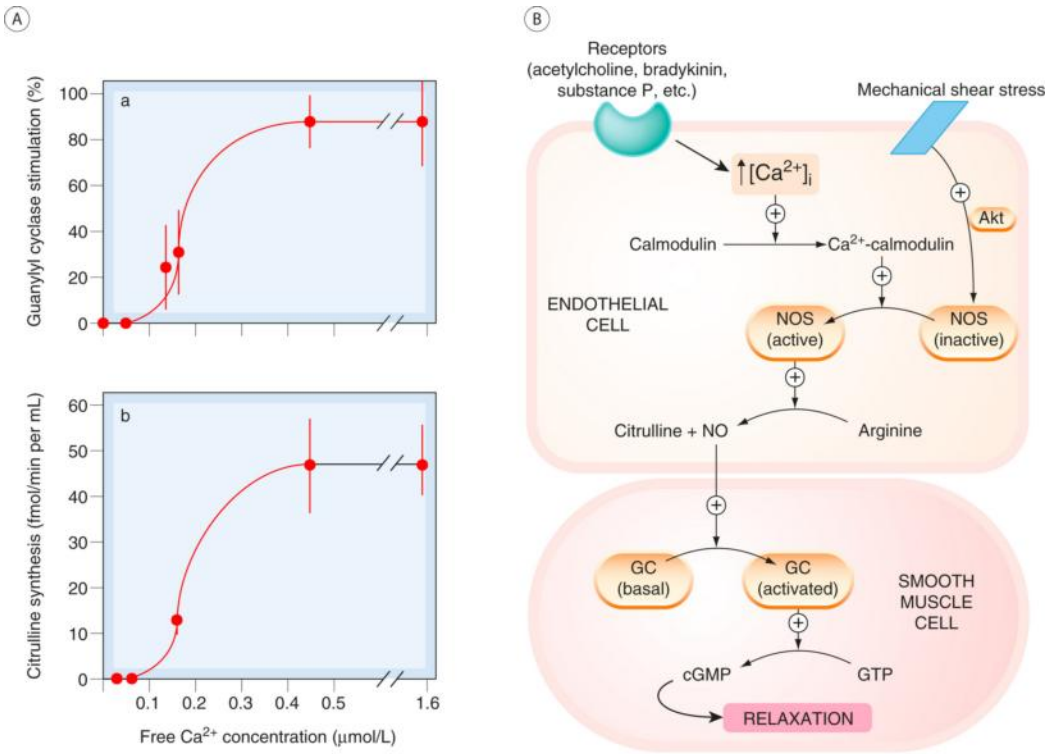

FIG. 19.3 Control of constitutive nitric oxide synthase (NOS) by calcium–calmodulin.(A) Dependence on Ca^{2+} of nitric oxide (NO) and citrulline synthesis from L-arginine by rat brain synaptosomal cytosol. Rates of synthesis of NO from L-arginine were determined by stimulation of guanylyl cyclase (GC) *(upper panel)* or by synthesis of [^{3}H]-citrulline from L-[^{3}H]-arginine *(lower panel)*. (B) Regulation of GC in smooth muscle by NO formed in adjacent endothelium. Akt is a protein kinase that phosphorylates NOS, making it more sensitive to calcium–calmodulin. Panel [A] from Knowles, R.G., et al., 1989. Proc. Natl. Acad. Sci. U. S. A. 86, 5159–5162.

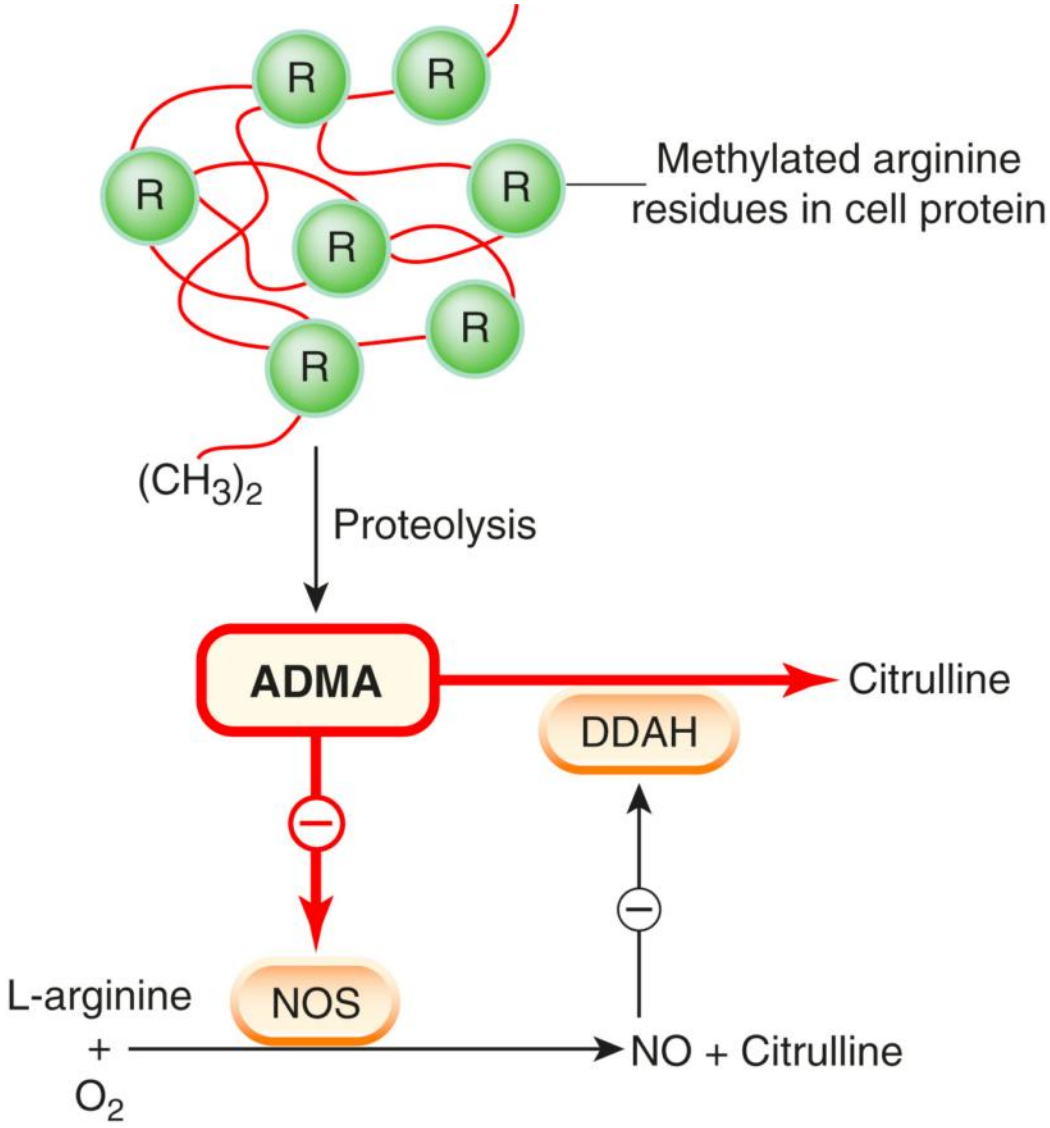

FIG. 19.4 Control of NOS by asymmetric dimethylarginine (ADMA). *DDAH,* Dimethylarginine dimethylamino hydrolase; *NO,* nitric oxide; *NOS,* nitric oxide synthase.

Degradation and Carriage of Nitric Oxide

NO reacts with oxygen to form N_2O_4, which combines with water to produce a mixture of nitric and nitrous acids. Nitrite ions are

oxidised to nitrate by oxyhaemoglobin. These reactions are summarised as follows:

$$2NO + O_2 \rightarrow N_2O_4 \quad \textbf{(19.1)}$$

$$N_2O_4 + H_2O \rightarrow NO_3^- + NO_2^- + 2H^+ \quad \textbf{(19.2)}$$

$$NO_2^- + HbO \rightarrow NO_3^- + Hb \quad \textbf{(19.3)}$$

Low concentrations of NO are relatively stable in air, because the rate of reaction shown in **Eq. 19.1** depends on the square of the NO concentration, so small amounts of NO produced in the lung escape degradation and can be

Nitric oxide: synthesis, inactivation and carriage

- NO is synthesised from L-arginine and molecular O_2 by NOS.
- NOS exists in three isoforms: inducible (NOS2) and constitutive 'endothelial' (NOS3, which is not restricted to endothelial cells) and neuronal (NOS1) forms. NOSs are dimeric flavoproteins, contain tetrahydrobiopterin and have homology with cytochrome P450. The constitutive enzymes

are activated by calcium–calmodulin. Sensitivity to calcium–calmodulin is controlled by phosphorylation of specific residues on the enzymes.

- NOS2 is induced in macrophages and other cells by inflammatory cytokines, especially interferon-γ.
- NOS1 is present in the central nervous system (see Chs **37**–**39**) and in some autonomic nerves (see **Ch. 13**).
- NOS3 is present in platelets and other cells in addition to endothelium.
- NO diffuses to sites of action in neighbouring cells. This is regulated by the redox state of haemoglobin alpha which is present in the myoendothelial junctions that act as diffusion corridors across the internal elastic lamina (and in other cells): signalling can occur when the haem is in the Fe^{3+} state but is stopped – like at a red traffic light – when haem is in the Fe^{2+} state.
- NO is inactivated by combination with the haem of haemoglobin or by oxidation to nitrite and nitrate, which are excreted in urine; it is also present in exhaled air, especially in patients who have exacerbations of their asthma.
- NO can react reversibly with cysteine residues (e.g. in globin or albumin) to form stable nitrosothiols; as a result, red cells can act as an O_2-regulated source of NO. NO released in this way escapes inactivation by haem by being exported via cysteine residues in the anion exchange protein in red cell membranes.

detected in exhaled air. Exhaled NO is increased in patients who have airway inflammation. Measurement of 'fractional exhaled NO' is used in clinical services to diagnose patients with suspected asthma, and to guide drug therapy for better control of the inflamed airways.

Effects of Nitric Oxide

NO reacts with various metals, thiols and oxygen species, thereby modifying proteins, DNA and lipids. One of its most important biochemical effects (see **Ch. 3**) is activation of soluble guanylyl cyclase, a heterodimer present in vascular and nervous tissue as two distinct isoenzymes. Guanylyl cyclase synthesises the second messenger cGMP. NO activates the enzyme by combining with its haem group, and many physiological effects of low concentrations of NO are mediated by cGMP. These effects are prevented by inhibitors of guanylyl cyclase (e.g. 1H-[1,2,4]-oxadiazole-[4,3-α]-quinoxalin-1-one, better known as 'ODQ'), which are useful investigational tools. NO activates soluble guanylyl cyclase in intact cells (neurons and platelets) extremely rapidly, and activation is followed by desensitisation to a steady-state level. This contrasts with its effect on the isolated enzyme, which is slower but more sustained. Guanylyl cyclase contains another regulatory site, which is NO independent. This is activated by **riociguat**, used to treat some forms of pulmonary hypertension, and **vericiguat** for treatment of heart failure (see **Ch. 21**).

The effects of cGMP are terminated by phosphodiesterase enzymes. **Sildenafil** and **tadalafil** are inhibitors of phosphodiesterase type V. They are used to treat erectile

dysfunction and work by potentiating NO actions in the corpora cavernosa of the penis by this mechanism (see **Ch. 35**). NO also combines with haem groups in other biologically important proteins, notably cytochrome c oxidase, where it competes with oxygen, contributing to the control of cellular respiration (see **Erusalimsky and Moncada, 2007**). Cytotoxic and/or cytoprotective effects of higher concentrations of NO relate to its chemistry as a free radical (see **Ch. 40**).

Biochemical and Cellular Aspects

The pharmacological effects of NO can be studied with NO gas dissolved in deoxygenated salt solution. More conveniently, but less directly, various donors of NO, such as **nitroprusside**, S-*nitrosoacetylpenicillamine* (SNAP) or S-*nitrosoglutathione* (SNOG), have been used as surrogates. This has pitfalls; for example, ascorbic acid potentiates SNAP but inhibits responses to authentic NO. [5]

NO can activate guanylyl cyclase in the same cells that produce it, giving rise to autocrine effects, for example on the barrier function of the endothelium. NO also diffuses from its site of synthesis and activates guanylyl cyclase in neighbouring cells. The resulting increase in cGMP affects protein kinase G, ion channels and possibly other proteins, inhibiting $[Ca^{2+}]_i$-induced smooth muscle contraction and platelet aggregation. NO hyperpolarises vascular smooth muscle as a consequence of potassium-channel activation, and inhibits monocyte adhesion and migration, adhesion and aggregation of platelets, and smooth muscle and fibroblast

proliferation. These cellular effects probably underlie the anti-atherosclerotic action of NO (see **Ch. 22**).

Large amounts of NO (released following induction of NOS or excessive stimulation of *N*-methyl-D-aspartate [NMDA] receptors in the brain, see Chs **39** and **40**) cause cytotoxic effects, either directly or via formation of peroxynitrite. Such cytotoxicity contributes to host defence, but also to the neuronal cell death that occurs when there is overstimulation of NMDA receptors by glutamate (see Chs **38** and **40**). Paradoxically, NO is also cytoprotective under some circumstances (see **Ch. 40**).

Vascular Effects (see also Ch. 21)

The L-arginine/NO pathway is tonically active in resistance vessels, reducing peripheral vascular resistance and hence systemic blood pressure. Genetically altered mice that lack coding for NOS3 are hypertensive, consistent with a role for NO biosynthesis in the physiological control of blood pressure. In addition, NO derived from NOS1 is implicated in the control of basal resistance vessel tone in human forearm and cardiac muscle vascular beds (**Seddon et al., 2008**, **2009**). NO is believed to contribute to the generalised vasodilatation that occurs during pregnancy. In addition to effects on basal resistance vessel tone and mediating the effects of endothelium-dependent vasodilator agonists such as acetylcholine and substance P, it has more recently been appreciated that NO promotes new vessel formation ('angiogenesis') and vascular remodelling (**Ghimire et al., 2017**; **Kraehling and Sessa, 2017**).

Neuronal Effects (see also Ch. 13)

NO is a non-noradrenergic non-cholinergic (NANC) neurotransmitter in many tissues (see **Fig. 13.5**), including the upper airways, gastrointestinal tract and corpora cavernosa of the penis (Chs **28**, **30** and **35**). It is implicated in the control of neuronal development and of synaptic plasticity in the CNS (Chs **37** and **40**). There also appears to be a role in hippocampal and cortical long-term potentiation (LTP) through NO activation of NMDA receptors mediated by protein kinases. However, there is still considerable debate as to whether NO is protective or harmful in neurodegenerative diseases, particularly in light of the diversity of pathology that afflicts the CNS.

In the eye, NO appears to increase outflow of aqueous humour by relaxing the trabecular meshwork and Schlemm's canal (thus helping to reduce intraocular pressure in patients with glaucoma).

Host Defence (see Ch. 7)

The cytotoxic and/or cytostatic effects of NO are implicated in primitive non-specific host defence mechanisms against numerous pathogens, including viruses, bacteria, fungi, protozoa and parasites, and against tumour cells. The importance of this is evidenced by the susceptibility of mice lacking NOS2 to *Leishmania major* (to which wild-type mice are highly resistant). Mechanisms whereby NO damages invading pathogens include nitrosylation of nucleic acids and combination with haem-containing enzymes, including the mitochondrial enzymes involved in cell respiration.

Actions of nitric oxide

- Nitric oxide (NO) acts by:
  - combining with haem in guanylyl cyclase, activating the enzyme, increasing cGMP and thereby lowering $[Ca^{2+}]_I$;
  - combining with haem groups in other proteins (e.g. cytochrome C oxidase);
  - combining with superoxide anion to yield the cytotoxic peroxynitrite anion;
  - nitrosation of proteins, lipids and nucleic acids.
- Effects of NO include:
  - vasodilatation, inhibition of platelet and monocyte adhesion and aggregation, inhibition of smooth muscle proliferation, protection against atheroma, vascular remodelling and angiogenesis;
  - synaptic effects in the peripheral and central nervous system;
  - host defence and cytotoxic effects on pathogens;
  - cytoprotection.

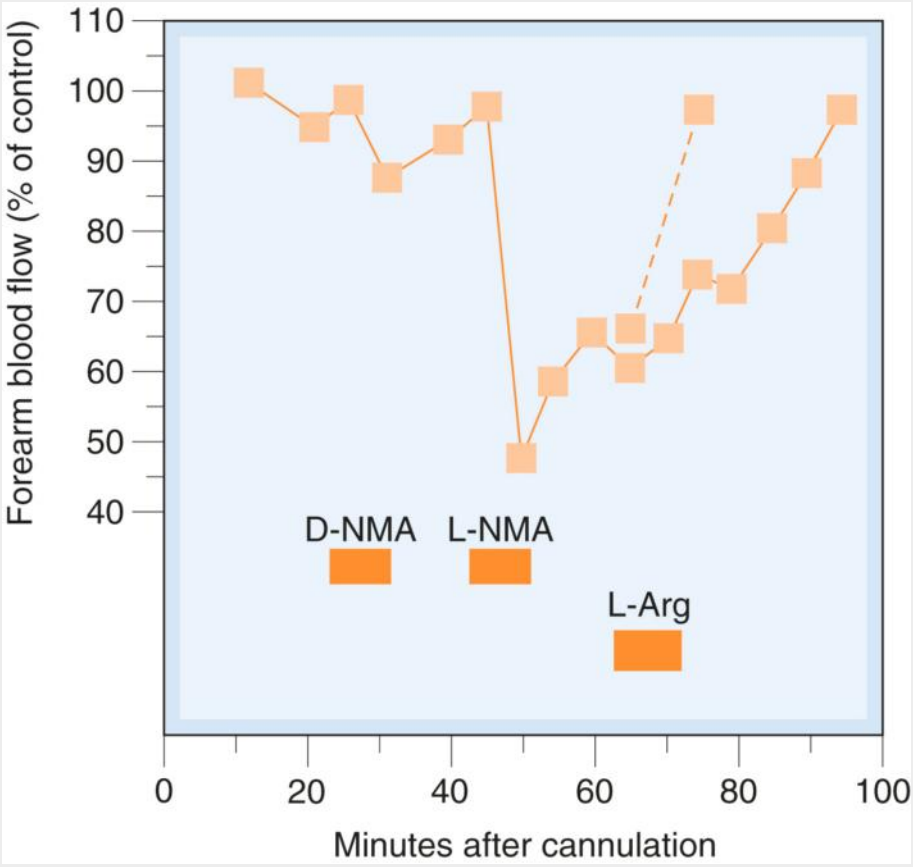

FIG. 19.5 Basal blood flow in the human forearm is influenced by nitric oxide (NO) biosynthesis.Forearm blood flow is expressed as a percentage of the flow in the non-cannulated control arm (which does not change). Brachial artery infusion of the D-isomer of the arginine analogue N^{G}-monomethyl-L-arginine (D-NMA) has no effect, while the L-isomer (L-NMA) causes vasoconstriction. L-arginine (L-Arg) accelerates recovery from such vasoconstriction *(dashed line)*. From Vallance, P., Collier, J., Moncada, S., et al., 1989. Effects of endothelium-derived

nitric oxide on peripheral arteriolar tone in man. Lancet 334, 997–1000.

Therapeutic Aspects

Novel therapeutic approaches under investigation to increase the bioavailability of NO include new ways to increase NOS activity; amplify the nitrate–nitrite–NO pathway, novel classes of NO donors and drugs that limit NO inactivation by reactive oxygen species; and modulate phosphodiesterases and soluble guanylyl cyclases (reviewed by **Lundberg et al., 2015**).

Nitric Oxide

Inhaling high concentrations of NO (as occurred when cylinders of nitrous oxide, N_2O, for anaesthesia were accidently contaminated) causes acute pulmonary oedema and methaemoglobinaemia, but concentrations below 50 ppm (parts per million) are not toxic. NO (5–300 ppm) inhibits bronchoconstriction (at least in guinea pigs), but the main action of low concentrations of inhaled NO in man is pulmonary vasodilatation. Inspired NO acts preferentially on ventilated alveoli, and is used therapeutically in respiratory distress syndrome, including acute hypoxic respiratory failure in newborn babies for which NO has regulatory approval in the United States. This condition is characterised by intrapulmonary ‘shunting’, that is, pulmonary arterial blood passing through non-ventilated alveoli and remaining deoxygenated. This causes arterial hypoxaemia and, because hypoxaemia causes pulmonary arterial vasoconstriction, acute pulmonary arterial hypertension. Inhaled NO dilates blood

vessels in ventilated alveoli (which are exposed to the inspired gas) and thus reduces shunting. NO is used in intensive care units to reduce pulmonary hypertension and to improve oxygen delivery in patients with respiratory distress syndrome, but it is not known whether this improves long-term survival in these severely ill patients.

Nitric Oxide Donors/Precursors

Nitrovasodilators have been used therapeutically for over a century. The common mode of action of these drugs is as a source of NO (see Chs **20** and **21**). There are numerous clinical trials evaluating the vascular effects of dietary inorganic nitrate ions (contained in beetroot juice) on arterial blood pressure as well as other cardiovascular parameters. These studies have yielded mixed findings; equally, trials of beetroot juice have failed to enhance exercise performance in populations as diverse as 5-km runners, basketball and tennis players and patients with heart failure.

Inhibition of Nitric Oxide Synthesis

Drugs can inhibit NO synthesis or action by several mechanisms. Certain arginine analogues compete with arginine for NOS, and the first inhibitors of NOS developed in the 1980s and 1990s were based on the L-arginine substrate. These non-selective inhibitors, for example N^{G}-monomethyl-L-arginine (L-NMMA) and N^{G}-nitro-L-arginine methyl ester (L-NAME), have been used as experimental tools and in clinical trials. Infusion of the non-selective NOS inhibitor L-NMMA into the brachial artery causes local vasoconstriction (**Fig. 19.5**), owing to inhibition of the basal

production of NO in the infused arm, probably partly by inhibiting NOS1 in autonomic nerve fibres (**Seddon et al., 2008**). Intravenous L-NMMA causes vasoconstriction in renal, mesenteric, cerebral and striated muscle resistance vessels, increases blood pressure and causes reflex bradycardia.

Elucidation of the crystal structure of NOS isoforms led to development of selective inhibitors of different isoforms of NOS. Early examples of this include 7-nitroindazole, which selectively inhibits NOS1, and aminoguanidine for NOS2. A wide range of selective NOS inhibitors (for each of the three isoforms) are now available for research purposes.

Nitric Oxide Replacement or Potentiation

Several means whereby the L-arginine/NO pathway could be enhanced are under investigation. Some of these rely on existing drugs of proven value in other contexts. The hope (as yet unproven) is that, by potentiating NO, they will prevent atherosclerosis or its thrombotic complications or have other beneficial effects attributed to NO. However, efforts to modulate NO concentrations through NO donors and use of NOS substrates have met limited clinical success; similarly, the use of general antioxidants to alleviate oxidative stress has been negative (reviewed by **Tejero et al., 2019**). Alternatively, oral ingestion of nitrate/nitrite (e.g. via leafy green vegetables) adds to the body stores and can generate NO through reduction in the nitrate–nitrite–NO pathway, particularly in hypoxic tissue.

Clinical Conditions in Which Nitric Oxide May Play a Part

The wide distribution of NOS enzymes and diverse actions of NO suggest that abnormalities in the L-arginine/NO pathway could be important in disease. Either increased or reduced production could play a part, and hypotheses abound.

We caution the reader that while there is a huge amount of pre-clinical research drawing possible associations between the NO pathway and diverse diseases, we also recognise that not all of these possibilities are likely to have genuine clinical relevance or withstand the test of time.

The ubiquity of NO in the vascular beds and NOS2 as an inducible form in response to hypoxia, infection, ischaemia and acidosis means that altered NO balance can be detected in experimental or observational studies across almost every organ system. There is increasing recognition that dysregulation of NO during serious illness can involve a deficit (e.g. of endothelial NO synthesis in microvascular areas), which at the same time is accompanied by an excess of NO on other systems that cause cardiac and macrovascular dysfunction (**Lambden, 2019**). For instance, it is thought that NOS3 in the sinusoidal endothelial cells of the liver confers protection against liver disease, whereas increased NOS1 contributes to harmful pathology. The complexity and interconnected nature of the NO pathways mean that clinical correlations can be hard to interpret. This creates major challenges for pharmacological targeting of specific disease processes, particularly with regards to unintended effects across other parts of the body where NO is ubiquitous.

Sepsis, and the resulting multiple organ failure, is another key example here. Whereas NO benefits host defence by killing invading

organisms, excessive NO causes harmful hypotension. Disappointingly, however, L-NMMA (which blocks synthesis of all three NO isoforms) worsens survival in sepsis. The bad news continues – a haemoglobin-based nitric oxide scavenger, pyridoxalated haemoglobin polyoxyethylene, was found to increase mortality and adverse events in a phase III trial of intensive care patients with shock. There is also ongoing debate regarding the possible signals of renal failure associated with inhaled NO therapy in critically ill patients.

Established clinical uses of drugs that influence the L-arginine/NO system are summarised in the 'Nitric oxide in therapeutics' clinical box.

Nitric oxide in pathophysiology

- NO is synthesised under physiological and pathological circumstances.
- Either reduced or increased NO production can contribute to disease.
- In serious illness, there may be a complex competing interplay between excess synthesis of NO in some organs occurring at the same time as decreased production in other systems

Nitric oxide in therapeutics

- NO donors (e.g. **nitroprusside** and organic nitrovasodilators) are well established in treatment of cardiovascular disease (see Chs **20** and **21**).
- Type V phosphodiesterase inhibitors (e.g. **sildenafil**, **tadalafil**) potentiate the action of NO. They are used to treat erectile dysfunction and pulmonary hypertension (see Chs **21** and **35**).
- Inhaled NO is used in intensive care of adult and neonatal respiratory distress syndrome.
- Latanoprostene bunod, an NO releasing prostaglandin F2 agonist, is licensed for treatment of glaucoma. This compound is metabolised into two components – latanoprost and butanediol mononitrate (which subsequently releases NO). It is unclear whether the NO component offers greater benefit above latanoprost alone (see **Ch. 27**)

Related Mediators

NO, promoted from pollutant to 'molecule of the year', [6] was joined, similarly implausibly, by carbon monoxide (CO) – a potentially lethal exhaust gas – and by hydrogen sulfide (H_2S), which are also formed in mammalian tissues. There are striking similarities between these three gases, as well as some contrasts. All three are highly diffusible labile molecules that are rapidly eliminated from the body: NO as nitrite and nitrate in urine as well as NO in exhaled air (see earlier discussion); CO in exhaled air; H_2S as thiosulfate, sulfite and sulfate in urine (**Fig. 19.6**) as well as in exhaled breath. All three react with haemoglobin, and all three affect cellular

energetics via actions on cytochrome C oxidase. All have vasodilator effects (although chronic exposure to CO can cause vasoconstriction), and all have anti-inflammatory and cytoprotective effects at low concentrations but cause cellular injury at higher concentrations.

Hydrogen Sulfide (H_2) AND CARBON MONOXIDE (CO)

H_2S has potent pharmacological effects in the cardiovascular system, including vasorelaxation secondary to activation of vascular smooth muscle K_{ATP} channels (see **Ch. 4**). It also acts on the nervous system and influences nociception, selectively modulating voltage-dependent T-type Ca^{2+} channels (**Elies et al., 2016**). It also influences inflammatory processes. For a review of the effects of H_2S on ion channels and intracellular transduction systems see **Li et al. (2011)**. There are clinical trials of the effects of H_2S donor diseases as diverse as heart failure, ischaemic heart disease, cancer and male subfertility (**Gojon et al., 2020**), but none of the studies have progressed to phase III randomised trials as yet.
Otenaproxesul, a sulfide-releasing derivative of naproxen, is moving towards phase III trials in chronic pain after demonstrating lower peptic ulcer rick than the parent naproxen compound in phase II trials. It is worth noting though that naproxcinod, a nitric-oxide releasing derivative of naproxen, failed to clear regulatory hurdles due to safety concerns.

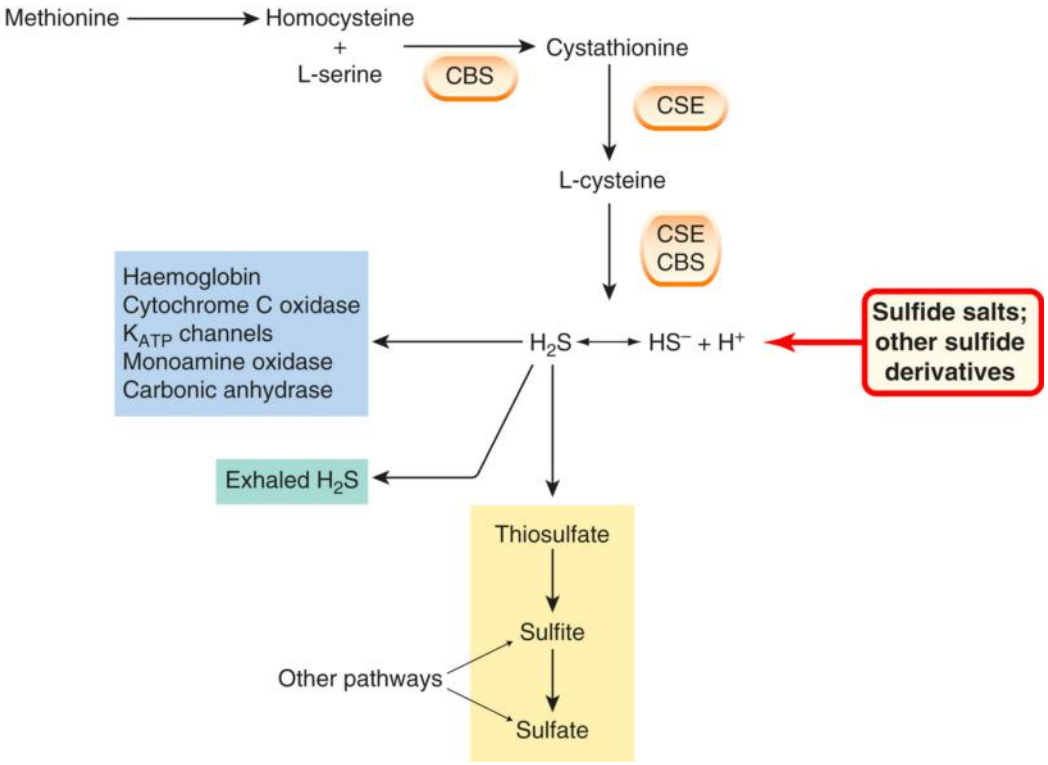

FIG. 19.6 Synthesis, sites of action and disposition of H_2S.Endogenous biosynthesis from sulphur-containing amino acids (methionine, cysteine) via actions of the regulated enzymes methionine cystathionine γ-lyase (CSE) and cystathionine β-synthase (CBS) is shown; pharmacological H_2S donors *(red-rimmed box)* may be administered exogenously. Most H_2S is probably renally excreted as sulfate *(yellow box)*. Some is eliminated in exhaled air *(green box)*. Some molecular targets of H_2S are indicated in the *blue box*. Adapted with permission from Ritter, J.M., 2010. Human pharmacology of hydrogen sulfide: putative

gaseous mediator. Br. J. Clin. Pharmacol. 69, 573–575.

Sodium thiosulfate, a downstream oxidation product of H_2S, has also showed therapeutic promise. Randomised trial data have indicated some efficacy in preventing chemotherapy-induced toxicity, whilst further trials are planned in a wide range of conditions (see **Zhang et al., 2021**, for description of potential clinical applications).

There are as yet no therapeutic drugs acting via CO pathways, but CO (perhaps surprisingly for a gas associated with lethal effects in a domestic setting) has potentially beneficial effects on cell survival, and CO-releasing molecules are under investigation (**Motterlini and Foresti, 2017**).

QUESTIONS

QUESTION 19.1

Nitric oxide (NO) is a ubiquitous circulating and local mediator with diverse functions and is generated from L-arginine by NO synthase (NOS).

Which of the following would NOT lead to an increase in NO synthesis?

OPTIONS:

A. β_2-adrenoceptor agonists

B. Activators of protein kinase C

C. Insulin

D. Interferon-γ

E. Calcium

QUESTION 19.2

High doses of L-arginine have been shown to be beneficial in the treatment of some pathological states.

The best explanation for the effectiveness of high dose L-arginine in the treatment of disorders involving impairment of endothelial function, such as hypercholesterolaemia, is…

OPTIONS:

A. Exogenous L-arginine compensates for lack of endogenous substrate.

B. It reduces the levels of intracellular calcium which decreases NOS activity.

C. Due to its ability to compete with endogenous inhibitors of NOS.

D. Due to restocking of selected compartments which become depleted.

E. Loss of endothelium decreases NOS_3 activity.

QUESTION 19.3

NO is a key signalling molecule in the cardiovascular system.

The most likely mechanism for the antihypertensive effect of NO is…

OPTIONS:

A. Through promoting new vessel formation (‘angiogenesis’) and vascular remodelling

B. Through the activation of *N*-methyl-D-aspartate (NMDA) receptors

C. By inhibition of platelet aggregation

D. By inhibition of smooth muscle proliferation

E. Through potassium-channel activation

ANSWERS

ANSWER 19.1

RATIONALE:

A. Agonists that increase cAMP in endothelial cells (e.g. β_2-adrenoceptor agonists) increase NOS_3 activity, via protein kinase A–mediated phosphorylation.

B.

C. Insulin increases NOS_3 activity via tyrosine kinase activation (and also increases the expression of NOS_1 in diabetic mice).

D. NOS_2 enzyme is induced by bacterial lipopolysaccharide and inflammatory cytokines, notably interferon-γ.

E. An increase in the cytoplasmic concentration of calcium ions $[Ca^{2+}]_i$ results in an increase in calcium–calmodulin binding so activating NOS_1 and NOS_3.

CORRECT ANSWER WITH EXPLANATION:

B. Activators of protein kinase C

Protein kinase C reduces NOS_3 activity by phosphorylating residues in the calmodulin-binding domain, thereby reducing the binding of calmodulin.

ANSWER 19.2

RATIONALE:

A. L-Arginine, the substrate of NOS, is usually present in excess in endothelial cell cytoplasm, so the rate of production of NO is determined by the activity of the enzyme rather than by substrate availability.

B. L-Arginine itself has no effect on calcium levels but the activity of constitutive isoforms of NOS is increased by intracellular calcium binding to an activating calmodulin.

C.

D. A possible mechanism could be due to restoration of substrate levels in distinct cell compartments where endogenous substrate has become depleted.

E. NOS_3 expression is not restricted to endothelium. It is also present in cardiac myocytes, renal mesangial cells, osteoblasts and osteoclasts, airway epithelium and, in small amounts, platelets so would be active even in the absence of endothelium.

CORRECT ANSWER WITH EXPLANATION:

C. Due to its ability to compete with endogenous inhibitors of NOS.

High concentrations of L-arginine can compete with endogenous competitive inhibitors of NOS such as asymmetric dimethylarginine which are elevated in plasma from patients with hypercholesterolaemia.

ANSWER 19.3

RATIONALE:

A. Although it has been shown to promote new vessel formation, the impact of this is likely to be secondary to its vasodilator effects.

B. Increased release of NO by excessive activation of NMDA receptors can lead to cytotoxicity, either directly or via the formation of peroxynitrite.

C. Production of cGMP by NO activates protein kinase G, ion channels and possibly other proteins, inhibiting $[Ca^{2+}]_i$-induced platelet aggregation which probably underlies the anti-atherosclerotic action of NO rather than its antihypertensive effects.

D. Production of cGMP by NO activates protein kinase G, ion channels and possibly other proteins, inhibiting $[Ca^{2+}]_i$-induced smooth muscle contraction which probably underlies the anti-atherosclerotic action of NO rather than its antihypertensive effects.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Through potassium-channel activation

NO hyperpolarises vascular smooth muscle as a consequence of potassium-channel activation resulting in reduced peripheral vascular resistance and hence systemic blood pressure.

---

[1] The pure substances (NO, CO and H_2S) are gases at room temperature and usual atmospheric pressure, and when pure NO is administered therapeutically (see later), it is in the form of a gas; when formed endogenously, the gases are, of course, dissolved in intra- and extracellular fluids.

[2] NOS3 is not restricted to endothelium. It is also present in cardiac myocytes, renal mesangial cells, osteoblasts and osteoclasts, airway epithelium and, in small amounts, platelets, so the term *eNOS* is somewhat misleading.

[3] It is possible that some of the NO made in healthy animals under basal conditions is derived from the action of NOS2, just as the

inducible form of cyclo-oxygenase is active under basal conditions (Ch. 17) – whether this is because there is some NOS2 expressed even when there is no pathology or because there is enough 'pathology' in healthy mammals, for example in relation to gut microflora, to induce it is a moot point.

[4] As explained in Chapter 4, $ß_2$ agonists also act directly on smooth muscle cells, causing relaxation via cAMP.

20: The heart

OVERVIEW

This chapter presents an overview of cardiac function in terms of electrophysiology, contraction, oxygen consumption and coronary blood flow, autonomic control and natriuretic peptides as a basis for understanding the effects of drugs on the heart and their place in treating cardiac disease. We concentrate on drugs that act directly on the heart, namely antidysrhythmic drugs and drugs that increase the force of contraction (especially digoxin), as well as anti-anginal drugs that act indirectly by reducing cardiac work. The commonest form of heart disease is caused by atheroma in the coronary arteries, complicated by thrombosis on ruptured atheromatous plaques; drugs to treat and prevent these are considered in **Chapters 22** and **23** Heart failure is mainly treated by drugs that work indirectly on the heart via actions on vascular smooth muscle, discussed in **Chapter 21**, by diuretics and sodium glucose transport 2 (SGLT2) inhibitors (Chs **29** and **31**) and β-adrenoceptor antagonists (see **Ch. 15**).

Introduction

In this chapter we consider the effects of drugs on the heart under three main headings:

1. Rate and rhythm
2. Myocardial contraction
3. Metabolism and blood flow

The effects of drugs on these aspects of cardiac function are not, of course, independent of each other. For example, if a drug affects the electrical properties of the myocardial cell membrane, it is likely to influence both cardiac rhythm and myocardial contraction. Similarly, a drug that affects contraction will inevitably alter metabolism and blood flow as well. Nevertheless, from a therapeutic point of view, these three classes of effect represent distinct clinical objectives in relation to the treatment, respectively, of cardiac dysrhythmias, cardiac failure and coronary insufficiency (as occurs during angina pectoris or myocardial infarction).

Physiology of Cardiac Function

Cardiac Rate and Rhythm

The chambers of the heart normally contract in a coordinated manner, pumping blood efficiently by a route determined by the valves. Coordination of contraction is achieved by a specialised conducting system. Normal *sinus rhythm* is generated by pacemaker impulses that arise in the sinoatrial (SA) node and are conducted in sequence through the atria, the atrioventricular (AV) node, bundle of His, Purkinje fibres and ventricles. Cardiac cells owe their electrical excitability to voltage-sensitive plasma membrane channels selective for various ions, including Na^+, K^+ and Ca^{2+}, the structure and function of which are described in

Chapter 4. The electrophysiological features of cardiac muscle that distinguish it from other excitable tissues include:

- pacemaker activity
- absence of fast Na^+ current in SA and AV nodes, where slow inward Ca^{2+} current initiates action potentials
- long action potential ('plateau') and refractory period
- influx of Ca^{2+} during the plateau

Several of these special features of cardiac rhythm relate to Ca^{2+} currents. The heart contains *intracellular* calcium channels (i.e. ryanodine receptors and inositol trisphosphate-activated calcium channels described in **Chapter 4**, which are important in myocardial contraction) and voltage-dependent calcium channels in the plasma membrane, which are important in controlling cardiac rate and rhythm. The main type of voltage-dependent calcium channel in adult working myocardium is the L-type channel, which is also important in vascular smooth muscle; L-type channels are important in specialised conducting regions as well as in working myocardium.

The action potential of an idealised cardiac muscle cell is shown in **Fig. 20.1A** and is divided into five phases: 0 (fast depolarisation), 1 (partial repolarisation), 2 (plateau), 3 (repolarisation) and 4 (pacemaker).

Ionic mechanisms underlying these phases can be summarised as follows.

Phase 0, rapid depolarisation, occurs when the membrane potential reaches a critical firing threshold (about –60 mV), at which the inward current of Na^+ flowing through the voltage-

dependent sodium channels becomes large enough to produce a regenerative ('all-or-nothing') depolarisation. This mechanism is the same as that responsible for action potential generation in neurons (see **Ch. 4**). Activation of sodium channels by membrane depolarisation is transient, and if the membrane remains depolarised for more than a few milliseconds, they close again (inactivation). They are therefore closed during the plateau of the action potential and remain unavailable for the initiation of another action potential until the membrane repolarises.

Phase 1, partial repolarisation, occurs as the Na^+ current is inactivated.

Phase 2, the plateau, results from an inward Ca^{2+} current. Calcium channels show a pattern of voltage-sensitive activation and inactivation qualitatively similar to sodium channels, but with a much slower time course. The plateau is assisted by a special property of the cardiac muscle membrane known as inward-going rectification, which means that the K^+ conductance falls to a low level when the membrane is depolarised. Because of this, there is little tendency for outward K^+ current to restore the resting membrane potential during the plateau, so a relatively small inward Ca^{2+} current suffices to maintain the plateau. A persistent sodium current (I_{Nap}) also contributes to the plateau; it is very small compared with the fast component of sodium current, but as it flows throughout the action potential it makes a substantial contribution to sodium loading during each cardiac cycle, and is a major contributor to ischaemic arrhythmias and a drug target (see later).

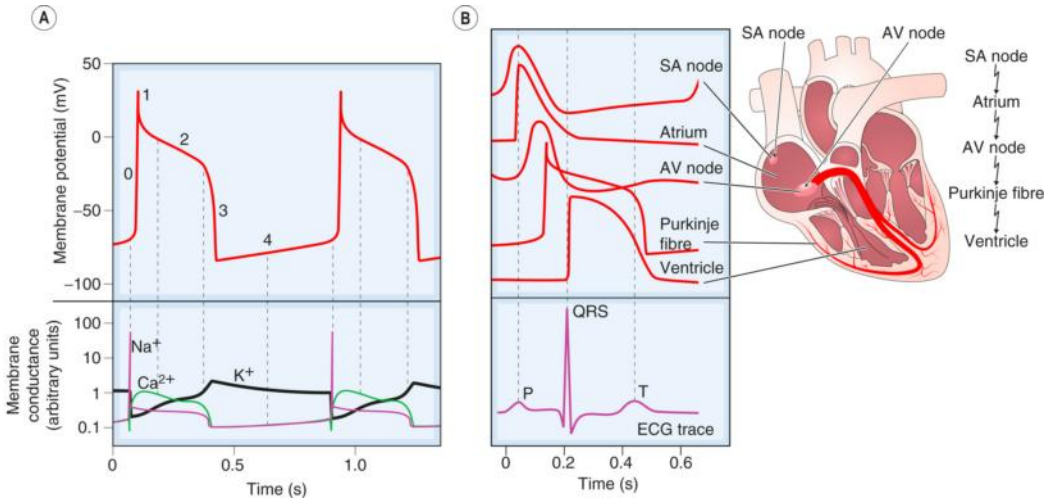

FIG. 20.1 The cardiac action potential.(A) Phases of the action potential: *(0)* rapid depolarisation; *(1)* partial repolarisation; *(2)* plateau; *(3)* repolarisation; *(4)* pacemaker depolarisation. The *lower panel* shows the accompanying changes in membrane conductance for Na^+, K^+ and Ca^{2+}. (B) Conduction of the impulse through the heart, with the corresponding electrocardiogram (ECG) trace. Note that the longest delay occurs at the atrioventricular (AV) node, where the action potential has a characteristically slow waveform. *SA,* Sinoatrial.

Phase 3, repolarisation, occurs as the Ca^{2+} current inactivates and a delayed outwardly rectifying K^+ current (analogous to, but much slower than, the K^+ current that causes repolarisation in nerve fibres; see **Ch. 4**) activates, causing outward K^+ current. This is augmented by another K^+ current, which is activated by high intracellular Ca^{2+} concentrations, $[Ca^{2+}]_i$, during the plateau, and

sometimes also by other K^+ currents, including one through channels activated by acetylcholine (see **Ch. 14** and later) and another that is activated by arachidonic acid, which is liberated under pathological conditions such as myocardial infarction.

Phase 4, the pacemaker potential, is a gradual depolarisation during diastole. Pacemaker activity is normally found only in nodal and conducting tissue. The pacemaker potential is caused by a combination of increasing inward currents and declining outward currents during diastole. It is usually most rapid in cells of the SA node, which therefore acts as pacemaker for the whole heart. Cells in the SA node have a greater background Na^+-conductance than do atrial or ventricular myocytes, leading to a greater background inward current. In addition, inactivation of voltage-dependent calcium channels wears off during diastole, resulting in increasing inward Ca^{2+} current during late diastole. Activation of T-type calcium channels during late diastole contributes to pacemaker activity in the SA node. The negative membrane potential early in diastole activates a cation channel that is permeable to Na^+ and K^+, giving rise to another inward current, called I_f. [1] An inhibitor of this current, **ivabradine**, slows the heart and is used therapeutically (see later).

Several voltage- and time-dependent outward currents play a part as well: delayed rectifier K^+ current (I_K), which is activated during the action potential, is turned off by the negative membrane potential early in diastole. Current from the electrogenic Na^+/K^+ pump also contributes to the outward current during the pacemaker potential.

Fig. 20.1B shows the action potential configuration in different parts of the heart. Phase 0 is absent in the nodal regions, where the conduction velocity is correspondingly slow (~5 cm/s) compared with other regions such as the Purkinje fibres (conduction velocity ~200 cm/s), which propagate the action potential rapidly to the ventricles. Regions that lack a fast inward current have a much longer refractory period than fast-conducting regions. With fast-conducting fibres, inactivation of the Na^+ current recovers rapidly, and the cell becomes excitable again almost as soon as it is repolarised.

The orderly pattern of sinus rhythm can be disrupted either by heart disease or by the action of drugs or circulating hormones, and an important therapeutic use of drugs is to restore a normal cardiac rhythm where it has become disturbed. The commonest cause of cardiac dysrhythmia is ischaemic heart disease, and between 25% and 50% of deaths following myocardial infarction result from *ventricular tachycardia or fibrillation* rather than directly from failure of the contractile machinery due to death of cardiac myocytes.

Disturbances of Cardiac Rhythm

Clinically, dysrhythmias are classified according to:

- the site of origin of the abnormality – atrial, junctional or ventricular;
- whether the rate is increased (>100 beats per minute [bpm] – *tachycardia*) or decreased (<60 bpm – *bradycardia*).

They may be asymptomatic, or cause chest pain and palpitations (awareness of the heartbeat), or symptoms from cerebral hypoperfusion (faintness or loss of consciousness). Their diagnosis depends on the surface electrocardiogram (ECG), and details are beyond the scope of this book – see **Hampton and Hampton (2019)**. The commonest types of tachyarrhythmia are *atrial fibrillation*, where the heartbeat is completely irregular, and *paroxysmal supraventricular tachycardia* (SVT), where the heartbeat is rapid but regular. Occasional ectopic beats (ventricular as well as supraventricular) are common. Sustained ventricular tachyarrhythmias are much less common but more serious; they include *ventricular tachycardia* and *ventricular fibrillation*, where the electrical activity in the ventricles is completely chaotic and cardiac output ceases. Bradyarrhythmias include various kinds of *heart block* (e.g. at the AV or SA node) and complete cessation of electrical activity ('asystolic arrest'). It is often unclear in individual patients which of the various mechanisms discussed later are directly responsible but disturbances of cardiac rhythm typically occur because of disruptions in electrical impulse formation and/or conduction (see **Tse, 2016**, for a detailed review on the cellular mechanisms for cardiac arrhythmias):

1. Tachycardia with greater impulse formation (through triggered activity or increased automaticity), and re-entry circuits
2. Bradycardia due to reduced automaticity at the sinus node, or impaired conduction along the pathway

Triggered activity describes premature activation of the cardiac myocytes and extra beats, due to a phenomenon known as 'after-depolarisation'. Here, fluctuations in the membrane potential can trigger additional depolarisations while repolarisation is still ongoing (known as 'early after-depolarisation'), or only after repolarisation is complete – known as 'delayed after-depolarisation' (**Fig. 20.2**). Important (and treatable) factors that cause after-depolarisation are hypokalaemia, hypercalcaemia, hypoxia and acidosis, usually in the context of underlying myocardial damage. Prolonged duration of the action potential, as seen in bradycardia, and long QT syndromes, which are often related drug toxicities (see later), are key factors behind early after-depolarisation and triggered activity. Recognised causes of delayed after-depolarisation include catecholamine excess (that triggers polymorphic ventricular tachycardia) and digitalis toxicity.

Some areas of the heart have pacemaker cells that spontaneously depolarise and discharge (known as 'automaticity'). The natural or physiological pacemaker in the SA node oversees the regulation of heart rate, but a number of other cardiac tissues can take on subsidiary pacemaker activity (albeit at a slower discharge rate). This provides a safety mechanism in the event of failure of the SA node but can also trigger tachyarrhythmias. Here, enhanced automaticity and ectopic pacemaker activity can be caused by ischaemic damage, electrolyte disturbances and sympathetic activity. For instance, catecholamines, acting on β_1 adrenoceptors (see **Ch. 15**), increase the rate of depolarisation during phase 4 and can provoke normally quiescent parts of the heart to take on a spontaneous rhythm. Several tachyarrhythmias (e.g. paroxysmal

atrial fibrillation) can be triggered by circumstances associated with increased sympathetic activity, e.g. pain during myocardial infarction.

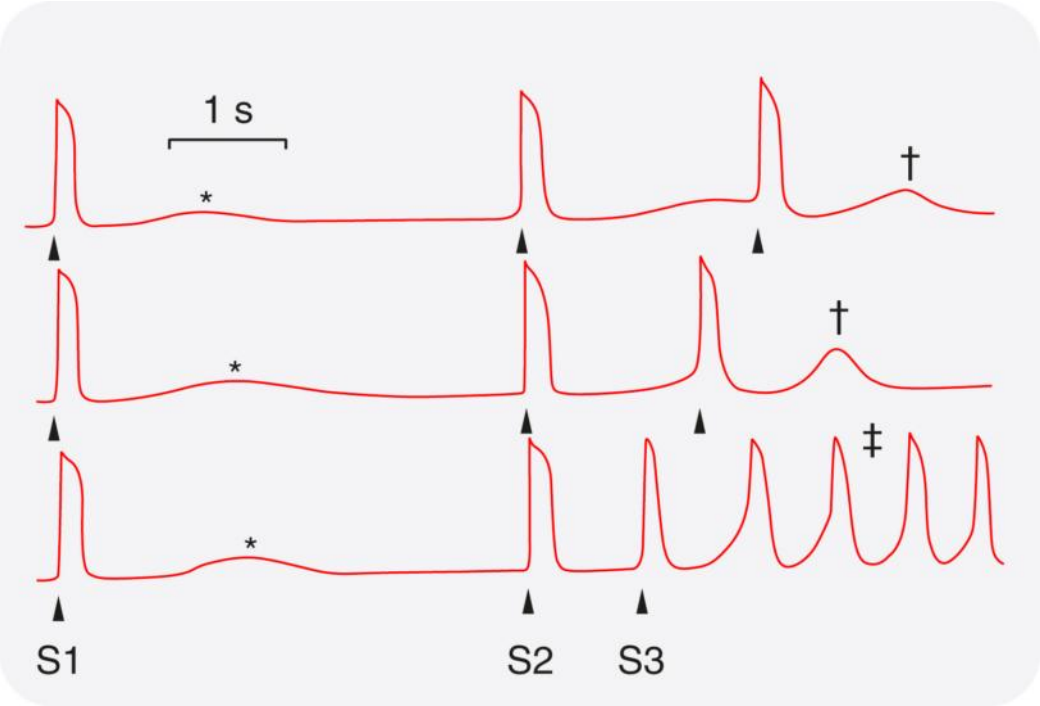

FIG. 20.2 After-depolarisation in cardiac muscle recorded from a dog coronary sinus in the presence of noradrenaline (norepinephrine).The first stimulus *(S1)* causes an action potential followed by a small after-depolarisation. As the interval *S2–S3* is decreased, the after-depolarisation gets larger (†) until it triggers an indefinite train of action potentials (‡). Adapted from Wit, A.L., Cranefield, P.F., 1977. Circ. Res. 41, 435.

Normally, a cardiac action potential dies out after it has activated the ventricles because it is surrounded by refractory tissue, which it has just traversed. *Re-entry* (**Fig. 20.3**) describes a situation in which the impulse re-excites regions of the myocardium after the refractory period has subsided, causing continuous circulation of action potentials. It can result from anatomical anomalies or, more commonly, from myocardial damage. Re-entry underlies many types of dysrhythmia, the pattern depending on the site of the re-entrant circuit, which may be in the atria, ventricles or nodal tissue. A simple ring of tissue can give rise to a re-entrant rhythm if a transient or unidirectional conduction block is present. Normally, an impulse originating at any point in the ring will propagate in both directions and die out when the two impulses meet, but if a damaged area causes either a transient block (so that one impulse is blocked but the second can get through; see **Fig. 20.3**) or a unidirectional block, continuous circulation of the impulse can occur. This is known as *circus movement* and was demonstrated experimentally on rings of jellyfish tissue many years ago.

Heart block results from fibrosis of, or ischaemic damage to, the conducting system (often in the AV node). In complete heart block, the atria and ventricles beat independently of one another, the ventricles beating at a slow rate determined by whatever pacemaker picks up distal to the block. Sporadic complete failure of AV conduction causes sudden periods of unconsciousness (Stokes–Adams attacks) and is treated by implanting an artificial pacemaker.

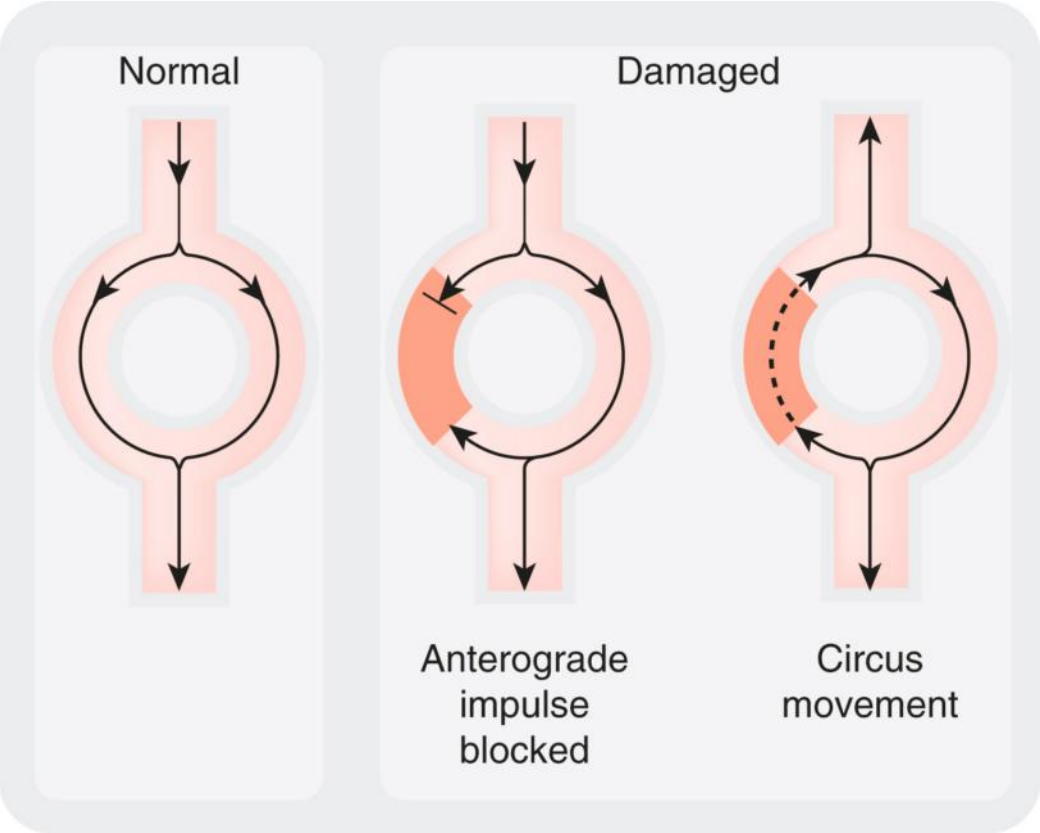

FIG. 20.3 Generation of a re-entrant rhythm by a damaged area of myocardium.The damaged area *(brown)* conducts in one direction only. This disturbs the normal pattern of conduction and permits continuous circulation of the impulse to occur.

Table 20.1

Summary of antidysrhythmic drugs (Vaughan Williams classification)

Class	Example(s)	Mechanism
Ia	Disopyramide	Sodium-channel block (intermediate dissociation)
Ib	Lidocaine	Sodium-channel block (fast dissociation)
Ic	Flecainide	Sodium-channel block (slow dissociation)
II	Atenolol	β-Adrenoceptor antagonism
III	Amiodarone, sotalol	Potassium-channel block
IV	Verapamil	Calcium-channel block

Drug-induced ventricular arrhythmias

In the 1990s and early 2000s, a number of drugs had to be withdrawn due to their propensity for exerting *proarrhythmic* effects, notably a dangerous polymorphic form of ventricular tachycardia called (somewhat whimsically) *torsade de pointes* (because the appearance of the ECG trace is said to be reminiscent of this ballet sequence). Torsade de pointes is associated with prolongation of the QT interval, and linked to drugs that inhibit the

HERG (human ether-a-go-go–related gene) repolarising potassium channel.

This pro-arrhythmic risk is most prominent in patients taking anti-arrhythmic agents (type Ia and Ic and sotalol in **Table 20.1**), as well as a long and varied list of other culprit drugs acting on sodium and potassium channels to prolong the QT interval. In clinical settings, the pro-arrhythmic risk is greatest when there are disturbances of electrolytes involved in repolarisation (e.g. potassium, calcium, magnesium) or serious co-morbid illnesses (such as sepsis, hypoxia and underlying cardiac damage). The drug-induced arrhythmia is similar to the congenital form seen in those with hereditary prolonged QT (e.g. Ward–Romano syndrome), [2] and 15 types of familial long QT syndrome have now been described.

The dangerous association of torsades de pointes with QT prolongation has led to regulatory requirements for 'thorough QT testing' to screen out potentially risky new compounds (e.g. those that block the hERG-related potassium channel and/or lengthen the QT). However, whilst such testing can prove highly sensitive in detecting drug-induced QT prolongation, the methods are poorly specific. QT prolongation per se is a poor surrogate for clinical outcomes – some drugs (e.g. ranolazine, verapamil) can have quite marked effect on the QT interval, but this may not actually result in ventricular arrhythmias. It has also become clear that drug-induced pro-arrhythmia risk involves not only inward potassium channels but also cardiac sodium and calcium channels that mediate the action potential. An ongoing international collaborative project is working to develop more accurate predictors of clinical risk than HERG potassium channel inhibition and QT prolongation alone,

incorporating drug effects on inward fast and slow sodium, L-type calcium channels (see **Roden, 2019**, and **Yim, 2018**, for clear and detailed descriptions of this challenging and evolving topic).

Cardiac dysrhythmias

- Dysrhythmias arise because of abnormalities in electrical impulse formation and/or conduction:
  - after-depolarisation, which triggers ectopic beats
  - increased automaticity with ectopic pacemaker activity
  - re-entry circuits
  - decreased automaticity and/or heart block.
- Triggered activity from after-depolarisation can be provoked by electrolyte disturbances (calcium, potassium), ischaemia and drug toxicity.
- Increased automaticity with ectopic pacemaker activity can occur with excess sympathetic activity, ischaemia and electrolyte disturbance.
- Re-entry is facilitated when conduction is disrupted in parts of the myocardium as a result of disease.
- Heart block results from disease (e.g. fibrosis) in the conducting system, especially the AV node, or due to the use of channel-blocking drugs such as b-adrenoceptor antagonists or calcium antagonists.
- Clinically, dysrhythmias are divided:
  - according to their site of origin (supraventricular and ventricular)

– according to whether the heart rate is increased or decreased (tachycardia or bradycardia).

Cardiac Contraction

Cardiac output is the product of heart rate and mean left ventricular stroke volume (i.e. the volume of blood ejected from the ventricle with each heartbeat). Heart rate is controlled by the autonomic nervous system (see Chs **13**–**15** and later). Stroke volume is determined by a combination of factors, including some intrinsic to the heart itself and other haemodynamic factors extrinsic to the heart. Intrinsic factors regulate myocardial contractility via $[Ca^{2+}]_i$ and ATP, and are sensitive to various drugs and pathological processes. Extrinsic circulatory factors include the elasticity and contractile state of arteries and veins, and the volume and viscosity of the blood, which together determine cardiac load (preload and afterload, see later). Drugs that influence these circulatory factors are of paramount importance in treating patients with heart failure. They are covered in **Chapter 21**.

Myocardial Contractility and Viability

The contractile machinery of myocardial striated muscle is basically the same as that of voluntary striated muscle (see **Ch. 4**). It involves binding of Ca^{2+} to troponin C; this changes the conformation of the troponin complex, permitting cross-bridging of myosin to actin and initiating contraction. **Levosimendan** (a drug used in some countries to treat acute decompensated heart failure; see **Ch. 21**), increases the force of contraction of the heart by

binding troponin C and sensitising it to the action of Ca^{2+}. New drugs in development that target cardiac myosin are described later.

Many effects of drugs on cardiac contractility can be explained in terms of actions on $[Ca^{2+}]_i$, via effects on calcium channels in plasma membrane or sarcoplasmic reticulum or on the Na^+/K^+ pump, which indirectly influences the Na^+/Ca^{2+} pump (see later). Other factors that affect the force of contraction are the availability of oxygen and a source of metabolic energy such as free fatty acids.

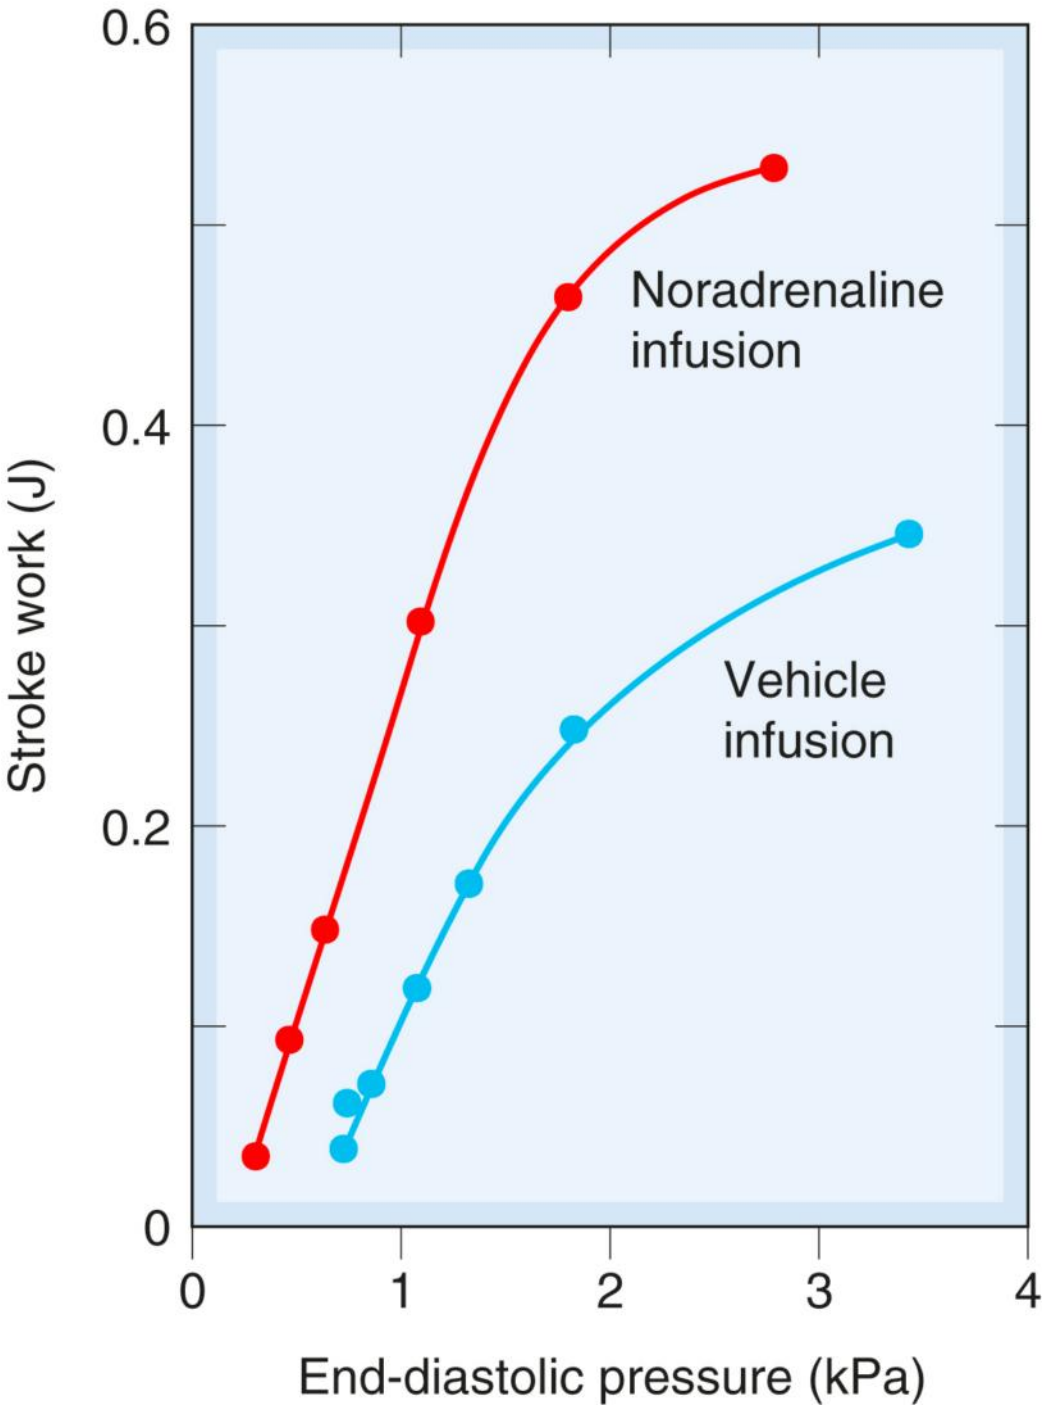

FIG. 20.4 Ventricular function curves in the dog.Infusion of physiological saline increases blood volume and hence end-diastolic pressure. This increases stroke work (‘extrinsic’ control) by increasing the force of contraction of the

heart. This relationship is called the Starling curve. Noradrenaline has a direct action on the heart ('intrinsic' control), increasing the slope of the Starling curve. Redrawn from Sarnoff, S.J., et al., 1960. Circ. Res. 8, 1108.

Ventricular Function Curves and Heart Failure

The force of contraction of the heart is determined partly by its intrinsic contractility (which, as described earlier, depends on $[Ca^{2+}]_i$ and availability of ATP), and partly by extrinsic haemodynamic factors that affect end-diastolic volume and hence the resting length of the muscle fibres. The end-diastolic volume is determined by the end-diastolic pressure, and its effect on stroke work is expressed in the Frank–Starling law of the heart, which reflects an inherent property of the contractile system. The Frank–Starling law can be represented as a ventricular function curve (**Fig. 20.4**). The area enclosed by the pressure–volume curve during the cardiac cycle provides a measure of ventricular stroke work. It is approximated by the product of stroke volume and mean arterial pressure. As Starling showed, factors extrinsic to the heart affect its performance in various ways, two patterns of response to increased load being particularly important:

- Increased cardiac filling pressure (*preload*), whether caused by increased blood volume or by venoconstriction (that returns more blood to the cardiac chambers), increases ventricular end-diastolic volume. This increases stroke volume and hence cardiac output and mean arterial

pressure. Cardiac work and cardiac oxygen consumption both increase.

- Resistance vessel vasoconstriction increases *afterload*. End-diastolic volume and, hence, stroke work are initially unchanged, but constant stroke work in the face of increased vascular resistance causes reduced stroke volume and hence increased end-diastolic volume. This in turn increases stroke work, until a steady state is re-established with increased end-diastolic volume and the same cardiac output as before. As with increased preload, cardiac work and cardiac oxygen consumption both increase.

Normal ventricular filling pressure is only a few centimetres of water, on the steep part of the ventricular function curve, so a large increase in stroke work can be achieved with only a small increase in filling pressure. The Starling mechanism plays little part in controlling cardiac output in healthy subjects (e.g. during exercise), because changes in contractility, mainly as a result of changes in sympathetic nervous activity, achieve the necessary regulation without any increase in ventricular filling pressure (see **Fig. 20.4**). In contrast, the denervated heart in patients who have received a heart transplant relies on the Starling mechanism to increase cardiac output during exercise.

In heart failure, the cardiac output is insufficient to meet the needs of the body, initially only when these are increased during exercise but ultimately, as disease progresses, also at rest. It has many causes, most commonly ischaemic heart disease and hypertension. In patients with heart failure (see **Ch. 21**), the heart may be unable to deliver as much blood as the tissues require, even

when its contractility is increased by sympathetic activity. Under these conditions, the basal (i.e. at rest) ventricular function curve is greatly depressed, and there is insufficient reserve, in the sense of extra contractility that can be achieved by sympathetic activity, to enable cardiac output to be maintained during exercise without a large increase in central venous pressure (see **Fig. 20.4**). Oedema of peripheral tissues (causing swelling of the legs) and the lungs (causing breathlessness) is an important consequence of cardiac failure. It is caused by the increased venous pressure, and retention of Na^+ (see **Ch. 21**).

Myocardial contraction

- Controlling factors are:
  - intrinsic myocardial contractility
  - extrinsic circulatory factors.
- Myocardial contractility depends critically on intracellular Ca^{2+}, and hence on:
  - Ca^{2+} entry across the cell membrane
  - Ca^{2+} storage in the sarcoplasmic reticulum.
- The main factors controlling Ca^{2+} entry are:
  - activity of voltage-gated calcium channels
  - intracellular Na^+, which affects Ca^{2+}/Na^+ exchange.
- Catecholamines, cardiac glycosides and other mediators and drugs influence these factors.
- Extrinsic control of cardiac contraction is through the dependence of stroke work on the end-diastolic volume,

expressed in the Frank–Starling law.

- Cardiac work is affected independently by afterload (i.e. peripheral resistance and arterial compliance) and preload (i.e. central venous pressure).

Myocardial Oxygen Consumption and Coronary Blood Flow

Relative to its large metabolic needs, the heart is one of the most poorly perfused tissues in the body and is therefore at greater risk of ischaemic damage. Coronary flow is, under normal circumstances, closely related to myocardial oxygen consumption, and both change over a nearly 10-fold range between conditions of rest and maximal exercise. Most drugs that influence cardiac metabolism do so indirectly by influencing coronary blood flow. [3]

Physiological Factors

The main physiological factors that regulate coronary flow are:

- physical factors
- vascular control by metabolites
- neural and humoral control

Physical factors

During systole, the pressure exerted by the myocardium on vessels that pass through it equals or exceeds the perfusion pressure, so coronary flow occurs only during diastole. Diastole is shortened more than systole during tachycardia, reducing the period available for myocardial perfusion. During diastole, the effective perfusion

pressure is equal to the difference between the aortic and ventricular pressures (**Fig. 20.5**). If diastolic aortic pressure falls or diastolic ventricular pressure increases, perfusion pressure falls and so (unless other control mechanisms can compensate) does coronary blood flow. Stenosis of the aortic valve reduces aortic pressure but increases left ventricular pressure upstream of the narrowed valve and hence reducing coronary perfusion pressure and often causes ischaemic chest pain (angina), even in the absence of coronary artery disease, by this mechanism.

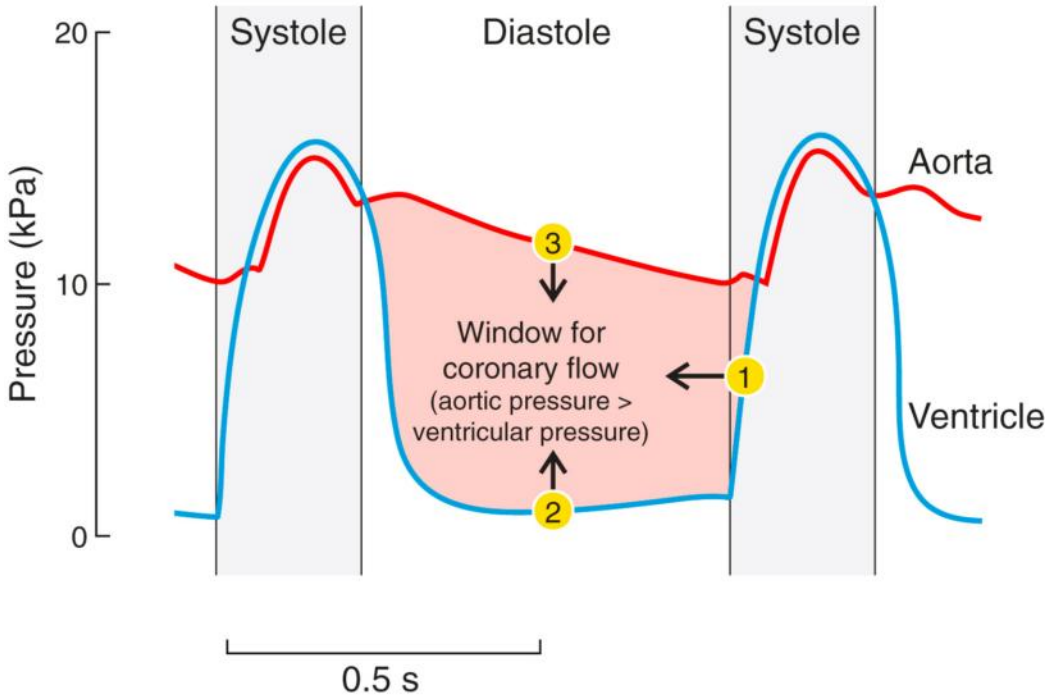

FIG. 20.5 Mechanical factors affecting coronary blood flow.The 'window' for coronary flow may be encroached on by *(1)* shortening diastole, when heart rate increases; *(2)* increased ventricular end-diastolic pressure; and *(3)* reduced diastolic arterial pressure.

Vascular control by metabolites/mediators

Vascular control by metabolites is the most important mechanism by which coronary flow is regulated. A reduction in arterial partial pressure of oxygen ($P\,O_2$) causes marked vasodilatation of coronary vessels in situ but has little effect on isolated strips of coronary artery, suggesting that it is a change in the metabolites produced by the myocardial cells, rather than the change in $P\,O_2$ per se, that

controls the state of the coronary vessels. *Adenosine* is a popular candidate for the dilator metabolite (see **Ch. 16**).

Neural and humoral control

Coronary vessels have a dense sympathetic innervation, but sympathetic nerves and circulating catecholamines exert only a small direct effect on the coronary circulation. Large coronary vessels possess α adrenoceptors that mediate vasoconstriction, whereas smaller vessels have β_2 adrenoceptors that have a dilator effect. Coronary vessels are also innervated by purinergic, peptidergic and nitrergic nerves, and basal coronary blood flow in patients with angiographically normal coronary arteries is reduced by about one-third by selective inhibition of NOS1 (**Seddon et al., 2009**). Coronary vascular responses to altered mechanical and metabolic activity during exercise or pathological events overshadow neural and endocrine effects.

Coronary flow, ischaemia and infarction

- The heart has a smaller blood supply in relation to its oxygen consumption than most organs.
- Coronary flow is controlled mainly by:
  - physical factors, including transmural pressure during systole
  - vasodilator metabolites.
- Autonomic innervation is less important.
- Coronary ischaemia is usually the result of atherosclerosis and causes angina.

- Thrombosis on a fissured atheromatous plaque may result in cardiac infarction (death of a region of the myocardium) or unstable angina (occurring with less than usual exertion or at rest).
- Coronary artery spasm sometimes causes angina at rest (vasospastic angina), but less commonly on exertion.
- Cellular Ca^{2+} overload results from ischaemia and may be responsible for:
  - cell death
  - dysrhythmias.

Autonomic Control of the Heart

The sympathetic and parasympathetic systems (see Chs **13**–**15**) each exert a tonic effect on the heart at rest and influence each of the aspects of cardiac function discussed earlier, namely rate and rhythm, myocardial contraction and myocardial metabolism and blood flow.

Sympathetic System

The main effects of sympathetic activity on the heart are:

- increased force of contraction (positive *inotropic* effect; **Fig. 20.6**);
- increased heart rate (positive *chronotropic* effect; **Fig. 20.7**);
- increased *automaticity* (i.e. tendency to generate ectopic beats);

- repolarisation and *restoration of function* following generalised cardiac depolarisation;

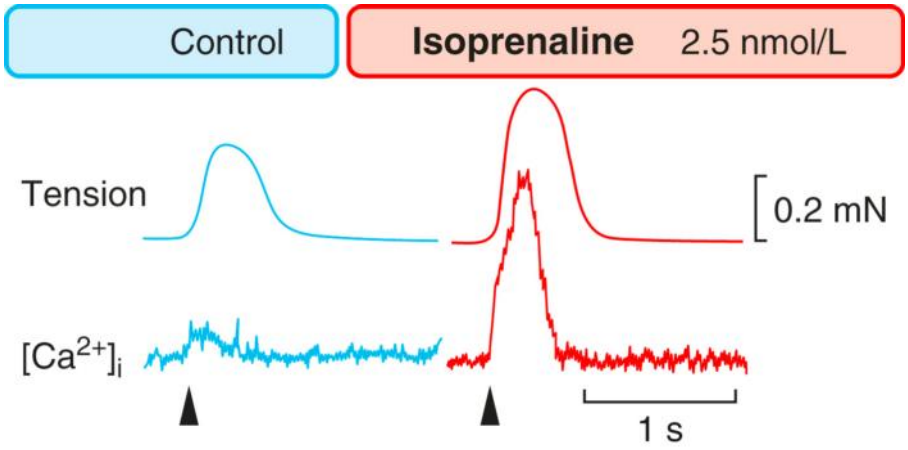

FIG. 20.6 The calcium transient in frog cardiac muscle.A group of cells was injected with the phosphorescent Ca^{2+} indicator aequorin, which allows $[Ca^{2+}]_i$ to be monitored optically. Isoprenaline causes a large increase in the tension and in the $[Ca^{2+}]_i$ transient caused by an electrical stimulus (▲). From Allen, D.G., Blinks, J.R., 1978. Nature 273, 509.

- reduced cardiac *efficiency* (i.e. oxygen consumption is increased more than cardiac work);
- cardiac hypertrophy (which seems to be directly mediated by stimulation of myocardial α and β adrenoceptors rather than by haemodynamic changes).

These effects mainly result from activation of β_1 adrenoceptors. The β_1 effects of catecholamines on the heart, although complex,

probably all occur through activation of adenylyl cyclase resulting in increased intracellular cAMP (see **Ch. 3**). cAMP activates protein kinase A, which phosphorylates sites on the α_1 subunits of calcium channels. This increases the probability that the channels will open, increasing inward Ca^{2+} current and hence force of cardiac contraction (see **Fig. 20.6**). Activation of β_1 adrenoceptors also increases the Ca^{2+} sensitivity of the contractile machinery, possibly by phosphorylating troponin C; furthermore, it facilitates Ca^{2+} capture by the sarcoplasmic reticulum, thereby increasing the amount of Ca^{2+} available for release by the action potential. The net result of catecholamine action is to elevate and steepen the ventricular function curve (see **Fig. 20.4**). The increase in heart rate results from an increased slope of the pacemaker potential (see Figs **20.1** and **20.7A**). Increased Ca^{2+} entry also increases automaticity because of the effect of $[Ca^{2+}]_i$ on the transient inward current, which can result in a train of action potentials following a single stimulus (see **Fig. 20.2**).

Activation of β_1 adrenoceptors repolarises damaged or hypoxic myocardium by stimulating the Na^+/K^+ pump. This can restore spontaneous circulation when **adrenaline** is given to patients with non-shockable rhythms during cardiac arrest.

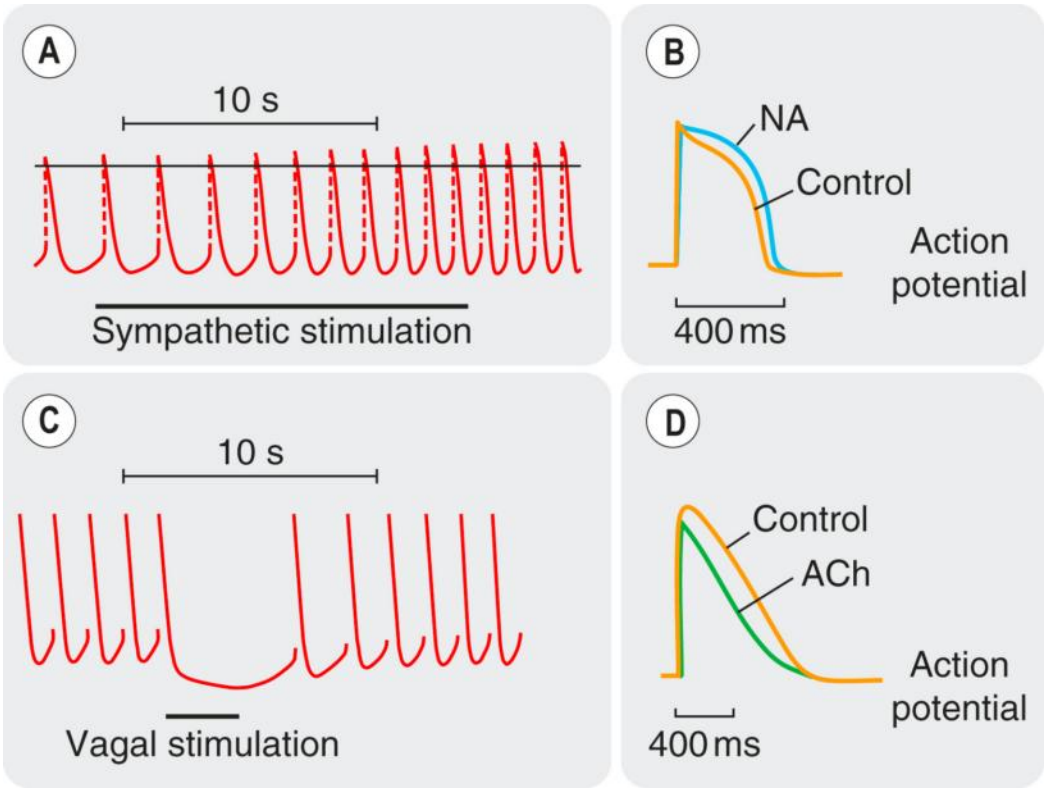

FIG. 20.7 Autonomic regulation of the heartbeat.(A) and (B) Effects of sympathetic stimulation and noradrenaline (NA). (C and D) Effects of parasympathetic stimulation and acetylcholine (ACh). Sympathetic stimulation (A) increases the slope of the pacemaker potential and increases heart rate, whereas parasympathetic stimulation (C) abolishes the pacemaker potential, hyperpolarises the membrane and temporarily stops the heart (frog sinus venosus). NA (B) prolongs the action potential, while ACh (D) shortens it (frog atrium). Panels [A] and [C] from Hutter, O.F., Trautwein, W., 1956. J. Gen. Physiol. 39, 715; panel [B] from Reuter, H., 1974. J. Physiol. 242,

429; [D] from Giles, W.R., Noble, S.J., 1976. J. Physiol. 261, 103.

The reduction of cardiac efficiency by catecholamines is important because it means that the oxygen requirement of the myocardium increases. This limits the use of β agonists such as adrenaline and **dobutamine** for circulatory shock (see **Ch. 21**). Myocardial infarction activates the sympathetic nervous system (see **Fig. 20.8**), which has the undesirable effect of increasing the oxygen needs of the damaged myocardium.

Parasympathetic System

Parasympathetic activity produces effects that are, in general, opposite to those of sympathetic activation. However, in contrast to sympathetic activity, the parasympathetic nervous system has little effect on ventricular contractility, its main effects being on rate and rhythm, namely:

- cardiac slowing and reduced automaticity
- inhibition of AV conduction

These effects result from activation of muscarinic (M_2) acetylcholine receptors, which are abundant in nodal and atrial tissue but sparse in the ventricles. These receptors are negatively coupled to adenylyl cyclase and thus reduce cAMP formation, acting to inhibit the opening of L-type Ca^{2+} channels and reduce the slow Ca^{2+} current, in opposition to β_1 adrenoceptors. M_2 receptors also open a type of K^+ channel known as GIRK (G protein–activated inward rectifying K^+ channel) via production of G β/γ subunits (see

Ch. 3). The resulting increase in K^+ permeability produces a hyperpolarising current that opposes the inward pacemaker current, slowing the heart and reducing automaticity (see **Fig. 20.7C**). Vagal activity is often increased during myocardial infarction, both in association with vagal afferent stimulation and as a side effect of opioids used to control pain, and parasympathetic effects are important in predisposing to acute dysrhythmias.

Vagal stimulation decreases the force of contraction of the atria associated with marked shortening of the action potential (see **Fig. 20.7D**). Increased K^+ permeability and reduced Ca^{2+} current both contribute to conduction block at the AV node, where propagation depends on the Ca^{2+} current. Shortening the atrial action potential reduces the refractory period, which can lead to re-entrant arrhythmias. Coronary vessels lack cholinergic innervation; consequently, the parasympathetic nervous system has little effect on coronary artery tone (see **Ch. 14**).

Autonomic control of the heart

- Sympathetic activity, acting through β_1 adrenoceptors, increases heart rate, contractility and automaticity, but reduces cardiac efficiency in relation to oxygen consumption.
- The β_1 adrenoceptors act by increasing cAMP formation, which increases Ca^{2+} currents.
- Parasympathetic activity, acting through muscarinic M_2 receptors, causes cardiac slowing, decreased force of contraction (atria only) and inhibition of AV conduction.

- M_2 receptors inhibit cAMP formation and also open potassium channels, causing hyperpolarisation.

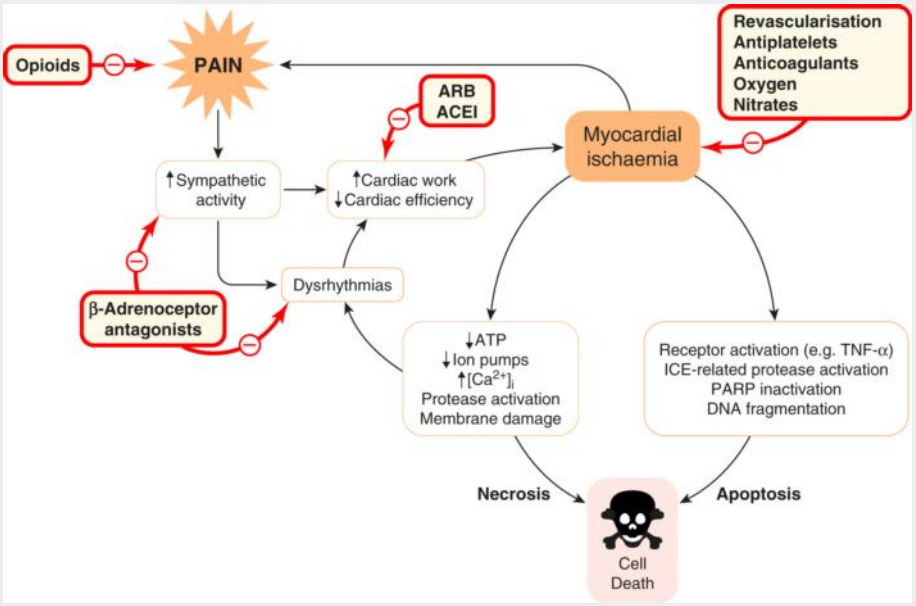

FIG. 20.8 Effects of myocardial ischaemia.This leads to cell death by one of two pathways: necrosis or apoptosis. *ACEI,* Angiotensin-converting enzyme inhibitor; *ARB,* angiotensin AT_1 receptor antagonist; *ICE,* interleukin-1-converting enzyme; *PARP,* poly-[ADP-ribose]-polymerase; *TNF-α,* tumour necrosis factor-α.

Cardiac Natriuretic Peptides

Cardiac natriuretic peptides are an important family of mediators that have diuretic and vasodilatory actions (see **Kuwahara, 2021**, for a review). Atrial cells contain secretory granules, and store and

release *atrial natriuretic peptide* (ANP). The release of ANP occurs during volume overload in response to stretching of the atria, and intravenous saline infusion is sufficient to stimulate its release. B-natriuretic peptide (BNP) is released from ventricular muscle and opposes ventricular fibrosis; its plasma concentration is increased in patients with heart failure and this (or the concentration of its precursor, N-terminal pro-BNP) helps clinicians to diagnose heart failure and titrate drug treatment. C-natriuretic peptide (CNP) is stored in endothelium and is considered to have wide-ranging effects on cardiovascular structure, function and remodelling. Both ANP and BNP are inactivated by neprilysin, also known as neutral endopeptidase (NEP) (see **Ch. 21**). **Sacubitril**, an inhibitor of neprilysin, increases circulating BNP and ANP and, in fixed combination with **valsartan**, is effective in treating heart failure.

Broadly speaking, these natriuretic peptides have actions that oppose the renin–angiotensin–aldosterone axis. The main effects of natriuretic peptides are to increase Na^+ and water excretion by the kidney, relax vascular smooth muscle, increase vascular permeability and inhibit the release and/or actions of several vasoconstrictor or salt-retaining hormones and mediators, including aldosterone, angiotensin II, endothelin and antidiuretic hormone. They exert their effects mainly through guanylyl cyclase membrane receptors (natriuretic peptide receptors [NPRs], the main subtypes of which are designated A and B). [4]

Recombinant human BNP (**nesiritide**) is licensed in the United States for treatment of heart failure, but it has failed to gain international acceptance due to lack of benefit on hard outcomes

such as hospital admissions or mortality, as well as safety concerns around hypotension.

Ischaemic Heart Disease

Atheromatous deposits are ubiquitous in the coronary arteries of adults living in developed countries. They are asymptomatic for most of the natural history of the disease (see **Ch. 22**), but can progress insidiously, culminating in acute myocardial infarction and its complications, including dysrhythmia and heart failure. Details of ischaemic heart disease are beyond the scope of this book, and excellent accounts (e.g. **Zipes et al., 2018**) are available for those seeking pathological and clinical information. Here, we merely set the scene for understanding the place of drugs that affect cardiac function in treating this most common form of heart disease.

Important consequences of coronary atherosclerosis include:

- angina (chest pain caused by cardiac ischaemia)
- myocardial infarction

Angina

Angina occurs when the oxygen supply to the myocardium is insufficient for its needs. The pain has a characteristic distribution in the chest, arm and neck, and is brought on by exertion, cold or excitement. A similar type of pain occurs in skeletal muscle when it is made to contract while its blood supply is interrupted, and Lewis showed many years ago that chemical factors released by ischaemic muscle are responsible. Possible candidates include K^+, H^+ and adenosine (see **Ch. 16**), all of which sensitise or stimulate

nociceptors (see **Ch. 43**). It is possible that the same mediator that causes coronary vasodilatation is responsible, at higher concentration, for initiating pain.

Stable angina

This is predictable chest pain on exertion. It is produced by an increased demand on the heart and is usually caused by fixed narrowing(s) of the coronary vessels by atheroma, although, as explained previously, narrowing of the aortic valve ('aortic stenosis') can cause angina by reducing coronary blood flow even in the absence of coronary artery narrowing. Symptomatic therapy is directed at reducing cardiac work with organic nitrates, β-adrenoceptor antagonists and/or calcium antagonists, together with treatment of the underlying atheromatous disease, usually including a statin (see **Ch. 22**), and prophylaxis against thrombosis with an antiplatelet drug, such as **aspirin** (see **Ch. 23**).

Vasospastic angina is relatively uncommon. It can occur at rest and is caused by coronary artery spasm, often in association with atheromatous disease. Therapy is with coronary artery vasodilators (e.g. organic nitrates, calcium antagonists).

Unstable angina

This is characterised by pain that occurs with less and less exertion, culminating in pain at rest, but without complete occlusion of the vessel. Treatment is similar to that for myocardial infarction and includes imaging and consideration of revascularisation procedures. Antiplatelet drugs (aspirin and/or an ADP antagonist such as **clopidogrel, ticagrelor** or **prasugrel**; see Chs **16** and **23**) reduce the risk of myocardial infarction in this setting, and anticoagulant

drugs add to this benefit (see **Ch. 23**) at the cost of increased risk of haemorrhage. Organic nitrates (see later) are used to relieve ischaemic pain.

Acute Coronary Syndrome

The term *acute coronary syndrome* is used to describe a range of clinical presentations (unstable angina, or non-ST-segment-elevation myocardial infarction [NSTEMI] or ST-segment-elevation myocardial infarction [STEMI]) that occur when blood flow to the heart is acutely reduced (usually from thrombosis in a coronary artery). In most instances, patients have either new onset of severe chest pain or progressive worsening of their previously stable angina, culminating in pain at rest. Clinical features and test results (ECG and biochemical markers) are instrumental in making the exact diagnosis.

The pathology in acute coronary syndrome is similar amongst the three presentations, namely coronary artery occlusion from platelet–fibrin thrombus associated with a ruptured atheromatous plaque. This may be fatal, usually as a result of mechanical failure of the ventricle or from dysrhythmia. Cardiac myocytes rely on aerobic metabolism. If the supply of oxygen remains below a critical value, a sequence of events leading to cell death ensues, detected clinically by an elevation of circulating *troponin* (a biochemical marker of myocardial injury) as well as of cardiac enzymes (e.g. the cardiac isoform of creatinine kinase) and changes in the surface ECG. The sequences leading from vascular occlusion to cell death via necrosis or apoptosis (see **Ch. 6**) are illustrated in **Fig. 20.8**. The relative importance of these two pathways in causing

myocardial cell death is unknown, but apoptosis may be an adaptive process in hypoperfused regions, sacrificing some jeopardised myocytes and thereby avoiding the disturbance of membrane function and risk of dysrhythmia inherent in necrosis. Consequently, it is currently unknown if pharmacological approaches to promote or inhibit this pathway could be clinically beneficial.

Prevention of irreversible ischaemic damage [5] following an episode of coronary thrombosis is crucial. Opening the occluded artery must be achieved as fast as possible. If logistically possible, *percutaneous coronary intervention* (involving a stent or balloon inserted into the coronary artery) with administration of a glycoprotein IIb/IIIa antagonist (see **Ch. 23**) is more effective than thrombolytic drugs, which are an alternative if percutaneous intervention is unavailable or unsuitable for the patient. The main therapeutic drugs for myocardial infarction (see **Fig. 20.8**) include drugs to improve cardiac function by maintaining oxygenation and reducing cardiac work, as well as treating pain and preventing further thrombosis. They are used in combination, and include:

- thrombolytic, antiplatelet and anticoagulant drugs to open the blocked artery and prevent reocclusion (see **Ch. 23**)
- oxygen if there is arterial hypoxia;
- opioids (given with an antiemetic) to prevent pain and reduce excessive sympathetic activity;
- organic nitrate to reduce pain from cardiac ischaemia;
- β-adrenoceptor antagonists;
- angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin AT_1 receptor antagonists (ARBs; see **Ch. 21**).

β-Adrenoceptor antagonists reduce cardiac work and thereby the metabolic needs of the heart, and are used as soon as the patient is stable. ACEIs and ARBs also reduce cardiac work and improve survival, as does opening the coronary artery (with percutaneous intervention or thrombolytic drug) and antiplatelet treatment.

Drugs that Affect Cardiac Function

Drugs that have a major action on the heart can be divided into three groups.

1. Drugs that affect myocardial cells directly. These include:
    a. autonomic neurotransmitters and related drugs
    b. antidysrhythmic drugs
    c. cardiac glycosides and other inotropic drugs
    d. miscellaneous drugs and hormones; these are dealt with elsewhere (e.g. **doxorubicin**, see **Ch. 57**; thyroxine, see **Ch. 34**; glucagon, see **Ch. 31**)
2. *Drugs that affect cardiac function indirectly*. These have actions elsewhere in the vascular system. Some anti-anginal drugs (e.g. nitrates) fall into this category, as do many drugs that are used to treat heart failure (e.g. diuretics, ACEIs and SGLT2 inhibitors; see **Ch. 21**).
3. *Calcium antagonists*. These affect cardiac function by a direct action on myocardial cells and also indirectly by relaxing vascular smooth muscle.

Antidysrhythmic Drugs

A classification of antidysrhythmic drugs based on their electrophysiological effects was proposed by Vaughan Williams in 1970 (**Table 20.1**). It provides a good starting point for discussing mechanisms, although many useful drugs do not fit neatly into this classification (**Table 20.2**). Antidysrhythmic drugs have at best an inconsistent track record and major safety and tolerability problems. Emergency treatment of serious dysrhythmias is usually by physical means (e.g. pacing or electrical cardioversion by applying a direct current shock to the chest or via an implanted device) rather than drugs and other devices and surgical procedures such as implantable converter defibrillators, and ablation procedures now dominate long-term dysrhythmia management as well.

There are four classes (see **Table 20.1**).

- Class I: drugs that block voltage-sensitive sodium channels. They are subdivided: Ia, Ib and Ic.
- Class II: β-adrenoceptor antagonists.
- Class III: drugs that substantially prolong the cardiac action potential.
- Class IV: calcium antagonists.

The phase of the action potential on which each of these classes of drug have their main effect is shown in **Fig. 20.9**.

Mechanisms of Action

Class I drugs

Class I drugs block sodium channels, just as local anaesthetics do, by binding to sites on the α subunit (see **Ch. 44**). Because this inhibits action potential propagation in many excitable cells, it has been referred to as a 'membrane-stabilising' activity, a phrase best avoided now that the ionic mechanism is understood. The characteristic effect on the action potential is to reduce the maximum rate of depolarisation during phase 0.

Table 20.2

Antidysrhythmic drugs unclassified in the Vaughan Williams system

Drug	Use
Atropine	Sinus bradycardia
Adrenaline (epinephrine)	Cardiac arrest
Isoprenaline	Heart block
Digoxin	Rapid atrial fibrillation
Adenosine	Supraventricular tachycardia
Calcium chloride	Ventricular tachycardia due to hyperkalaemia
Magnesium chloride	Ventricular fibrillation, digoxin toxicity

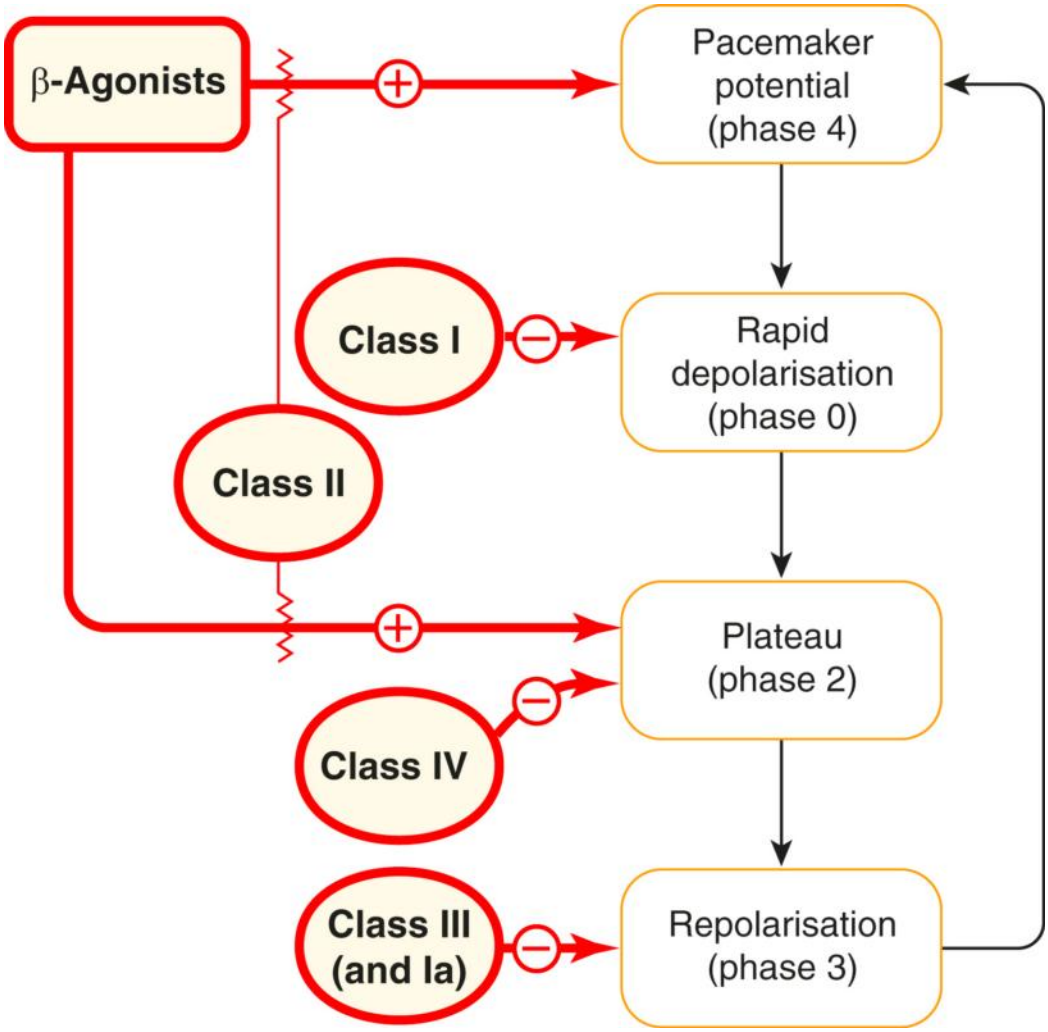

FIG. 20.9 Effects of antidysrhythmic drugs on the different phases (as defined in Fig. 20.1) of the cardiac action potential.

The reason for further subdivision of these drugs into classes Ia, Ib and Ic is that the earliest examples, **quinidine** and **procainamide** (class Ia), have different effects from many of the more recently developed drugs, even though all share the same basic mechanism of action. A partial explanation for these functional differences comes from electrophysiological studies of

the characteristics of the sodium-channel block produced by different class I drugs.

The central concept is of use-dependent channel block. It is this characteristic that enables all class I drugs to block the high-frequency excitation of the myocardium that occurs in tachyarrhythmias, without preventing the heart from beating at normal frequencies. Sodium channels exist in three distinct functional states: resting, open and inactivated (see **Ch. 4**). Channels switch rapidly from resting to open in response to depolarisation; this is known as activation. Maintained depolarisation, as in ischaemic muscle, causes channels to change more slowly from open to inactivated, and the membrane, which is then refractory, must then be repolarised for a time to restore the channel to the resting state before it can be activated again. Class I drugs bind to channels most strongly when they are in either the open or the inactivated state, less strongly to channels in the resting state. Their action therefore shows the property of 'use dependence' (i.e. the more frequently the channels are activated, the greater the degree of block produced).

Class Ib drugs, for example, **lidocaine**, associate and dissociate rapidly within the timeframe of the normal heartbeat. The drug binds to open channels during phase 0 of the action potential (affecting the rate of rise very little but leaving many of the channels blocked by the time the action potential reaches its peak). Dissociation occurs in time for the next action potential, provided the cardiac rhythm is normal. A premature beat, however, will be aborted because the channels are still blocked. Furthermore, class Ib drugs bind selectively to inactivated channels and thus block

preferentially when the cells are depolarised, for example, in ischaemia.

Class Ic drugs, such as **flecainide** and **encainide**, associate and dissociate much more slowly, thus reaching a steady-state level of block that does not vary appreciably during the cardiac cycle. They markedly inhibit conduction through the His–Purkinje system.

Class Ia, the oldest group (e.g. **quinidine**, **procainamide**, **disopyramide**), lies midway in its properties between Ib and Ic but, in addition, prolongs repolarisation, albeit less markedly than class III drugs (see later).

Class II drugs

Class II drugs comprise the β-adrenoceptor antagonists (e.g. **bisoprolol** and **metoprolol**).

Adrenaline can cause dysrhythmias by its effects on the pacemaker potential and on the slow inward Ca^{2+} current (see above). Ventricular dysrhythmias following myocardial infarction are partly the result of increased sympathetic activity (see **Fig. 20.8**), providing a rationale for using β-adrenoceptor antagonists in this setting. AV conduction depends critically on sympathetic activity; β-adrenoceptor antagonists increase the refractory period of the AV node and can therefore prevent recurrent attacks of SVT. The β-adrenoceptor antagonists are also used to prevent paroxysmal attacks of atrial fibrillation when these occur in the setting of sympathetic activation.

Class III drugs

The class III category was originally based on the unusual behaviour of a single drug, **amiodarone** (see later), although

others with similar properties (e.g. D-**sotalol** and **vernakalant**) have since been described. All three agents have more than one mechanism of antidysrhythmic action. The special feature that defines them as class III drugs is that they substantially prolong the cardiac action potential. The mechanism of this effect is not fully understood, but it involves blocking some of the potassium channels involved in cardiac repolarisation, including the outward (delayed) rectifier. Vernakalant acts mainly on the atria and also exerts some class I effect through sodium channel blockade.

Action potential prolongation increases the refractory period, accounting for powerful and varied antidysrhythmic activity, for example, by interrupting re-entrant tachycardias and suppressing ectopic activity.

Class IV drugs

Class IV agents act by blocking voltage-sensitive calcium channels. Class IV drugs in therapeutic use as antidysrhythmic drugs (e.g. **verapamil**) act on L-type channels. Class IV drugs slow conduction in the SA and AV nodes where action potential propagation depends on inward Ca^{2+} current, slowing the heart, thus terminating SVT by causing partial AV block. They shorten the plateau of the action potential and reduce the force of contraction. Decreased Ca^{2+} entry reduces after-depolarisation and thus suppresses premature ectopic beats. Functionally distinct classes of L-type voltage-gated calcium channels are expressed in heart and vascular smooth muscle, and L-type calcium-channel blockers that act mainly on vascular smooth muscle (e.g. **nifedipine**) indirectly increase sympathetic tone via their hypotensive effect, causing reflex tachycardia.

Details of Individual Drugs

Quinidine, procainamide and disopyramide (class Ia)

Quinidine and **procainamide**, now mainly of historical interest, are pharmacologically similar. **Disopyramide** resembles quinidine, but additionally possesses an atropine-like effect, distinct from its class Ia action, which can cause blurred vision, dry mouth, constipation and urinary retention. It has more negative inotropic action than quinidine but is less likely to cause hypersensitivity reactions.

Lidocaine (class Ib)

Lidocaine, also well known as a local anaesthetic (see **Ch. 44**), has been given by intravenous infusion, to treat and prevent ventricular dysrhythmias in the immediate aftermath of myocardial infarction or in cardiac arrest, but is less commonly used than amiodarone.

The adverse effects of lidocaine are mainly due to its actions on the central nervous system and include drowsiness, disorientation and convulsions.

Flecainide and encainide (class Ic)

Flecainide and **encainide** are efficacious in suppressing ectopic beats and tachyarrhythmias. However, in clinical trials, they unexpectedly increased the incidence of sudden death associated with ventricular fibrillation after myocardial infarction. As such, these drugs must not be used in patients who have underlying ischaemic or structural heart disease.

Clinical uses of class I antidysrhythmic drugs

- Class Ia (e.g. disopyramide)
  - ventricular dysrhythmias
  - prevention of recurrent paroxysmal atrial fibrillation triggered by vagal overactivity.
- **Class Ib** (e.g. intravenous **lidocaine**)
  - now seldom used.
- **Class Ic – use only in those who are free from underlying ischaemic or structural heart disease**
  - to prevent paroxysmal atrial fibrillation, or to restore sinus rhythm (pharmacological cardioversion) in atrial fibrillation (**flecainide**)
  - recurrent tachyarrhythmias associated with abnormal conducting pathways (e.g. Wolff–Parkinson–White syndrome).

β-Adrenoceptor antagonists (class II)

β-Adrenoceptor antagonists are described in **Chapter 15**. They are highly efficacious for a wide range of tachyarrhythmias and are often prescribed first line for rhythm disorders as shown in the 'Clinical uses of class II antidysrhythmic drugs (e.g. bisoprolol, metoprolol)' clinical box.

Adverse effects include worsening bronchospasm in patients with asthma, a negative inotropic effect, bradycardia and fatigue. It was

hoped that the use of β_1-selective drugs (e.g. **bisoprolol**, **metoprolol**, **atenolol**) would remove the risk of bronchospasm, but their selectivity is insufficient to always achieve this goal in clinical practice, although the once-a-day convenience of several such drugs has led to their widespread use.

Clinical uses of class II antidysrhythmic drugs (e.g. bisoprolol, metoprolol)

- To reduce mortality following myocardial infarction.
- To prevent recurrence of supraventricular and ventricular tachyarrhythmias, and ectopic beats.

For rate control in patients with atrial fibrillation

- In managing hyperthyroidism while control with antithyroid drugs is being established (see **Ch. 34**).

Class III

Amiodarone is highly effective at suppressing dysrhythmias (see the 'Clinical uses of class III antidysrhythmic drugs' clinical box). Unfortunately, several peculiarities complicate its use. It is extensively bound in tissues, has a long elimination half-life (10–100 days) and accumulates in the body during repeated dosing. For this reason, a loading dose is used, and for life-threatening dysrhythmias this is given intravenously via a central vein (it causes phlebitis if given into a peripheral vessel). Adverse effects are numerous and important; they include photosensitive rashes and a

slate-grey/bluish discoloration of the skin; thyroid abnormalities (hypo- and hyper-, connected with its iodine content); pulmonary fibrosis, which is late in onset but may be irreversible; corneal deposits; and neurological and gastrointestinal disturbances, including hepatitis. Surprisingly (since it delays repolarisation and prolongs the QT interval), reports of *torsades de pointes* and ventricular tachycardia are very unusual. **Dronedarone** is a related benzofuran with somewhat different effects on individual ion channels. It does not incorporate iodine and was designed to be less lipophilic than amiodarone in hopes of reducing thyroid and pulmonary toxicities. Its elimination $t_{1/2}$ is shorter than that of amiodarone and it is indicated to maintain sinus rhythm after cardioversion of atrial fibrillation, but only as a last resort, due to safety concerns: it increased the rates of stroke, heart failure and death from cardiovascular causes in patients with permanent atrial fibrillation and risk factors for vascular events (**Connolly et al., 2011**). Dronedarone is contraindicated in patients with heart failure or left ventricular systolic dysfunction.

Sotalol is a non-selective β-adrenoceptor antagonist, this activity residing in the L isomer. Unlike other β antagonists, it prolongs the cardiac action potential and the QT interval by delaying the slow outward K^+ current. This class III activity is present in both L and D isomers. Racemic sotalol (the form prescribed) appears to be somewhat less effective than amiodarone in preventing chronic life-threatening ventricular tachyarrhythmias. It can cause torsades de pointes; it is used in patients in whom β-adrenoceptor antagonists are not contraindicated. Close monitoring of plasma K^+ is important

for all class III drugs because of their effects on cardiac repolarisation.

Clinical uses of class III antidysrhythmic drugs

- **Amiodarone**: tachycardia associated with the Wolff–Parkinson–White syndrome. It is also effective in preventing many other supraventricular and ventricular tachyarrhythmias, but because of its serious adverse effects, amiodarone is prescribed only when other drugs (such as beta-antagonists) have failed. Intravenous amiodarone is an option for emergency treatment in life-threatening arrhythmias, or during cardiac resuscitation.
- (Racemic) **sotalol** combines class III with class II actions. It can be used in paroxysmal supraventricular dysrhythmias as well as ventricular tachycardia. However, the role of sotalol is limited because it has significant pro-arrhythmic risk.

Verapamil and diltiazem (class IV)

Verapamil is given by mouth. (Intravenous preparations are available but are seldom used because they provoke serious bradycardia and hypotension.) It has a plasma half-life of 6–8 h and is subject to quite extensive first-pass metabolism, which is more marked for the isomer that is responsible for its cardiac effects. A slow-release preparation is available for once-daily use, but it is less effective when used for prevention of dysrhythmia than the regular

preparation because the bioavailability of the cardioactive isomer is reduced through the presentation of a steady low concentration to the drug-metabolising enzymes in the liver. If verapamil is added to **digoxin** in patients with poorly controlled atrial fibrillation, the dose of digoxin should be reduced and plasma digoxin concentration checked after a few days, because verapamil both displaces digoxin from tissue-binding sites and reduces its renal elimination, hence predisposing to digoxin accumulation and toxicity.

Verapamil is contraindicated in patients with Wolff–Parkinson–White syndrome (a pre-excitation syndrome caused by a rapidly conducting pathway between atria and ventricles, anatomically distinct from the physiological conducting pathway, that predisposes to re-entrant tachycardia), and is ineffective and dangerous in ventricular dysrhythmias. The adverse effects of verapamil and diltiazem are described later in the section on calcium-channel antagonists.

Diltiazem is similar to verapamil but has relatively more effect on vascular smooth muscle while producing less bradycardia (said to be 'rate neutral').

Adenosine (unclassified in the Vaughan Williams classification)

Adenosine is produced endogenously and is an important chemical mediator (see **Ch. 16**) with effects on breathing, cardiac and smooth muscle, vagal afferent nerves and on platelets, in addition to the effects on cardiac conducting tissue that underlie its therapeutic use. The A_1 receptor is responsible for its effect on the AV node. These receptors are linked to the same cardiac potassium channel

that is activated by acetylcholine, and adenosine hyperpolarises cardiac conducting tissue and slows the rate of rise of the pacemaker potential accordingly. It is administered intravenously to terminate paroxysmal SVTs if this rhythm persists despite manoeuvres such as carotid artery massage to increase vagal tone. It has largely replaced verapamil for this purpose, because it is safer owing to its effect being short-lived as a consequence of uptake by red blood cells via a specific nucleoside transporter and metabolism by adenosine deaminase on the lumenal surface of vascular endothelium and in red cell cytoplasm. Consequently, the effects of an intravenous bolus dose of adenosine last only 20–30 s. Once SVT has terminated, the patient usually remains in sinus rhythm, even though adenosine is no longer present in plasma. Its short-lived unwanted effects include chest pain, shortness of breath, dizziness and nausea. **Regadenoson** is an A_{2A} adenosine receptor agonist that is used diagnostically in pharmacological cardiac stress testing see later). It is claimed that its selectivity and short duration of action are advantages over adenosine for this indication. It has a 2- to 3-min biological half-life and is administered as a bolus,

Theophylline and other xanthines (Chs **16** and **28**) block adenosine receptors and inhibit the actions of intravenous adenosine, whereas **dipyridamole** (a vasodilator and antiplatelet drug; see later and see **Ch. 23**) blocks the nucleoside uptake mechanism, potentiating adenosine and prolonging its adverse effects. Both these interactions are clinically important.

Clinical uses of class IV antidysrhythmic drugs

- **Verapamil** and diltiazem are used:
  - to prevent recurrence of paroxysmal SVT
  - to reduce the ventricular rate in patients with atrial fibrillation, provided they do not have Wolff–Parkinson–White or a related disorder.
- **Verapamil** was previously given intravenously to terminate SVT; it is now seldom used for this because **adenosine** is safer. (Slow-release preparations of verapamil or diltiazem are sometimes used to treat hypertension and/or angina, especially where it is desired to slow the heart rate but a β-adrenoceptor antagonist is contraindicated.)

Drugs that Act on Myocardial Contraction

Cardiac Glycosides

Cardiac glycosides come from foxgloves (*Digitalis* spp.) and related plants. Withering wrote on the use of the foxglove in 1775: 'it has a power over the motion of the heart to a degree yet unobserved in any other medicine…' Foxgloves contain several cardiac glycosides with similar actions. Their basic chemical structure consists of three components: a sugar moiety, a steroid and a lactone ring. The lactone is essential for activity, the other parts of the molecule mainly determining potency and pharmacokinetic properties. Therapeutically the most important cardiac glycoside is **digoxin**.

Endogenous digitalis-like factors have been mooted for nearly half a century. There is evidence in mammals of an endogenous digitalis-like factor closely similar to **ouabain**, a short-acting cardiac glycoside implicated in cardiovascular function (see

Schoner and Scheiner-Bobis, 2007; **Blaustein et al., 2018**). Endogenous cardiotonic steroids were first considered important in the regulation of renal sodium transport and arterial pressure, but have also been implicated in the regulation of cell growth, differentiation, apoptosis, fibrosis, the modulation of immunity and of carbohydrate metabolism and the control of various central nervous functions (**Bagrov et al., 2009**).

Actions and adverse effects

The main actions of glycosides are on the heart, but some of their adverse effects are extracardiac, including nausea, vomiting, diarrhoea and confusion. The cardiac effects are:

- cardiac slowing and reduced rate of conduction through the AV node, due to increased vagal activity;
- increased force of contraction;
- disturbances of rhythm, especially:
    - block of AV conduction;
    - increased ectopic pacemaker activity.

Adverse effects are common and can be severe. One of the main drawbacks of glycosides in clinical use is the narrow margin between effectiveness and toxicity.

Mechanism

The mechanism whereby cardiac glycosides increase the force of cardiac contraction (positive inotropic effect) is inhibition of the Na^+/K^+ pump in the cardiac myocytes. This causes increased $[Na^+]_i$, and a secondary rise in $[Ca^{2+}]_i$ (see later). Cardiac glycosides bind

to a site on the extracellular aspect of the α subunit of the Na^+-K^+-ATPase and are useful experimental tools for studying this important transporter. The molecular mechanism underlying increased vagal tone (negative chronotropic effect) is unknown but could also be due to inhibition of the Na^+/K^+ pump.

Rate and rhythm

Cardiac glycosides slow, and in higher concentrations may block, AV conduction by increasing vagal outflow. Their beneficial effect in established rapid atrial fibrillation results partly from this. If ventricular rate is excessively rapid, the time available for diastolic filling is inadequate, so slowing heart rate by partly blocking AV conduction increases stroke volume and cardiac efficiency even if atrial fibrillation persists. Digoxin can terminate paroxysmal atrial tachycardia by its effect on AV conduction, although adenosine (see earlier discussion) is preferred for this indication.

Toxic concentrations of glycosides disturb sinus rhythm. This can occur at plasma concentrations of digoxin within, or only slightly above, the therapeutic range. AV block and ectopic beats can occur. Because Na^+/K^+ exchange is electrogenic, inhibition of the pump by glycosides causes depolarisation, predisposing to disturbances of cardiac rhythm. Furthermore, the increased $[Ca^{2+}]_i$ causes increased after-depolarisation, leading first to coupled beats (bigeminy), in which a normal ventricular beat is followed by an ectopic beat; ventricular tachycardia and eventually ventricular fibrillation may ensue.

Force of contraction

Glycosides cause a large increase in twitch tension in isolated preparations of cardiac muscle. Unlike catecholamines, they do not accelerate relaxation (compare **Fig. 20.6** with **Fig. 20.10**). Increased tension is caused by an increased $[Ca^{2+}]_i$ transient (see **Fig. 20.10**). The action potential is only slightly affected and the slow inward current little changed, so the increased $[Ca^{2+}]_i$ transient probably reflects a greater release of Ca^{2+} from intracellular stores. The most likely mechanism is as follows (see also **Ch. 4**):

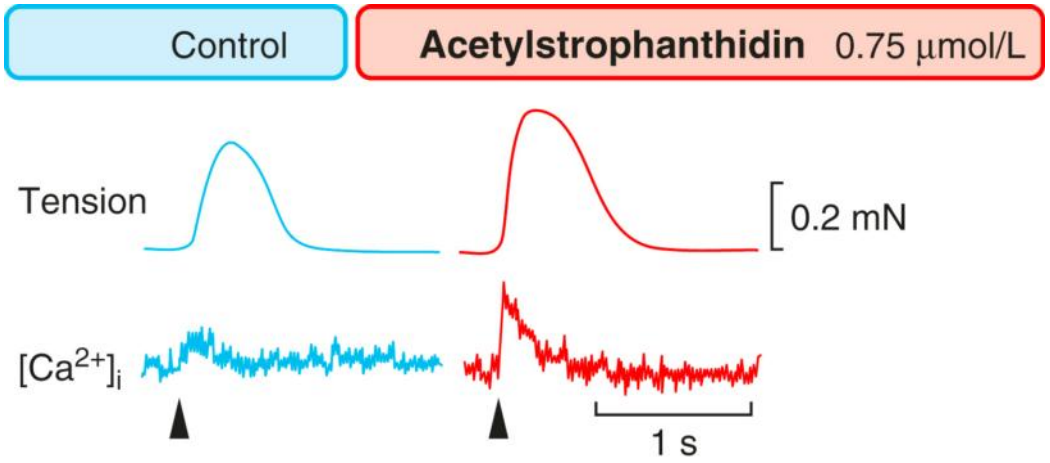

FIG. 20.10 Effect of a cardiac glycoside (acetylstrophanthidin) on the Ca^{2+} transient and tension produced by frog cardiac muscle.The effect was recorded as in Fig. 20.6. From Allen, D.G., Blinks, J.R., 1978. Nature 273, 509.

1. Glycosides inhibit the Na^+/K^+ pump.
2. Increased $[Na^+]_i$ slows extrusion of Ca^{2+} via the Na^+/Ca^{2+} exchange transporter since increasing $[Na^+]_i$ reduces the

inwardly directed gradient for Na^+ which drives extrusion of Ca^{2+} by Na^+/Ca^{2+} exchange.

3. Increased $[Ca^{2+}]_i$ is stored in the sarcoplasmic reticulum, and thus increases the amount of Ca^{2+} released by each action potential.

The effect of extracellular potassium

The effects of cardiac glycosides are increased if plasma $[K^+]$ decreases, because of reduced competition at the K^+-binding site on the Na^+-K^+-ATPase. This is clinically important, because many diuretics, which are often used to treat heart failure (see **Ch. 29**), decrease plasma $[K^+]$ thereby increasing the risk of glycoside-induced dysrhythmia.

Pharmacokinetic aspects

Digoxin is administered by mouth or, in urgent situations, intravenously. It is a polar molecule; elimination is mainly by renal excretion and involves P-glycoprotein (see **Ch. 9**), leading to clinically significant interactions with other drugs used to treat heart failure, such as **spironolactone**, and with antidysrhythmic drugs such as **verapamil** and **amiodarone**. Elimination half-time is approximately 36 h in patients with normal renal function, but considerably longer in elderly patients and those with overt renal failure, for whom the maintenance dose must be reduced. A loading dose is used to achieve therapeutic concentrations for rapid heart rate control in urgent situations. The therapeutic range of plasma concentrations, below which digoxin is unlikely to be effective and above which the risk of toxicity increases substantially, is rather

narrow (1–2.6 nmol/L). Determination of plasma digoxin concentration is useful when lack of efficacy or toxicity is suspected.

Clinical uses of cardiac glycosides (e.g. digoxin)

- To slow ventricular rate in rapid persistent atrial fibrillation. This is effective at rest but less so during exercise when vagal tone is reduced and sympathetic tone increased, limiting its usefulness.
- Treatment of heart failure in patients who remain symptomatic despite optimal use of diuretics and ACEIs (see **Ch. 21**).

Other Drugs that Act on Myocardial Contraction

Certain β_1-adrenoceptor agonists, for example **dobutamine**, are used to treat acute but potentially reversible heart failure (e.g. following cardiac surgery or in some cases of cardiogenic or septic shock) because of their positive inotropic action. Dobutamine, for reasons that are not well understood, produces less tachycardia than other β_1 agonists. It is used intravenously for short-term treatment of acute heart failure, or for pharmacological cardiac stress testing and echocardiography. **Glucagon** also increases myocardial contractility by increasing synthesis of cAMP, and has been used in patients with acute cardiac dysfunction caused by overdosage of β-adrenoceptor antagonists.

Inhibitors of the heart-specific subtype (type III) of phosphodiesterase, the enzyme responsible for the intracellular degradation of cAMP, increase myocardial contractility. Consequently, like β-adrenoceptor agonists, they increase intracellular cAMP and can cause dysrhythmias for the same reason. Compounds in this group include **amrinone** and **milrinone**. They improve haemodynamic indices in patients with heart failure but paradoxically worsen survival in chronic heart failure, presumably because of dysrhythmias. As with the encainide/flecainide and dronedarone examples, this disparity has had a sobering effect on clinicians and drug regulatory authorities.

Recent developments have led to phase III trials of drugs targeted at cardiac myosin. **Omecamtiv** mecarbil is a selective cardiac myosin activator that lowers the risk of hospital admissions in patients who have heart failure with reduced left ventricular ejection fraction. In contrast, **mavacamten** is a beta cardiac myosin inhibitor that decreases the excess contraction of heart muscles in patients with hypertrophic cardiomyopathy and currently under consideration by regulatory authorities for treating this disorder.

Anti-Anginal Drugs

The mechanism of anginal pain is discussed previously. Angina is managed by using drugs that improve perfusion of the myocardium or reduce its metabolic demand, or both. Two of the main groups of drugs, organic nitrates and calcium antagonists, are vasodilators and produce both these effects. The third group, β-adrenoceptor antagonists, slow the heart and hence reduce metabolic demand.

Organic nitrates and calcium antagonists are described later. The β-adrenoceptor antagonists are covered in **Chapter 15**, and their antidysrhythmic actions are described earlier. **Ivabradine** slows the heart by inhibiting the sinus node I_f current (see earlier discussion) and is an alternative to β-adrenoceptor antagonists in patients in whom these are not tolerated or are contraindicated. Combined use of ivabradine with a β-adrenoceptor antagonist is indicated in patients whose symptoms are not adequately controlled despite an optimal dose of the β-adrenoceptor antagonist. **Ranolazine** was introduced as an adjunct to other anti-anginal drugs: it inhibits late sodium current and hence indirectly reduces intracellular calcium and force of contraction (the opposite of the effects of cardiac glycosides), without affecting heart rate; more potent and selective inhibitors of the persistent sodium current are in development. Newer anti-anginal drugs are described by **Jones et al. (2013)**.

Organic Nitrates

The ability of organic nitrates (see also Chs **19** and **21**) to relieve angina was discovered by Lauder Brunton, a distinguished British physician, in 1867. He had found that angina could be partly relieved by bleeding, and knew that **amyl nitrite**, which had been synthesised 10 years earlier, caused flushing and tachycardia with a fall in blood pressure when its vapour was inhaled. He thought that the effect of bleeding resulted from hypotension and found that amyl nitrite inhalation worked much better. Amyl nitrite has now been replaced by **glyceryl trinitrate** (GTN). [6] Several related organic nitrates, of which the most important is **isosorbide**

mononitrate, have a prolonged action. **Nicorandil**, a potassium-channel activator with additional nitrovasodilator activity, is sometimes combined with other anti-anginal treatment in resistant cases.

Actions

Organic nitrates relax smooth muscle (especially vascular smooth muscle, but also oesophageal and biliary smooth muscle). They relax veins, with a consequent reduction in central venous pressure (reduced preload). In healthy subjects, this reduces stroke volume; venous pooling occurs on standing and can cause postural hypotension and dizziness. Therapeutic doses have less effect on small resistance arteries than on veins, but there is a marked effect on larger muscular arteries. This reduces pulse wave reflection from arterial branches (as appreciated in the 19th century by Murrell but neglected for many years thereafter), and consequently reduces central (aortic) pressure and cardiac afterload (see **Ch. 21** for the role of these factors in determining cardiac work). The direct dilator effect on coronary arteries opposes coronary artery spasm in vasospastic angina. With larger doses, resistance arteries and arterioles dilate, and arterial pressure falls. Nevertheless, coronary flow increases because of coronary vasodilatation. Myocardial oxygen consumption is reduced because of the reductions in cardiac preload and afterload. This, together with the increased coronary blood flow, causes a large increase in the oxygen content of coronary sinus blood. Studies in experimental animals have shown that GTN diverts blood from normal to ischaemic areas of myocardium. The mechanism involves dilatation of collateral

vessels that bypass narrowed coronary artery segments (**Fig. 20.11**).

This contrasts with the effect of other vasodilators, notably **dipyridamole**, which dilate arterioles but not collaterals. Dipyridamole is at least as effective as nitrates in increasing coronary flow in normal subjects but actually worsens angina. This is probably because arterioles in an ischaemic region are fully dilated by the ischaemia, and drug-induced dilatation of the arterioles in normal areas has the effect of diverting blood away from the ischaemic areas (see **Fig. 20.11**), producing what is termed a *vascular steal*. This effect is exploited in a pharmacological 'stress test' for coronary arterial disease, in which dipyridamole is administered intravenously to patients in whom this diagnosis is suspected, while monitoring myocardial perfusion and the ECG. **Regadenoson** is an A_{2A} adenosine receptor agonist that is used similarly in pharmacological cardiac stress testing.

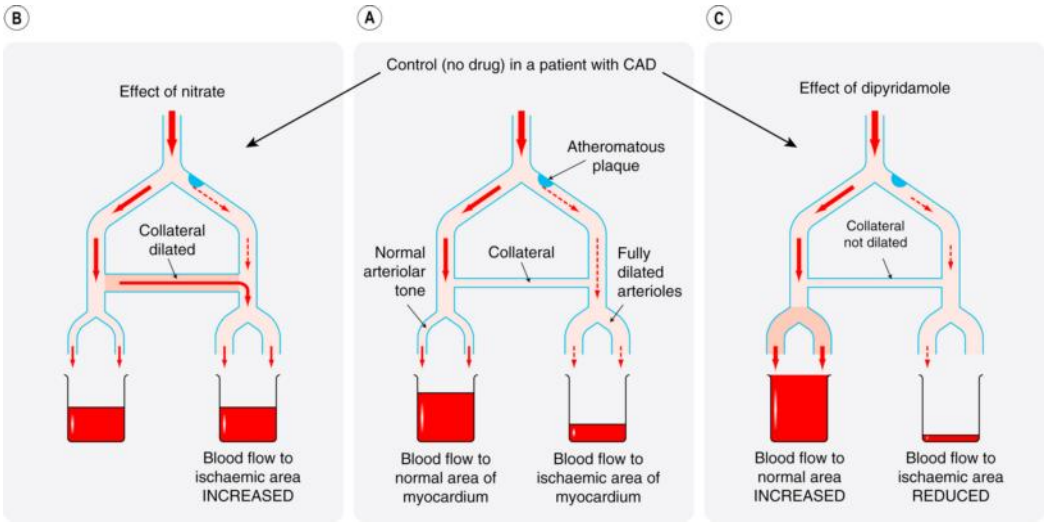

FIG. 20.11 Comparison of the effects of organic nitrates and an arteriolar vasodilator (dipyridamole) on the coronary circulation.(A) Control. (B) Nitrates dilate the collateral vessel, thus allowing more blood through to the underperfused region (mostly by diversion from the adequately perfused area). (C) Dipyridamole dilates arterioles, increasing flow through the normal area at the expense of the ischaemic area (in which the arterioles are anyway fully dilated). *CAD,* Coronary artery disease.

In summary, the anti-anginal action of nitrates involves:

- reduced cardiac work, because of reduced cardiac preload (venodilatation) and afterload (reduced arterial pressure wave reflection), leading to reduced myocardial oxygen requirement;
- redistribution of coronary flow towards ischaemic areas via collaterals;

- relief of coronary spasm.

In addition to its effects on smooth muscle, nitric oxide (NO) increases the rate of relaxation of cardiac muscle (dubbed a 'lusiotropic' action). It is probable that organic nitrates mimic this action, which could be important in patients with impaired diastolic function, a common accompaniment of hypertension and of heart failure.

Mechanism of action

Organic nitrates are metabolised with release of NO. At concentrations achieved during therapeutic use, this involves an enzymic step and possibly a reaction with tissue sulfhydryl (–SH) groups. NO activates soluble guanylyl cyclase (see **Ch. 19**), increasing the formation of cGMP, which activates protein kinase G (see **Ch. 4**) and leads to a cascade of effects in smooth muscle culminating in dephosphorylation of myosin light chains, sequestration of intracellular Ca^{2+} and relaxation.

Tolerance and unwanted effects

Repeated administration of nitrates to smooth muscle preparations in vitro results in diminished relaxation, possibly partly because of depletion of free –SH groups, although attempts to prevent tolerance by agents that restore tissue –SH groups have not been clinically useful. Tolerance to the anti-anginal effect of nitrates does not occur to a clinically important extent with ordinary formulations of short-acting drugs (e.g. GTN) but does occur with longer-acting drugs (e.g. isosorbide mononitrate) or when GTN is

administered by prolonged intravenous infusion or by frequent application of slow-release transdermal patches (see later).

The main adverse effects of nitrates are a direct consequence of their main pharmacological actions and include postural hypotension and headache. This was the cause of 'Monday morning sickness' among workers in explosives factories. Tolerance to these effects develops quite quickly but wears off after a brief nitrate-free interval (which is why the symptoms appeared on Mondays and not later in the week). Formation of *methaemoglobin*, an oxidation product of haemoglobin that is ineffective as an oxygen carrier, seldom occurs when nitrates are used clinically but is induced deliberately with **amyl nitrite** in the treatment of *cyanide poisoning*, because methaemoglobin binds and inactivates cyanide ions.

Pharmacokinetic and pharmaceutical aspects

GTN is rapidly inactivated by hepatic metabolism. It is well absorbed from the mouth and is taken as a tablet under the tongue or as a sublingual spray, producing its effects within a few minutes. If swallowed, it is ineffective because of presystemic metabolism in the liver. Given sublingually, the trinitrate is converted to di- and mononitrates. Its effective duration of action is approximately 30 min. It is appreciably absorbed through the skin, and a more sustained effect can be achieved by applying it as a transdermal patch. Once a bottle of the tablets has been opened, its shelf-life is quite short because the volatile active substance evaporates; spray preparations avoid this problem.

Isosorbide mononitrate is longer acting than GTN because it is absorbed and metabolised more slowly but has similar pharmacological actions. It is not subject to first-pass metabolism in the liver and so can be swallowed rather than taken sublingually. It is usually administered in slow-release form for once-daily use in the morning, with the gradual absorption and elimination allowing a relative nitrate-free interval during the night.

Organic nitrates

- Important compounds include **glyceryl trinitrate** and longer-acting **isosorbide mononitrate.**
- These drugs are powerful vasodilators, acting on veins to reduce cardiac preload and on arteries to reduce arterial pressure wave reflection and hence afterload.
- Act via NO, to which they are metabolised. NO stimulates formation of cGMP and hence activates protein kinase G, affecting contractile proteins (myosin light chains) and Ca^{2+} regulation.
- Tolerance occurs experimentally and is important clinically with frequent use of long-acting drugs or sustained-release preparations.
- Effectiveness in angina results partly from reduced cardiac load and partly from dilatation of collateral coronary vessels, causing more effective distribution of coronary flow. Dilatation of constricted coronary vessels is particularly beneficial in variant angina.

- Serious unwanted effects are uncommon; headache and postural hypotension may occur initially. Overdose can rarely cause methaemoglobinaemia.

Clinical uses of organic nitrates

- Stable angina:
  - prevention (e.g. daily **isosorbide mononitrate**, or **glyceryl trinitrate** sublingually immediately before exertion);
  - treatment (sublingual **glyceryl trinitrate**).
- Unstable angina: intravenous **glyceryl trinitrate.**
- Acute heart failure: intravenous **glyceryl trinitrate.**
- Chronic heart failure: **isosorbide mononitrate**, with **hydralazine** in patients of African origin (see **Ch. 21**).

Potassium-Channel Activators

Nicorandil combines activation of the potassium K_{ATP} channel (see **Ch. 4**) with nitrovasodilator (NO donor) actions. It is both an arterial and a venous dilator, and causes the expected unwanted effects of headache, flushing and dizziness. It is used for patients who remain symptomatic despite optimal management with other drugs, often while they await surgery or angioplasty, or if coronary intervention is not a feasible option.

β-adrenoceptor antagonists

β-Adrenoceptor antagonists (see **Ch. 15**) are important in the prophylaxis of stable angina, and in treating patients with unstable angina, acting by reducing cardiac oxygen consumption. They reduce the risk of death following myocardial infarction, possibly via their antidysrhythmic action. Any effects on coronary vessel diameter are of minor importance, although these drugs are avoided in vasospastic angina because of the theoretical risk that they will increase coronary spasm. Their astonishingly diverse clinical uses are summarised in the previous clinical boxes and in **Chapter 15**.

Calcium Antagonists

The term *calcium antagonist* is used for drugs that block cellular entry of Ca^{2+} through calcium channels rather than preventing its intracellular actions (see **Ch. 4**). Some authors use the term *Ca^{2+} entry blockers* to make this distinction clearer. Therapeutically important calcium antagonists act on L-type channels. L-type calcium antagonists comprise three chemically distinct classes: *phenylalkylamines* (e.g. **verapamil**), *dihydropyridines* (e.g. **nifedipine**, **amlodipine**) and *benzothiazepines* (e.g. **diltiazem**).

Mechanism of action: types of calcium channel

The properties of voltage-gated calcium channels have been studied by voltage clamp and patch clamp techniques (see **Ch. 3**). Drugs of each of the three chemical classes mentioned earlier all bind the α_1 subunit of the L-type calcium channel but at distinct sites. These interact allosterically with each other and with the gating machinery of the channel to prevent its opening (see later and **Fig. 20.12**), thus reducing Ca^{2+} entry. Many calcium antagonists show properties of use dependence (i.e. they block most effectively in

cells in which the calcium channels are most active; see the discussion of class I antidysrhythmic drugs earlier). For the same reason, they also show voltage-dependent blocking actions, blocking more strongly when the membrane is depolarised, causing calcium-channel opening and inactivation.

Dihydropyridines affect calcium-channel function in a complex way, not simply by physical plugging of the pore. Calcium channels can exist in one of three distinct states, termed *modes* (see **Fig. 20.12**). When a channel is in mode 0, it does not open in response to depolarisation; in mode 1, depolarisation produces a low opening probability, and each opening is brief. In mode 2, depolarisation produces a very high opening probability, and single openings are prolonged. Under normal conditions, about 70% of the channels at any one moment exist in mode 1, with only 1% or less in mode 0; each channel switches randomly and quite slowly between the three modes. Dihydropyridine antagonists bind selectively to channels in mode 0, thus favouring this non-opening state, whereas agonists bind selectively to channels in mode 2 (see **Fig. 20.12**). This type of two-directional modulation resembles the phenomenon seen with the GABA/benzodiazepine interaction (see **Ch. 45**) and invites speculation about possible endogenous dihydropyridine-like mediator(s) with a regulatory effect on Ca^{2+} entry.

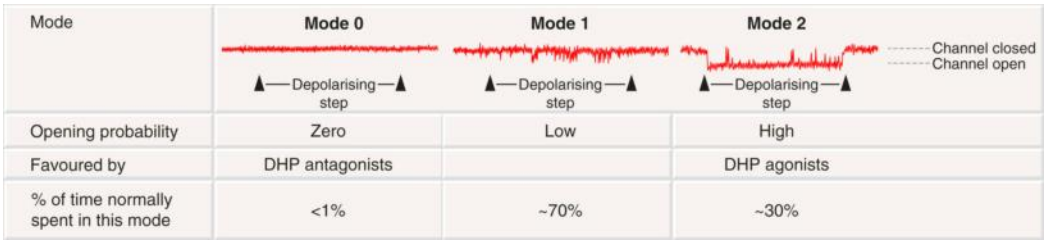

FIG. 20.12 Mode behaviour of calcium channels.The traces are patch clamp recordings (see **Ch. 3**) of the opening of single calcium channels *(downward deflections)* in a patch of membrane from a cardiac muscle cell. A depolarising step is imposed close to the start of each trace, causing an increase in the opening probability of the channel. When the channel is in mode 1 *(centre)*, this causes a few brief openings to occur; in mode 2 *(right)*, the channel stays open for most of the time during the depolarising step; in mode 0 *(left)*, it fails to open at all. Under normal conditions, in the absence of drug, the channel spends most of its time in modes 1 and 2, and only rarely enters mode 0. *DHP,* Dihydropyridine. Redrawn from Hess, et al., 1984. Nature 311, 538–544.

Ethosuximide (used to treat absence seizures; see **Ch. 46**) blocks T channels in thalamic and reticular neurons.

Pharmacological effects

The main effects of calcium antagonists, as used therapeutically, are on cardiac and smooth muscle. Verapamil preferentially affects the

heart, whereas most of the dihydropyridines (e.g. nifedipine) exert a greater effect on smooth muscle than on the heart. Diltiazem is intermediate in its actions.

Cardiac actions

The antidysrhythmic effects of verapamil and diltiazem have been discussed earlier. Calcium antagonists can cause AV block and cardiac slowing by their actions on conducting tissues, but this is offset by a reflex increase in sympathetic activity secondary to their vasodilator action. For example, nifedipine typically causes reflex tachycardia; diltiazem causes little or no change in heart rate and verapamil slows the heart rate. Calcium antagonists also have a negative inotropic effect, from their inhibition of Ca^{2+} entry during the action potential plateau. Verapamil has the most marked negative inotropic action, and is contraindicated in heart failure, whereas amlodipine does not worsen cardiovascular mortality in patients with severe but stable chronic heart failure.

Vascular smooth muscle

Calcium antagonists cause generalised arterial/arteriolar dilatation, thereby reducing blood pressure, but do not much affect the veins. They affect all vascular beds, although regional effects vary considerably between different drugs. They cause coronary vasodilatation and are used in patients with coronary artery spasm (vasospastic angina). Other types of smooth muscle (e.g. biliary tract, urinary tract and uterus) are also relaxed by calcium antagonists, but these effects are less important therapeutically than their actions on vascular smooth muscle.

Protection of ischaemic tissues

Randomised clinical trials have been disappointing, with little or no evidence of beneficial (or harmful) effects of calcium antagonists on cardiovascular morbidity or mortality in patient groups other than patients with hypertension, in whom calcium antagonists have beneficial effects comparable with those of other drugs that lower blood pressure to similar extents (see **Ch. 21**). **Nimodipine** is partly selective for cerebral vasculature and there is some evidence that it reduces cerebral vasospasm following subarachnoid haemorrhage.

Pharmacokinetics

Calcium antagonists in clinical use are well absorbed from the gastrointestinal tract, and are given by mouth except for some special indications, such as following subarachnoid haemorrhage, for which intravenous preparations are available. They are extensively metabolised. Pharmacokinetic differences between different drugs and different pharmaceutical preparations are clinically important because they determine the dose interval and the intensity of some of the unwanted effects, such as headache and flushing. Amlodipine has a long elimination half-life and is given once daily, whereas nifedipine, diltiazem and verapamil have shorter elimination half-lives and are either given more frequently or are formulated in various slow-release preparations to permit once-daily dosing.

Unwanted effects

Most of the unwanted effects of calcium antagonists are extensions of their main pharmacological actions. Short-acting dihydropyridines cause flushing and headache because of their vasodilator action, and in chronic use dihydropyridines often cause ankle swelling (oedema) related to arteriolar dilatation and increased permeability of postcapillary venules. Verapamil can cause constipation, probably because of effects on calcium channels in gastrointestinal nerves or smooth muscle. Effects on cardiac rhythm (e.g. heart block) and force of contraction (e.g. worsening heart failure) were discussed earlier.

Apart from these predictable effects, calcium-channel antagonists, as a class, have few idiosyncratic adverse effects.

Calcium antagonists

- Block Ca^{2+} entry by preventing opening of voltage-gated L-type calcium channels.
- There are three main L-type antagonists, typified by **verapamil**, **diltiazem** and dihydropyridines (e.g. **nifedipine**).
- Mainly affect heart and smooth muscle.
- **Verapamil** is relatively cardioselective, **nifedipine** is relatively smooth muscle selective, and diltiazem is intermediate.
- Vasodilator effect (mainly dihydropyridines) is mainly on resistance vessels, reducing afterload. Calcium antagonists dilate coronary vessels, which is important in vasospastic angina.

- Effects on heart (**verapamil**, **diltiazem**): antidysrhythmic action; impaired AV conduction; reduced contractility.
- Clinical uses:
  - antidysrhythmic (mainly **verapamil**)
  - angina, antidysrhythmic (e.g. **diltiazem**)
  - hypertension (mainly dihydropyridines).
- Unwanted effects include headache, constipation (**verapamil**) and ankle oedema (dihydropyridines). There is a risk of causing cardiac failure or heart block, especially with **verapamil.**

Clinical uses of calcium antagonists

- Dysrhythmias (**verapamil, diltiazem**):
  - to slow ventricular rate in rapid atrial fibrillation
  - to prevent recurrence of SVT (intravenous administration of **verapamil** to terminate SVT attacks has been replaced by use of **adenosine**).
- Hypertension: usually a dihydropyridine (e.g. **amlodipine** or slow-release **nifedipine**; see **Ch. 21**).
- To prevent angina (e.g. a dihydropyridine or **diltiazem**).

QUESTIONS

QUESTION 20.1

The chambers of the heart normally contract in a coordinated manner, pumping blood efficiently by a route determined by the valves. Coordination of contraction is achieved by a specialised conducting system.

Which of the following statements about the cardiac conducting system is incorrect?

OPTIONS:

A. Pacemaker impulses arise in the sinoatrial (SA) node.

B. Cardiac cells are activated by ion influx through voltage-sensitive plasma membrane channels.

C. Fast Na^+ currents in the SA and atrioventricular (AV) nodes initiate action potentials.

D. Cardiac cells have a long action potential ('plateau').

E. Intracellular calcium channels are important in myocardial contraction.

QUESTION 20.2

The action potential of a cardiac muscle cell is divided into five phases.

Which of the following statements about each of these phases is incorrect?

OPTIONS:

A. During phase 0, rapid depolarisation occurs when Na+ influx reaches a threshold level.

B. In phase 1, partial repolarisation occurs as the Na^+ current is inactivated.

C. Phase 2, the plateau, results from an inward Ca^{2+} current.

D. Phase 3, repolarisation, occurs due to a fast outward K+ current triggered by the high intracellular calcium concentration.

E. Phase 4 involves a gradual depolarisation during diastole.

QUESTION 20.3

Tachyarrhythmias could be triggered by all of the following except...

OPTIONS:

A. Increased catecholamine release

B. Fibrosis

C. Re-entry circuits

D. After-depolarization

E. HERG (human ether-a-go-go related gene) channels

ANSWERS

ANSWER 20.1

RATIONALE:

A. Normal sinus rhythm is generated by pacemaker impulses that arise in the SA node and are conducted in sequence through the atria, the AV node, bundle of His, Purkinje fibres and ventricles.

B. Cardiac cells owe their electrical excitability to voltage-sensitive plasma membrane channels selective for various ions, including Na^+, K^+ and Ca^{2+}.

C.

D. Cardiac cells have a long action potential ('plateau') mediated by an influx of Ca^{2+} and subsequent refractory period.

E. Intracellular calcium channels, i.e. ryanodine receptors and inositol trisphosphate-activated calcium channels, are important in myocardial contraction.

CORRECT ANSWER WITH EXPLANATION:

C. Fast Na^+ currents in the SA and AV nodes initiate action potentials.

There is an absence of a fast Na^+ current in the SA and AV nodes, where instead a slow inward Ca^{2+} current initiates action potentials.

ANSWER 20.2

RATIONALE:

A. Phase 0, rapid depolarisation, occurs when the membrane potential reaches a critical firing threshold (about –60 mV), at which the inward current of Na^+ flowing through the voltage-dependent sodium channels becomes large enough to produce a regenerative ('all-or-nothing') depolarisation.

B. Activation of sodium channels by membrane depolarisation is transient, and if the membrane remains depolarised for more than a few milliseconds, they close again (inactivation).

C. Phase 2, the plateau, results from an inward Ca^{2+} current. Calcium channels show a pattern of voltage-sensitive activation and inactivation qualitatively similar to sodium channels, but with a much slower time course.

D.

E. Phase 4, the pacemaker potential, is a gradual depolarisation during diastole. The pacemaker potential is caused by a combination of increasing inward currents and declining outward currents during diastole.

CORRECT ANSWER WITH EXPLANATION:

D. Phase 3, repolarisation, occurs due to a fast outward K+ current triggered by the high intracellular calcium concentration.

Phase 3, repolarisation, occurs as the Ca^{2+} current inactivates and a delayed outwardly rectifying K^+ current (analogous to, but much slower than, the K^+ current that causes repolarisation in nerve fibres) activates, causing outward K^+ current.

ANSWER 20.3

RATIONALE:

A. Catecholamines, acting on β_1 adrenoceptors, increase the rate of depolarisation during phase 4 and can provoke normally quiescent parts of the heart to take on a spontaneous rhythm. Several tachyarrhythmias can be triggered by circumstances associated with increased sympathetic activity, e.g. pain during myocardial infarction.

B.

C. Re-entry describes a situation in which the impulse re-excites regions of the myocardium after the refractory period has subsided, causing continuous circulation of action potentials.

D. After-depolarisation is triggered activity involving premature activation of the cardiac myocytes and extra beats. Fluctuations in the membrane potential can trigger additional depolarisations while repolarisation is still ongoing after repolarisation is complete and leads to tachycardias.

E. A dangerous polymorphic form of ventricular tachycardia called torsade de pointes is associated with prolongation of the QT interval, and linked to drugs that inhibit the HERG repolarising potassium channel.

CORRECT ANSWER WITH EXPLANATION:

B. Fibrosis

Heart block results from fibrosis of, or ischaemic damage to, the conducting system (often in the AV node). In complete heart block, the atria and ventricles beat independently of one another, the ventricles beating at a slow rate (bradycardia) determined by whatever pacemaker picks up distal to the block.

[1] 'f' for 'funny', because it is unusual for cation channels to be activated by hyperpolarisation; cardiac electrophysiologists have a peculiar sense of humour!

[2] A 3-year-old girl began to have blackouts, which decreased in frequency with age. Her ECG showed a prolonged QT interval. When she was 18 years of age, she lost consciousness running for a bus. When she was 19, she became quite emotional as a participant in a live television audience and died suddenly. The molecular basis of this rare inherited disorder is now known. It is most commonly caused by mutations in the genes coding for potassium voltage-gated channels –KCNQ1 and KCNH2 (also known as *HERG*) – or sodium voltage-gated channel, *SCN5A*, which results in a loss of inactivation of the Na^+current.

[3] **Trimetazidine,** used to treat angina in some European countries, is claimed to improve cardiac metabolism by blocking fatty acid oxidation, thereby increasing the use of glucose as an energy source, which requires less oxygen per unit of energy generated. However, a large trial in patients after coronary intervention did not demonstrate significant benefit over placebo (Ferrari et al., 2020).

[4] The nomenclature of natriuretic peptides and their receptors is peculiarly obtuse. The peptides are named 'A' for atrial, 'B' for brain – despite being present mainly in cardiac ventricle – and 'C' for A, B, C…; NPRs are named NPR-A, which preferentially binds ANP; NPR-B, which binds CNP preferentially; and NPR-C for 'clearance' receptor, because clearance of natriuretic peptide via cellular uptake

and degradation by lysosomal enzymes was previously thought to be the only definite function of this binding site.

[5] Irreversible' by present technologies; cell therapies based on cardiac stem cells have been attempted therapeutically, and are a beacon of hope for the future.

[6] Nobel discovered how to stabilise GTN with kieselguhr, enabling him to exploit its explosive properties in dynamite, the manufacture of which earned him the fortune with which he endowed the eponymous prizes.

21: The vascular system

OVERVIEW

This chapter is concerned with the pharmacology of blood vessels. The walls of arteries, arterioles, venules and veins contain smooth muscle, the contractile state of which is controlled by circulating hormones and by mediators released locally from sympathetic nerve terminals (**Ch. 15**), endothelial cells and other cells resident in the vessel wall or visiting it from the circulating blood. These work mainly by regulating Ca^{2+} in vascular smooth muscle cells, as described in **Chapter 4**. In the present chapter, we first consider the control of vascular smooth muscle by the endothelium and by the renin–angiotensin system, followed by the actions of vasoconstrictor and vasodilator drugs. Finally, we consider briefly some of the clinical uses of vasoactive drugs in selected important diseases, namely hypertension (pulmonary as well as systemic), heart failure, shock, peripheral vascular disease and Raynaud's disease. The use of vasoactive drugs to treat angina is covered in **Chapter 20**.

Introduction

The actions of drugs on the vascular system can be broken down into effects on:

- total systemic ('peripheral') vascular resistance, one of the main determinants of arterial blood pressure;
- the resistance of individual vascular beds, which determines the local distribution of blood flow to and within different organs; such effects are relevant to the drug treatment of angina (see **Ch. 20**), Raynaud's phenomenon, pulmonary hypertension and circulatory shock;
- aortic compliance and pulse wave reflection, which are relevant to the treatment of hypertension, cardiac failure and angina;
- venous tone and blood volume (the 'fullness' of the circulation), which together determine the central venous pressure and are relevant to the treatment of cardiac failure and angina; diuretics (which reduce blood volume) are discussed in **Chapter 29**;
- atheroma (see **Ch. 22**) and thrombosis (see **Ch. 23**);
- new vessel formation (angiogenesis) – important, for example, in diabetic retinopathy (see **Ch. 27**) and in treating malignant disease (see **Ch. 57**).

Drug effects considered in this chapter are caused by actions on vascular smooth muscle cells. Like other muscles, vascular smooth muscle contracts when cytoplasmic Ca^{2+} ($[Ca^{2+}]_i$) rises, but the coupling between $[Ca^{2+}]_i$ and contraction is less tight than in striated voluntary or cardiac muscle (see **Ch. 4**). Vasoconstrictors and vasodilators act by increasing or reducing $[Ca^{2+}]_i$ and/or by altering the sensitivity of the contractile machinery to $[Ca^{2+}]_i$. **Fig. 4.10** (see **Ch. 4**) summarises the cellular mechanisms that are involved in the control of smooth muscle contraction and

relaxation. The control of vascular smooth muscle tone by various mediators is described in other chapters (noradrenaline in **Ch. 15**, 5-hydroxytryptamine [5-HT] in **Ch. 16**, prostanoids in **Ch. 17**, nitric oxide [NO] in **Ch. 19**, cardiac natriuretic peptides in **Ch. 20** and antidiuretic hormone [ADH] in **Ch. 33**). Here we focus on endothelium-derived mediators and on the renin–angiotensin–aldosterone system (RAAS), before describing the actions of vasoactive drugs and their uses in some important clinical disorders (hypertension, heart failure, shock, peripheral vascular disease and Raynaud's disease).

Vascular Structure and Function

Blood is ejected with each heartbeat from the left ventricle into the aorta, whence it flows rapidly to the organs via large conduit arteries. Successive branching leads via muscular arteries to arterioles (endothelium surrounded by a layer of smooth muscle only one cell thick) and capillaries (naked tubes of endothelium), where gas and nutrient exchanges occur. Capillaries coalesce to form postcapillary venules, venules and progressively larger veins leading, via the vena cava, to the right heart. Deoxygenated blood ejected from the right ventricle travels through the pulmonary artery, pulmonary capillaries and pulmonary veins back to the left atrium. [1] Small muscular arteries and arterioles are the main resistance vessels, while veins are capacity vessels that contain a large fraction of the total blood volume. In terms of cardiac function, therefore, arteries and arterioles regulate the *afterload*, while veins and pulmonary vessels regulate the *preload* of the ventricles (see **Ch. 20**).

The viscoelastic properties of large arteries determine arterial compliance (i.e. the degree to which the volume of the arterial system increases as the pressure increases). This is an important factor in a circulatory system that is driven by an intermittent pump such as the heart. Blood ejected from the left ventricle is accommodated by distension of the aorta, which absorbs the pulsations and delivers a relatively steady flow to the tissues. The greater the compliance of the aorta, the more effectively are fluctuations damped out, [2] and the smaller the oscillations of arterial pressure with each heartbeat (i.e. the difference between the systolic and diastolic pressure, known as the 'pulse pressure'). Reflection [3] of the pressure wave from branch points in the vascular tree also sustains arterial pressure during diastole. In young people, this helps to preserve a steady perfusion of vital organs, such as the kidneys, during diastole.

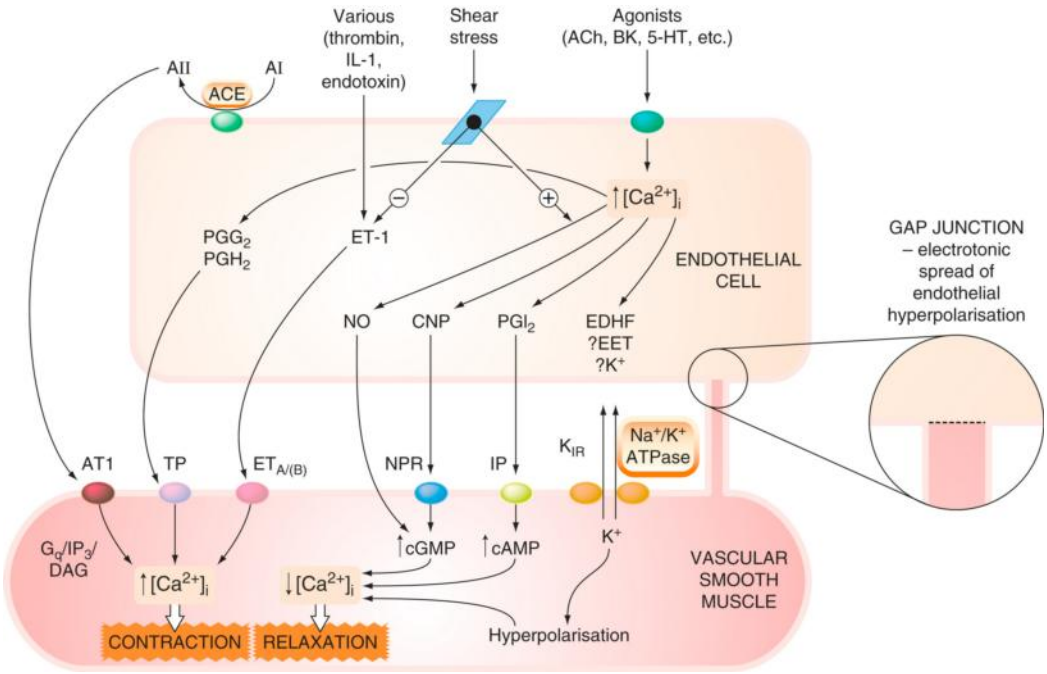

FIG. 21.1 Endothelium-derived mediators.The schematic shows some of the more important endothelium-derived contracting and relaxing mediators; many (if not all) of the vasoconstrictors also cause smooth muscle mitogenesis, while vasodilators commonly inhibit mitogenesis. *5-HT,* 5-Hydroxytryptamine; *A,* angiotensin; *ACE,* angiotensin-converting enzyme; *ACh,* acetylcholine; AT_1, angiotensin AT_1 receptor; *BK,* bradykinin; *CNP,* C-natriuretic peptide; *DAG*, diacylglycerol; *EDHF*, endothelium-derived hyperpolarising factor; *EET,* epoxyeicosatetraenoic acid; *ET-1,* endothelin-1; $ET_{A/(B)}$, endothelin A (and B) receptors; G_q, G protein; *IL-1,* interleukin-1; *IP,* I prostanoid receptor; IP_3, inosinol 1,4,5-trisphosphate; K_{IR}, inward rectifying potassium

channel; *Na^+/K^+ ATPase,* electrogenic pump; *NO,* nitric oxide; *NPR,* natriuretic peptide receptor; *PG,* prostaglandin; *TP,* T prostanoid receptor.

However, excessive reflection can pathologically augment aortic systolic pressure, because the less compliant the aorta, the greater the pulse wave velocity. Consequently, returning (reflected) pressure waves collide with the forward-going pulse wave from the next heartbeat earlier in the cardiac cycle. This results from stiffening of the aorta due to loss of elastin during ageing, especially in people with hypertension. Elastin is replaced by inelastic collagen. Cardiac work (see **Ch. 20**) can be reduced by increasing arterial compliance or by reducing arterial wave reflection (both of which decrease the pulse pressure), even if the cardiac output and mean arterial pressure are unchanged. Over the age of around 55 years, pulse pressure and aortic stiffness are important risk factors for cardiac disease.

Control of Vascular Smooth Muscle Tone

In addition to the sympathetic nervous system (see **Ch. 15**), two important physiological systems that regulate vascular tone, namely the vascular endothelium and the renin–angiotensin system, deserve special attention.

The Vascular Endothelium

A new chapter in our understanding of vascular control opened with the discovery that vascular endothelium acts not only as a passive

barrier between plasma and extracellular fluid, but also as a source of numerous potent mediators. These actively control the underlying smooth muscle as well as influencing platelet and mononuclear cell function: the roles of the endothelium in haemostasis and thrombosis are discussed in **Chapter 23**. Several distinct classes of mediator are involved (**Fig. 21.1**).

Vascular smooth muscle

- Vascular smooth muscle is controlled by mediators secreted by sympathetic nerves (see **Ch. 15**) and vascular endothelium, and by circulating hormones.
- Smooth muscle cell contraction is initiated by a rise in $[Ca^{2+}]_i$, which activates myosin light-chain kinase, causing phosphorylation of myosin, or by sensitisation of the myofilaments to Ca^{2+} by inhibition of myosin phosphatase (see **Ch. 4**).
- Agents cause contraction via one or more mechanisms:
  - release of intracellular Ca^{2+} via inositol trisphosphate,
  - depolarising the membrane, opening voltage-gated calcium channels and causing Ca^{2+} entry,
  - increasing sensitivity to Ca^{2+} via actions on myosin light-chain kinase and/or myosin phosphatase (see **Ch. 4**, **Fig. 4.9**).
- Agents cause relaxation by:
  - inhibiting Ca^{2+} entry through voltage-gated calcium channels either directly (e.g. **nifedipine**) or indirectly by

hyperpolarising the membrane (e.g. potassium-channel activators such as the active metabolite of **minoxidil**);
  - increasing intracellular cAMP or cGMP; cAMP inactivates myosin light-chain kinase and facilitates Ca^{2+} efflux, cGMP opposes agonist-induced increases in $[Ca^{2+}]_i$.
- *Prostanoids* (see **Ch. 17**). The discovery by **Bunting et al. (1976)** of prostaglandin PGI_2 (prostacyclin) ushered in this era. This mediator, acting on I prostanoid (IP) receptors (see **Ch. 17**), relaxes smooth muscle and inhibits platelet aggregation by activating adenylyl cyclase. Endothelial cells from microvessels also synthesise PGE_2, which is a direct vasodilator and additionally inhibits noradrenaline release from sympathetic nerve terminals, while lacking the effect of PGI_2 on platelets. Prostaglandin endoperoxide intermediates (PGG_2, PGH_2) are endothelium-derived contracting factors acting via thromboxane (TX) T prostanoid (TP) receptors.
- *NO* (see **Ch. 19**). *Endothelium-derived relaxing factor* (EDRF) was first described in 1980, and subsequently identified as NO later on. NO activates guanylyl cyclase. It is released continuously in resistance vessels, giving rise to vasodilator tone and contributing to the physiological control of blood pressure. As well as causing vascular relaxation, it inhibits vascular smooth muscle cell proliferation, platelet adhesion and aggregation and monocyte adhesion and migration; consequently, it may protect blood vessels from atherosclerosis and thrombosis (see Chs **22** and **23**).
- *Peptides*. The endothelium secretes several vasoactive peptides (see **Ch. 17** for general mechanisms of peptide

secretion). *C-natriuretic peptide* (CNP) (see **Ch. 20**) and *adrenomedullin* (a vasodilator peptide originally discovered in an adrenal tumour – phaeochromocytoma – but expressed in many tissues, including vascular endothelium) are vasodilators working, respectively, through cGMP and cAMP. *Angiotensin II*, formed by angiotensin-converting enzyme (ACE) on the surface of endothelial cells, and *endothelin* are potent endothelium-derived vasoconstrictor peptides.

In addition to secreting vasoactive mediators, endothelial cells express several enzymes and transport mechanisms that act on circulating hormones and are important targets of drug action. ACE is a particularly important example (see later, including Figs **21.2** and **21.3**).

Many endothelium-derived mediators are mutually antagonistic, conjuring an image of opposing rugby football players swaying back and forth in a scrum; in moments of exasperation, one sometimes wonders whether all this makes sense or whether the designer simply could not make up their mind! An important distinction is made between mechanisms that are tonically active in resistance vessels under basal conditions, as is the case with the noradrenergic nervous system (see **Ch. 15**), NO (see **Ch. 19**) and endothelin (ET) (see later), and those that operate mainly in response to injury, inflammation, etc., as with PGI_2. Some of the latter group may be functionally redundant, perhaps representing vestiges of mechanisms that were important to our evolutionary forebears, or they may simply be taking a breather on the touchline and are ready to rejoin the fray if called on by the occurrence of some vascular

insult. Evidence for such a 'back-up' role comes, for example, from mice that lack the IP receptor for PGI_2; they have a normal blood pressure and do not develop spontaneous thrombosis but are more susceptible to vasoconstrictor and thrombotic stimuli than their wild-type litter mates (**Murata et al., 1997**).

The Endothelium in Angiogenesis

As touched on in **Chapter 9**, the barrier function of vascular endothelium differs markedly in different organs, and its development during angiogenesis is controlled by several growth factors, including *vascular endothelial growth factor* (VEGF) and various tissue-specific factors such as endocrine gland VEGF. These are involved in repair processes and in pathogenesis (e.g. tumour growth and in neovascularisation in the eye – an important cause of blindness in patients with new vessel proliferation due to age-related macular degeneration, or diabetes mellitus; see **Ch. 27**). These factors and their receptors are potentially fruitful targets for drug development and new therapies (including gene therapies; see **Ch. 5**).

Endothelin

Discovery, biosynthesis and secretion

Hickey et al. described a vasoconstrictor factor produced by cultured endothelial cells in 1985. This was identified as *endothelin (ET)*, a 21-residue peptide, by Yangisawa, which at that time was the most potent vasoconstrictor known [4] (**Barton and Yanagisawa, 2019**).

There are three isoforms. ET-1 is the only ET present in endothelial cells and is also expressed in many other tissues. ET-2 is much less widely distributed: it is present in kidney and intestine. ET-3 is present in brain, lung, intestine and adrenal gland.

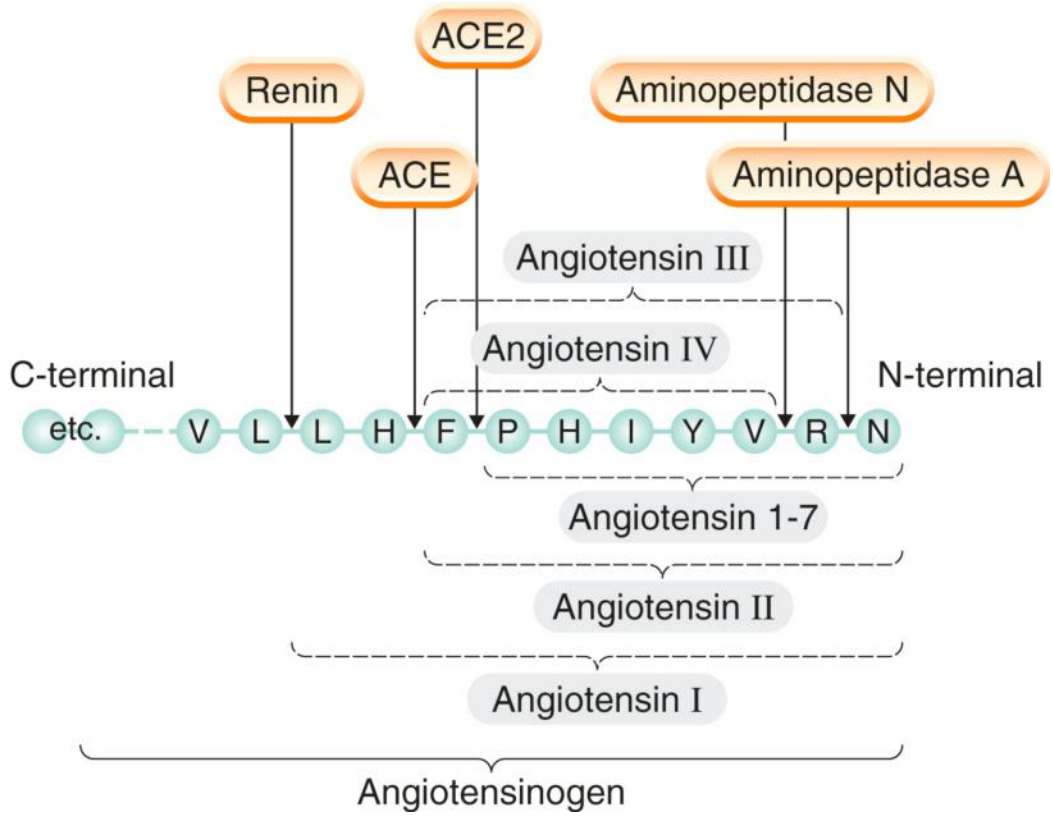

FIG. 21.3 Formation of angiotensins I–IV from the N-terminal of the precursor protein angiotensinogen.Also shown is angiotensin 17 which is a product of the action of angiotensin-converting enzyme 2 (ACE2) and opposing actins to angiotensin II.

Stimuli of ET synthesis include many vasoactive mediators released by trauma or inflammation, including activated platelets, endotoxin, thrombin, various cytokines and growth factors, angiotensin II, ADH, adrenaline, insulin, hypoxia and low shear stress. ET concentrations are elevated in cardiac failure, hypertension, and connective tissue disorders such as scleroderma. Inhibitors of ET synthesis include NO, natriuretic peptides, PGE_2, PGI_2, heparin and high shear stress.

Endothelin receptors and responses

There are two types of ET receptors, designated ET_A and ET_B, both of which are G protein coupled (see **Ch. 3**). ET receptors are distributed widely across the entire body with a complex, multi-faceted range of tissue-specific expression and physiological effects that vary depend on the tissue site. For instance, the predominant overall response with ET_A is vasoconstriction through its action on smooth muscle, but ET_A also promotes inflammation and cell proliferation. In contrast, *ET* $_B$ stimulates vasodilation (through endothelial NO release), as well as salt and water excretion in the kidney (**Davenport et al., 2016**).

ET-1 preferentially activates ET_A receptors. Messenger RNA for the ET_A receptor is expressed in many human tissues, including vascular smooth muscle, heart, lung and kidney. It is not expressed in endothelium. ET_A-mediated responses include vasoconstriction, bronchoconstriction and aldosterone secretion. ET_A receptors are coupled to phospholipase C, which stimulates Na^+/H^+ exchange, protein kinase C and mitogenesis, as well as causing vasoconstriction through inositol trisphosphate-mediated Ca^{2+} release (see **Ch. 3**). There are several partially selective ET_A-receptor antagonists of therapeutic value, including orally active non-peptide drugs (e.g. **bosentan**, a mixed ET_A/ET_B antagonist, and **ambrisentan**, ET_A selective, both of which are used in treating pulmonary arterial hypertension). ET_B receptors are activated to a similar extent by each of the three ET isoforms and, in the endothelium, are thought to mediate release of vascular relaxing factors such as NO and PGI_2. ET_B is also present in vascular smooth muscle, where it initiates vasoconstriction like the ET_A receptor.

ET_B receptors play a part in clearing ET-1 from the circulation, and ET antagonists with appreciable affinity for ET_B receptors consequently increase plasma concentrations of ET-1, complicating interpretation of such concentrations during experiments with these drugs.

Functions of endothelin

ET-1 is a local mediator rather than a circulating hormone, although it stimulates secretion of several hormones. ET-1 is a key player in vasoconstrictor tone and the regulation of peripheral vascular resistance in man, but ETs have several other possible functions, including roles in:

- release of various hormones, including atrial natriuretic peptide, aldosterone, adrenaline, and hypothalamic and pituitary hormones;
- natriuresis and diuresis via actions of collecting duct-derived ET-1 on ET_B receptors on tubular epithelial cells;
- renal and cerebral vasospasm;
- Organogenesis (pharyngeal arch derived organs) – ET antagonists are teratogenic in rodents.

The role of the endothelium in controlling vascular smooth muscle

- Endothelial cells release vasoactive mediators including prostacyclin (PGI_2), NO and distinct but incompletely characterised hyperpolarising factor(s) 'EDHF' (vasodilators)

and ET and endoperoxide thromboxane receptor agonists (vasoconstrictors).

- Many vasodilators (e.g. acetylcholine and bradykinin) act via endothelial NO production. The NO derives from arginine and is produced when $[Ca^{2+}]_i$ increases in the endothelial cell, or the sensitivity of endothelial NO synthase to Ca^{2+} is increased (see **Fig. 19.3**).
- NO relaxes smooth muscle by increasing cGMP formation.
- ET is a potent and long-acting vasoconstrictor peptide released from endothelial cells by many chemical and physical factors. It is not confined to blood vessels, and it has several functional roles.

The Renin–Angiotensin System

The renin–angiotensin system synergises with the sympathetic nervous system, for example, by increasing the release of noradrenaline from sympathetic nerve terminals. It stimulates aldosterone secretion and plays a central role in the control of Na^+ excretion and fluid volume, as well as of vascular tone.

The control of renin secretion (**Fig. 21.2**) is only partly understood. It is a proteolytic enzyme that is secreted by the *juxtaglomerular apparatus* (see **Ch. 29**, **Fig. 29.2**) in response to various physiological stimuli including reduced renal perfusion pressure, or reduced Na^+ concentration in distal tubular fluid, which is sensed by the *macula densa* (a specialised part of the distal tubule apposed to the juxtaglomerular apparatus). Renal sympathetic nerve activity, β-adrenoceptor agonists and PGI_2 all

stimulate renin secretion directly, whereas angiotensin II causes feedback inhibition. Atrial natriuretic peptide (see **Ch. 20**) also inhibits renin secretion. Renin is cleared rapidly from plasma. It acts on *angiotensinogen* (a plasma globulin made in the liver), splitting off a decapeptide, *angiotensin I*.

Angiotensin I is inactive, but is converted by *ACE* to an octapeptide, *angiotensin II*, which is a potent vasoconstrictor. Angiotensin II is a substrate for enzymes (aminopeptidase A and N) that remove single amino acid residues, giving rise, respectively, to angiotensin III and angiotensin IV (**Fig. 21.3**). Angiotensin III exerts effects on the brain renin–angiotensin system to stimulate sympathetic activity and release vasopressin, thus increasing blood pressure. Angiotensin IV also has distinct actions, probably via its own receptor, including release of *plasminogen activator inhibitor-1* from the endothelium (see **Ch. 23**). Receptors for angiotensin IV have a distinctive distribution, including the hypothalamus.

ACE is a membrane-bound enzyme on the surface of endothelial cells, and is particularly abundant in the lung, which has a vast surface area of vascular endothelium. [5] The common isoform of ACE is also present in other vascularised tissues, including heart, brain, striated muscle and kidney, and is not restricted to endothelial cells. Consequently, local formation of angiotensin II can occur in different vascular beds, and it provides local control independent of blood-borne angiotensin II. ACE inactivates bradykinin (see **Ch. 17**) and several other peptides. This may contribute to the pharmacological actions of ACE inhibitors (ACEIs), as discussed later.

ACE2, a homologue of ACE, converts angiotensin II to angiotensin 1-7 (Ang 1-7) as shown in **Fig. 21.3**. Ang 1-7 acts on the Mas receptor (a G-protein–coupled receptor coded by the *MAS1* oncogene) opposing the effects of angiotensin II. ACE2 is widely expressed, including in cardiomyocytes, pneumocytes and endothelial cells, and potentially protects against heart failure by breaking down angiotensin II, thus reducing blood pressure and inflammatory cardiac damage. Unfortunately, the spike protein of the SARS-CoV-2 virus binds to ACE2 in the cell membrane, and uses it as a 'cellular gateway' to enter and infect cells.

Recombinant human ACE2 has been tested in humans without adverse effects while lowering plasma angiotensin II and increasing Ang 1-7 concentration. For a recent review of the therapeutic potential of enhancing ACE2/Ang 1-7 action for heart failure, see **Patel et al. (2016)**.

The main actions of angiotensin II are mediated via AT_1 and/or AT_2 receptors, which belong to the family of G protein–coupled receptors. Effects mediated by AT_1 receptors include:

- generalised vasoconstriction, especially marked in efferent arterioles of the renal glomeruli;
- increased noradrenaline release, reinforcing sympathetic effects;

Table 21.1

ACE, Angiotensin-converting enzyme.

- proximal tubular reabsorption of Na^+;

- secretion of aldosterone from the adrenal cortex (see **Ch. 33**);
- pro-inflammatory effect, growth of cardiac and vascular cells. **6**

AT_2 receptors are expressed during fetal life and in distinct brain regions in adults. They are believed to be involved in growth, development and exploratory behaviour. The cardiovascular effects of AT_2 receptors (inhibition of cell growth and lowering of blood pressure) are relatively subtle and oppose those of AT_1 receptors.

The renin–angiotensin–aldosterone pathway contributes to the pathogenesis of heart failure, and several leading classes of therapeutic drug act on it at different points (see **Fig. 21.2**).

Vasoactive Drugs

Drugs can affect vascular smooth muscle by acting either directly on smooth muscle cells, or indirectly, for example, on endothelial cells, on sympathetic nerve terminals or on the central nervous system (CNS) (**Table 21.1**). Mechanisms of directly acting vasoconstrictors and vasodilators are summarised in Fig. 4.10 (see **Ch. 4**). Many indirectly acting drugs are discussed in other chapters (see **Table 21.1**). We concentrate here on agents that are not covered elsewhere.

Vasoconstrictor Drugs

The α_1-adrenoceptor agonists and drugs that release noradrenaline from sympathetic nerve terminals or inhibit its reuptake (sympathomimetic amines) are discussed in **Chapter 15**. Some

eicosanoids (e.g. *thromboxane A* $_2$; see Chs **17** and **23**) and several peptides, notably *ET*, *angiotensin* and *ADH*, are also predominantly vasoconstrictor. **Sumatriptan** and ergot alkaloids acting on certain 5-HT receptors (5-HT_2 and 5-HT_{1D}) also cause vasoconstriction (see **Ch. 42**).

Angiotensin II

The physiological role of the renin–angiotensin system has been described previously. Angiotensin II is roughly 40 times as potent as noradrenaline in raising blood pressure. Like α_1-adrenoceptor agonists, it constricts mainly cutaneous, splanchnic and renal vasculature, with less effect on blood flow to brain and skeletal muscle. It has no routine clinical uses, although it has promise in the treatment of vasodilatory shock (**Khanna et al., 2017**), its main therapeutic importance lying in the fact that other drugs (e.g. **captopril** and **losartan**; see later) affect the cardiovascular system by reducing its production or action.

Antidiuretic Hormone

ADH (also known as vasopressin) is a posterior pituitary peptide hormone (see **Ch. 33**). It is physiologically important for its antidiuretic action on the kidney (see **Ch. 29**) but is also a powerful vasoconstrictor. Its effects are initiated by two distinct receptors (V_1 and V_2). Water retention is mediated through V_2 receptors, occurs at low plasma concentrations of ADH and involves activation of adenylyl cyclase in renal collecting ducts. Vasoconstriction is mediated through V_1 receptors (two subtypes, see **Ch. 33**), requires higher concentrations of ADH and involves activation of phospholipase C (see **Ch. 3**). ADH causes generalised

vasoconstriction, including the skin, coeliac, mesenteric and coronary vessels. It also affects other (e.g. gastrointestinal and uterine) smooth muscle and causes abdominal cramps for this reason. Vasopressin or its analogue, **terlipressin**, is commonly used to treat patients with bleeding oesophageal varices and portal hypertension before more definitive endoscopic treatment; although gastroenterologists also have the option of using **octreotide** (see **Ch. 33**) for this. Vasopressin may also have a place in treating vasodilatory shock (see later).

Endothelin

ETs were discussed earlier in the context of their physiological roles; as explained previously, they have vasodilator and vasoconstrictor actions, but vasoconstriction predominates. Intravenous administration causes transient vasodilatation followed by profound and long-lived vasoconstriction. The ETs are even more potent vasoconstrictors than angiotensin II. As yet, clinical trials in a wide range of disease conditions have failed to yield consistent benefit, and ET antagonists are licensed only for their vasodilatory effects in pulmonary arterial hypertension, and scleroderma-induced digital ulcers (related to connective tissue disruption in scleroderma as well as poor blood supply from secondary Raynaud's phenomenon – see later). There are ongoing trials of ET antagonists for renal disease in diabetes (**atrasentan**) and treatment-resistant hypertension (**aprocitentan**).

Vasoconstrictor substances

- The main groups are sympathomimetic amines (direct and indirect; see **Ch. 15**), certain eicosanoids (especially thromboxane A_2; see **Ch. 17**), peptides (angiotensin II, ADH and ET) and a group of miscellaneous drugs (e.g. ergot alkaloids; see **Ch. 16**).
- Clinical uses include local applications (e.g. nasal decongestion, co-administration with local anaesthetics). Sympathomimetic amines and **ADH** are used in circulatory shock. **Adrenaline** is life-saving in anaphylactic shock and used in cardiac arrest. **ADH** and **terlipressin** (an analogue) are potent splanchnic vasoconstrictors given intravenously to reduce portal blood flow and stop bleeding from oesophageal varices in patients with portal hypertension caused by liver disease.

Vasodilator Drugs

Vasodilator drugs play a major role in the treatment of common conditions, including hypertension, cardiac failure and angina pectoris, as well as several less common but serious diseases, including pulmonary hypertension and Raynaud's disease.

Direct-Acting Vasodilators

Targets on which drugs act to relax vascular smooth muscle include plasma membrane voltage-dependent calcium channels, sarcoplasmic reticulum channels (Ca^{2+} release or reuptake) and enzymes that determine Ca^{2+} sensitivity of the contractile proteins (see Fig. 4.10).

Calcium antagonists

L-type calcium antagonists are discussed in **Chapter 20**.

Drugs that activate potassium channels

Some drugs (e.g. **minoxidil**, **diazoxide**) relax smooth muscle by opening K_{ATP} channels (**Fig. 21.4**). This hyperpolarises the cells and switches off voltage-dependent calcium channels. Potassium-channel activators work by antagonising the action of intracellular ATP on these channels.

Minoxidil (acting through an active sulfate metabolite) is an especially potent and long-acting vasodilator, used as a drug of last resort (in combination with a diuretic and β-adrenoceptor antagonist) for treating severe hypertension. It causes hirsutism (the active metabolite is actually used as a rub-on cream to treat baldness; see **Ch. 26**). It causes marked salt and water retention, so is usually prescribed with a loop diuretic. It causes reflex tachycardia, and a β-adrenoceptor antagonist is used to prevent this. **Nicorandil** (see **Ch. 20**) combines K_{ATP} channel activation with NO donor activity and is used in refractory angina.

Drugs that act via cyclic nucleotides

Cyclase activation

Many drugs relax vascular smooth muscle by increasing the cellular concentration of either cGMP or cAMP. For example, NO, nitrates and the natriuretic peptides act through cGMP (see Chs **19** and **20**); riociguat and vericiguat stimulate soluble guanylyl cyclase via an NO-independent site to increase cGMP (see **Ch. 19**). The *β_2 agonists*, *adenosine* and *PGI_2* increase cytoplasmic cAMP (see Chs

15 and **17**). *Dopamine* has mixed vasodilator and vasoconstrictor actions. It selectively dilates renal vessels, where it increases cAMP by activating adenylyl cyclase. Dopamine, when administered as an intravenous infusion, produces a mixture of cardiovascular effects resulting from agonist actions on α and β adrenoceptors, as well as on dopamine receptors. Blood pressure increases slightly, but the main effects are vasodilatation in the renal circulation and increased cardiac output. Dopamine was widely used in intensive care units in patients in whom renal failure associated with decreased renal perfusion appeared imminent; despite its beneficial effect on renal haemodynamics, clinical trials have shown that it does not improve survival in these circumstances and this use is obsolete. **Nesiritide**, a recombinant form of human B-type natriuretic peptide (BNP) (see **Ch. 20**), is licensed in the United States for the treatment of acutely decompensated heart failure, but efficacy data have not been impressive. However, **sacubitril**, a prodrug of an active metabolite sacubitilat, an inhibitor of neprilysin (also known as neutral endopeptidase [NEP]), increases circulating natriuretic peptides (BNP and ANP) and, in fixed combination with **valsartan**, is effective in treating chronic heart failure (see later).

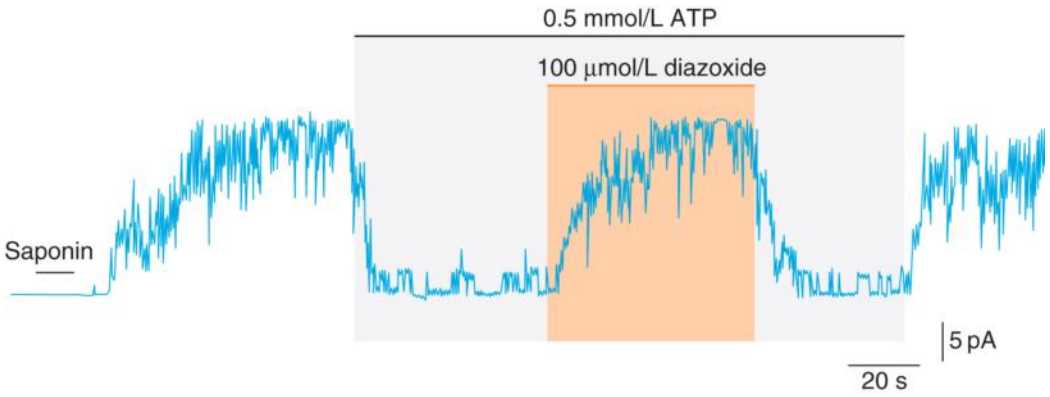

FIG. 21.4 ATP-sensitive potassium channels.Patch clamp (see **Ch. 3**) record from insulin-secreting pancreatic B cell: saponin permeabilised the cell, with loss of intracellular ATP, causing the channels to open (upward deflection) until they were inhibited by ATP. The addition of diazoxide, a vasodilator drug (which also inhibits insulin secretion; see text), reopens the channels. In smooth muscle, this causes hyperpolarisation and relaxation. Redrawn from Dunne, et al., 1990. Br. J. Pharmacol. 99, 169.

Nitroprusside (nitroferricyanide) is a powerful vasodilator which acts by releasing NO (see **Ch. 19**). Unlike the organic nitrates, it acts equally on arterial and venous smooth muscle. Its clinical usefulness is limited because it must be given intravenously. In solution, particularly when exposed to light, nitroprusside hydrolyses with formation of cyanide. The intravenous solution must therefore be made up freshly from dry powder and protected from light. Nitroprusside is rapidly converted to thiocyanate in the body, its plasma half-life being only a few minutes, so it must be given as a continuous infusion with careful

monitoring to avoid hypotension. Prolonged use causes thiocyanate accumulation and toxicity (weakness, nausea and inhibition of thyroid function); consequently, nitroprusside is useful only for short-term treatment (usually up to 72 h maximum). It is used in intensive care units for hypertensive emergencies, and to produce controlled hypotension during surgery.

Phosphodiesterase inhibition

Phosphodiesterases (PDEs; see **Ch. 3**) include at least 14 distinct isoenzymes. Methylxanthines (e.g. **theophylline**) and **papaverine** are non-isozyme selective PDE inhibitors (and have additional actions). Methylxanthines exert their main effects on bronchial smooth muscle and on the CNS and are discussed in **Chapters 28** and **49**. In addition to inhibiting PDE, some methylxanthines are also purine receptor antagonists (see **Ch. 16**). Papaverine is produced by opium poppies (see **Ch. 43**) and relaxes vascular smooth muscle. Its mechanism is poorly understood but seems to involve a combination of PDE inhibition and block of calcium channels. Selective PDE type III inhibitors (e.g. **milrinone**) increase cAMP in cardiac muscle. They have a positive inotropic effect but, despite short-term haemodynamic improvement, increase mortality in patients with heart failure, possibly by causing dysrhythmias. **Dipyridamole**, as well as enhancing the actions of adenosine (see **Ch. 16**), also causes vasodilatation by inhibiting PDE. Selective *PDE type V* inhibitors (e.g. **sildenafil**) inhibit the breakdown of cGMP, thereby potentiating NO signalling. It revolutionised treatment of erectile dysfunction (see **Ch. 35**) and is

used in other situations, including pulmonary hypertension and Raynaud's phenomenon (see clinical box).

Vasodilator drugs

- Vasodilators act:
  - to increase local tissue blood flow
  - to reduce arterial pressure
  - to reduce central venous pressure
- Reduce cardiac work by reducing cardiac preload (reduced filling pressure) and afterload (reduced vascular resistance).
- Main uses are:
  - antihypertensive therapy (e.g. angiotensin II type 1 [AT_1] antagonists, calcium antagonists and α_1-adrenoceptor antagonists)
  - treatment/prophylaxis of angina (e.g. calcium antagonists, nitrates)
  - treatment of cardiac failure (e.g. ACEIs, AT_1 antagonists)
  - treatment of erectile dysfunction and Raynaud's phenomenon.

Vasodilators with Uncertain Mechanism of Action

Hydralazine

Hydralazine acts mainly by relaxing arteries and arterioles, causing a fall in blood pressure accompanied by reflex tachycardia and increased cardiac output. It interferes with the action of inositol

trisphosphate on Ca^{2+} release from the sarcoplasmic reticulum. Its original clinical use was in hypertension and it is still used for short-term treatment of severe hypertension in pregnancy but it can cause an immune disorder resembling systemic lupus erythematosus (SLE), [7] so alternative agents are now preferred for long-term treatment of hypertension. It has a place in treating heart failure in patients of African origin in combination with a long-acting organic nitrate (see clinical box).

Ethanol

Ethanol (see **Ch. 50**) dilates cutaneous vessels, causing the familiar drunkard's flush. Several general anaesthetics (e.g. **propofol**) cause vasodilatation as an unwanted effect (see **Ch. 41**).

Indirectly Acting Vasodilator Drugs

Indirectly acting vasodilator drugs work by inhibiting vasoconstrictor systems, namely the sympathetic nervous system (see **Ch. 15**) and the renin–angiotensin–aldosterone and ET systems, or by potentiating endogenous vasodilators such as the natriuretic peptides (see **Ch. 20** and further in this chapter).

The central control of sympathetically mediated vasoconstriction involves α_2 adrenoceptors and *imidazoline I_1 receptors* (see **Ch. 15**). **Clonidine** (an α_2-adrenoceptor agonist, now largely obsolete as an antihypertensive drug) and **moxonodine**, an I_1-receptor agonist, lower blood pressure by reducing sympathetic activity centrally. In addition, many vasodilators (e.g. acetylcholine, bradykinin, substance P) exert some or all of their effects by stimulating biosynthesis of vasodilator prostaglandins or of NO (or of both) by vascular endothelium (see previously and **Ch. 19**),

thereby causing functional antagonism of the constrictor tone caused by sympathetic nerves and angiotensin II.

Many therapeutically useful drugs block the RAAS (see **Table 21.2** for a summary of selective antagonists) at one of several points:

- renin release: β-adrenoceptor antagonists inhibit renin release (see **Ch. 15**)
- renin activity: renin inhibitors inhibit conversion of angiotensinogen to angiotensin I
- ACE: ACEIs (see later) block conversion of angiotensin I to angiotensin II
- angiotensin II receptors: AT_1-receptor antagonists (ARBs, see later)
- aldosterone receptors: aldosterone-receptor antagonists (see later)

Renin inhibitors

Aliskiren, an orally active non-peptide renin inhibitor, was developed and registered as an antihypertensive drug. It has adverse effects that include diarrhoea (common), acute renal failure, cardiovascular events in patients with diabetes mellitus and, rarely, angioedema and severe allergic reactions.

Angiotensin-converting enzyme inhibitors

The first ACEI to be marketed was **captopril** (**Fig. 21.5**), an early example of successful drug design based on a chemical knowledge of the target molecule. Various small peptides had been found to be weak inhibitors of the enzyme. [8] Captopril was designed to combine

the steric properties of such peptide antagonists in a non-peptide molecule that was active when given by mouth. Captopril has a short plasma half-life (about 2 h) and must be given two or three times daily. Many of the ACEIs developed subsequently (see **Table 21.2**), which are widely used in the clinic, have a longer duration of action and are administered once daily.

Table 21.2

ACE, Angiotensin-converting enzyme; *ACEI,* angiotensin-converting enzyme inhibitor; *ARB,* angiotensin receptor blocker; *MI,* myocardial infarction.

[a] All drugs listed are orally active.

[b] Adverse effects common to all drugs listed include hyperkalaemia (especially in patients with impaired renal function) and teratogenesis.

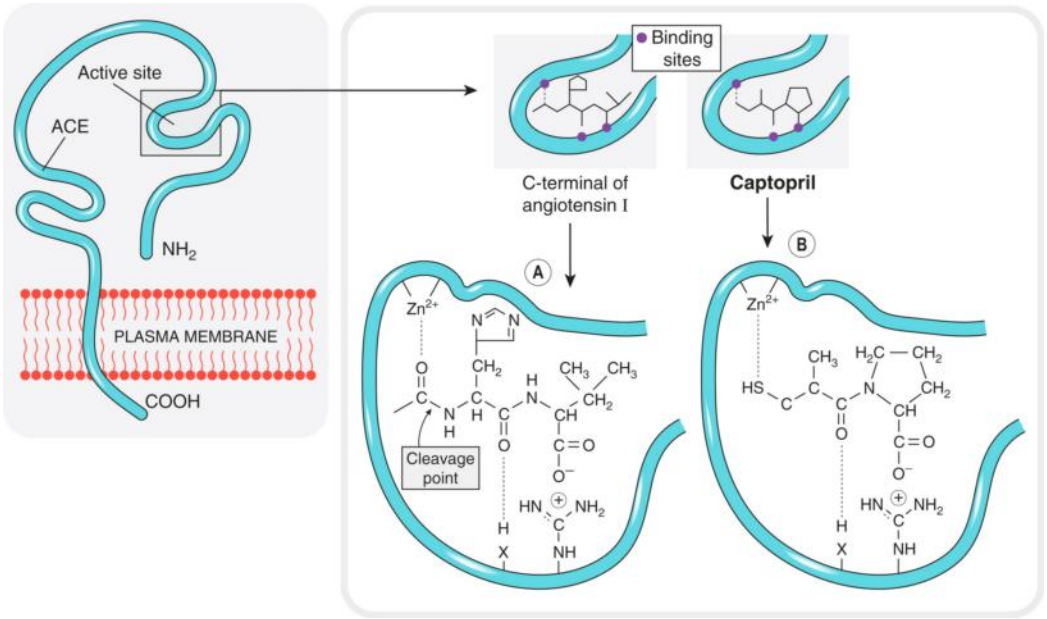

FIG. 21.5 The active site of angiotensin-converting enzyme (ACE).(A) Binding of angiotensin I. (B) Binding of the inhibitor captopril, which is an analogue of the terminal dipeptide of angiotensin I.

Pharmacological effects

ACEIs cause only a small fall in arterial pressure in healthy human subjects who are consuming the amount of salt contained in a usual Western diet, but a much larger fall in hypertensive patients, particularly those in whom renin secretion is enhanced (e.g. in patients receiving diuretics). ACEIs affect capacitance and resistance vessels and reduce cardiac load as well as arterial pressure. They act preferentially on angiotensin-sensitive vascular beds, which include those of the kidney, heart and brain. This selectivity may be important in sustaining adequate perfusion of these vital organs in the face of reduced perfusion pressure. Critical

renal artery stenosis [9] represents an exception to this, where ACE inhibition results in a fall in glomerular filtration rate (see later).

Clinical uses of ACEIs are summarised in the clinical box.

Clinical uses of angiotensin-converting enzyme inhibitors

- Hypertension
- Cardiac failure
- Following myocardial infarction (especially when there is ventricular dysfunction)
- Diabetic nephropathy
- Chronic renal insufficiency to prevent progression

Unwanted effects

Adverse effects (see **Table 21.2**) directly related to ACE inhibition are common to all drugs of this class. These include hypotension, especially after the first dose and especially in patients with heart failure who have been treated with loop diuretics, in whom the renin–angiotensin system is activated. A dry cough, possibly the result of accumulation of bradykinin (see **Ch. 17**), is the commonest persistent adverse effect. Kinin accumulation may also underlie *angioedema* (painful swelling in tissues which can be life-threatening if it involves the airway); this adverse effect aborted the introduction of **omapatrilat**, a combined ACEI/NEP inhibitor, and can also occur, albeit less frequently, during treatment with **sacubitril**, a selective NEP inhibitor used for chronic heart failure

(see later). Patients with severe bilateral renal artery stenosis predictably develop renal failure if treated with ACEIs, because glomerular filtration is normally maintained, in the face of low afferent arteriolar pressure, by angiotensin II, which selectively constricts *efferent* arterioles. Such renal failure is reversible provided that it is recognised promptly and ACEI treatment discontinued. ACEI predispose to hyperkalaemia, which may be severe, caused by inhibition of aldosterone secretion. Monitoring of renal function and electrolytes is essential when initiating, or escalating, ACEI therapy.

Angiotensin II receptor antagonists

Losartan, **candesartan**, **valsartan** and **irbesartan** (sartans) are non-peptide, orally active AT_1 receptor antagonists (ARBs). ARBs differ pharmacologically from ACEIs (**Fig. 21.6**) but behave similarly to ACEIs apart from not causing cough – consistent with the 'bradykinin accumulation' explanation of this side effect, mentioned earlier. However, ACEIs are usually the preferred first-line agents as they have a more robust evidence base than ARBs. The comparison is clouded by the relative lack of head-to-head trial data, but in clinical practice, ARBs tend to be prescribed for patients who are intolerant or have not responded favourably to ACEIs.

FIG. 21.6 Comparison of effects of angiotensin-converting enzyme inhibition and angiotensin receptor blockade in the human forearm vasculature.(A) Effect of brachial artery infusion of angiotensin II on forearm blood flow after oral administration of placebo, enalapril (10 mg) or losartan (100 mg). (B) Effect of brachial artery infusion of bradykinin, as in (A). From Cockcroft, J.R., et al., 1993. J. Cardiovasc. Pharmacol. 22, 579–584.

ACE is not the only enzyme capable of forming angiotensin II, *chymase* (which is not inhibited by ACEIs) providing one alternative route. It is not known if alternative pathways of angiotensin II formation are important in vivo, but if so, then ARBs could be more effective than ACEIs when such alternative pathways are active. Again, it is not known whether any of the beneficial effects of ACEIs are bradykinin/NO mediated. It is therefore unwise to assume that ARBs will necessarily share all the therapeutic properties of ACEIs, although there is considerable overlap in the clinical indications for these drugs (see **Table 21.2**).

Neutral endopeptidase (NEP, neprilysin) inhibition

NEP (see also **Ch. 20**) is a zinc-dependent metalloprotease that inactivates several peptide mediators including not only natriuretic peptides (ANP and BNP) but also glucagon, enkephalins, substance P, neurotensin, oxytocin and bradykinin. In health it is expressed in many tissues including kidney, brain and lung.

Types of vasodilator drug

Directly acting vasodilators

- Calcium antagonists (e.g. **nifedipine**, **diltiazem**, **verapamil**): block Ca^{2+} entry in response to depolarisation. Common adverse effects include ankle swelling and (especially with verapamil) constipation.
- K_{ATP} channel activators (e.g. **minoxidil**): open potassium channels, hyperpolarising vascular smooth muscle cells. Ankle swelling and increased hair growth are common.
- Drugs that increase cytoplasmic cyclic nucleotide concentrations by:
  - increasing adenylyl cyclase activity, for example prostacyclin (epoprostenol), β2-adrenoceptor agonists, adenosine;
  - increasing guanylyl cyclase activity: nitrates (e.g. **glyceryl trinitrate**, **nitroprusside**) and soluble guanylyl cyclase stimulators (riociguat, vericiguat) working independently but synergistically with NO;
  - inhibiting PDE activity (e.g. **sildenafil**).

Indirectly acting vasodilators

- Drugs that interfere with the sympathetic nervous system (e.g. α_1-adrenoceptor antagonists). Postural hypotension is a common adverse effect.
- Drugs that block the renin–angiotensin system:

  - renin inhibitors (e.g. **aliskiren**)
  - ACEIs (e.g. **ramipril**); dry cough may be troublesome
  - AT_1 receptor antagonists (e.g. **losartan**).
- Drugs or mediators that stimulate endothelial NO release (e.g. acetylcholine, bradykinin).
- Drugs that block the ET system:
  - ET receptor antagonists (e.g. **bosentan**)
- Drugs that potentiate vasodilator peptides by blocking their breakdown (e.g. **sacubitril**).

Vasodilators whose mechanism is uncertain

- Miscellaneous drugs including alcohol, **propofol** (see **Ch. 41**) and **hydralazine.**

Clinical uses of angiotensin II subtype 1 receptor antagonists (sartans)

The AT_1 antagonists are extremely well tolerated but are teratogenic. Their uses include the following:

- Hypertension, especially in:
  - younger men, e.g. <55 years (circulating renin decreases with increasing age, and sartans are avoided during pregnancy).
- Heart failure; especially the combination of valsartan with sacubitril (NEP inhibitor).

- Chronic kidney disease, particularly with co-morbid diabetes mellitus or hypertension.

Clinical Uses of Vasoactive Drugs

It is beyond the scope of this book to provide a detailed account of the clinical uses of vasoactive drugs, but it is nonetheless useful to consider briefly the treatment of certain important disorders, namely:

- systemic hypertension
- heart failure
- vasodilatory shock
- peripheral vascular disease
- Raynaud's disease
- pulmonary hypertension

Clinical disorders for which vasoactive drugs are important

- Systemic hypertension:
  - secondary to underlying disease (e.g. renal or endocrine)
  - primary 'essential' hypertension, an important risk factor for atheromatous disease (see **Ch. 22**). Treatment reduces the excess risk of stroke or myocardial infarction, the main classes of drugs being (a) ACEI or AT_1 receptor antagonists, (b) calcium antagonists and (c) diuretics.

- Cardiac failure. Several diseases (most commonly ischaemic heart disease) impair the ability of the heart to deliver an output adequate to meet metabolic needs. Oedema can be improved with diuretics. Life expectancy is reduced but can be improved by treatment of haemodynamically stable patients with:
  - ACEIs or AT_1 receptor antagonists (with or without neprilysin)
  - β-adrenoceptor antagonists (e.g. **carvedilol**, **bisoprolol**)
  - aldosterone antagonists (e.g. **spironolactone**).
- Shock. Several diseases (e.g. overwhelming bacterial infections, see **Ch. 52**; anaphylactic reactions, see **Ch. 28**) lead to inappropriate vasodilatation, hypotension and reduced tissue perfusion with raised circulating concentrations of lactic acid. Pressors (e.g. **noradrenaline**) are used first-line, with vasopressin and dobutamine as second-line options.
- Peripheral vascular disease. Atheromatous plaques in the arteries of the legs are often associated with atheroma in other vascular territories. Statins (see **Ch. 22**) and antiplatelet drugs (see **Ch. 23**) are important.
- Raynaud's disease. Inappropriate vasoconstriction in small arteries in the hands causes blanching of the fingers followed by blueness and pain. **Nifedipine** or other vasodilators are used.
- Pulmonary hypertension, which can be:
  - idiopathic (a rare disorder): **epoprostenol**, **iloprost**, **bosentan** and **sildenafil** are of benefit in selected

patients;
– associated with hypoxic lung disease.

Systemic Hypertension

Systemic hypertension is a common disorder that, if not effectively treated, increases the risk of coronary artery disease, heart failure, strokes, vascular dementia, and renal failure. Until about 1950, there was no effective treatment, and the development of antihypertensive drugs has been a major success story. Systemic blood pressure is an excellent 'surrogate marker' for increased cardiovascular risk in that there is good evidence from randomised controlled trials that common antihypertensive drugs (diuretics, ACEIs, calcium antagonists) combined with lifestyle changes not only lower blood pressure but also prolong life and reduce the extra risks of cardiac complications and, especially, strokes associated with high blood pressure.

Correctable causes of hypertension include phaeochromocytoma, [10] steroid-secreting tumours of the adrenal cortex and narrowing (coarctation) of the aorta, but most cases involve no obvious cause and are grouped as *essential hypertension* (so-called because it was originally, albeit incorrectly, thought that the raised blood pressure was 'essential' to maintain adequate tissue perfusion). Increased cardiac output may be an early feature, but by the time essential hypertension is established (commonly in middle life) there is usually increased peripheral resistance and the cardiac output is normal. Blood pressure control is intimately related to the kidneys, as demonstrated in humans requiring renal transplantation:

hypertension ‘goes with’ the kidney from a hypertensive donor and donating a kidney from a normotensive to a hypertensive corrects hypertension in the recipient (see also **Ch. 29**). It seems likely that the cause of most cases of essential hypertension stems from a complex interplay of genetic, renal, endocrine, and neural factors. (**Harrison et al, 2021**; **Meneton et al., 2005**). Persistently raised arterial pressure leads to hypertrophy of the left ventricle and remodelling of resistance arteries, with narrowing of the lumen, and predisposes to atherosclerosis in larger conduit arteries.

Fig. 21.7 summarises the physiological mechanisms that control arterial blood pressure and shows sites at which antihypertensive drugs act, notably the sympathetic nervous system, the RAAS and endothelium-derived mediators. Remodelling of resistance arteries in response to raised pressure reduces the ratio of lumen diameter to wall thickness and increases the peripheral vascular resistance. The role of cellular growth factors (including angiotensin II) and inhibitors of growth (e.g. NO) in the evolution of these structural changes is of great interest to vascular biologists and is potentially important for ACEIs and ARBs.

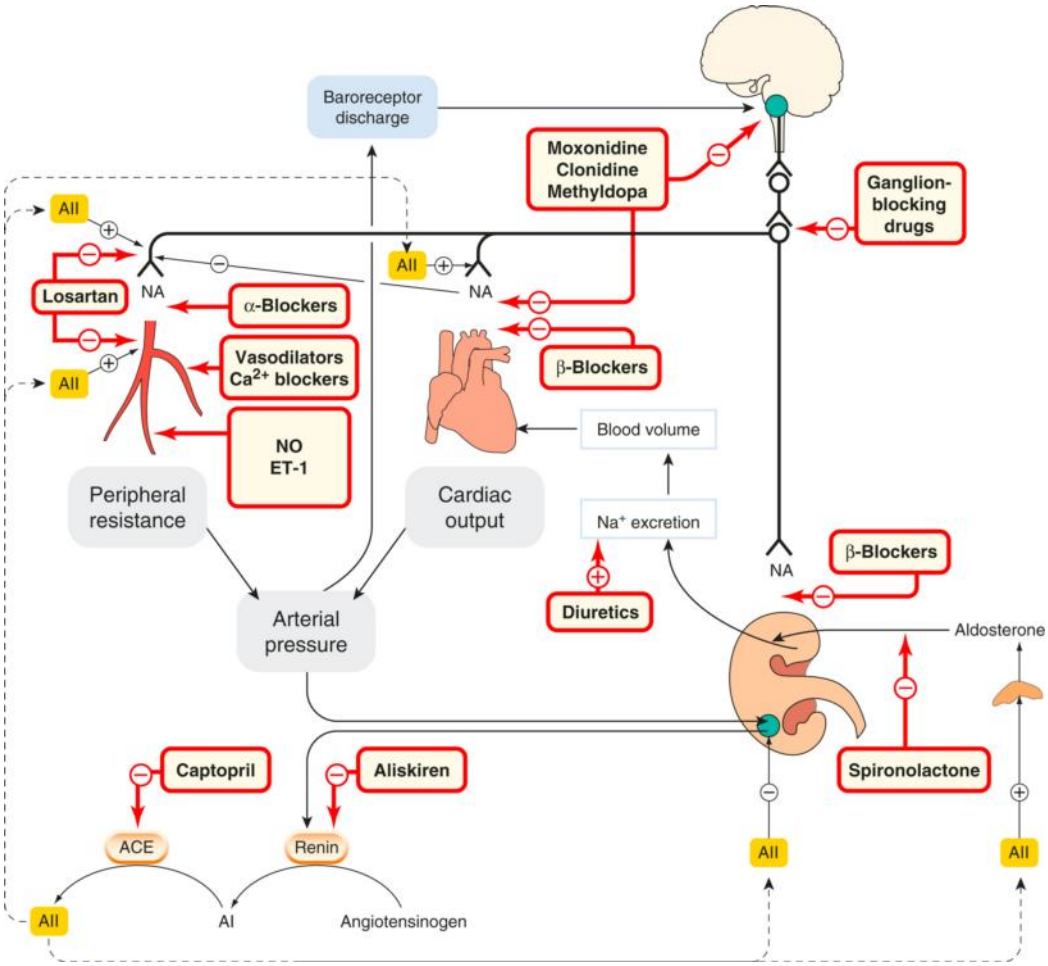

FIG. 21.7 Main mechanisms involved in arterial blood pressure regulation *(black lines)*, and the sites of action of antihypertensive drugs *(hatched boxes + orange lines)*. *ACE,* Angiotensin-converting enzyme; *AI,* angiotensin I; *AII,* angiotensin II; *ET-1*, endothelin-1; *NA,* noradrenaline; *NO,* nitric oxide.

Reducing arterial blood pressure greatly improves the prognosis of patients with hypertension. Controlling hypertension (which is asymptomatic) without producing unacceptable side effects is therefore an important clinical need, which is, in general, well

catered for by modern drugs. Treatment involves non-pharmacological measures (e.g. increased exercise, reduced dietary salt and saturated fat with increased fruit and fibre, and weight and alcohol reduction) followed by the staged introduction of drugs, starting with those of proven benefit and least likely to produce adverse effects. Some of the drugs that were used to lower blood pressure in the early days of antihypertensive therapy, including *ganglion blockers*, *adrenergic neuron blockers* and **reserpine** (see **Ch. 15**), produced a fearsome array of adverse effects and are now obsolete. The preferred regimens have changed progressively as better-tolerated drugs have become available. A rational strategy is to start treatment with either an ACEI or an ARB in patients who are likely to have normal or raised plasma renin (i.e. younger White people), and with a calcium antagonist in older people and people of African origin (who are more likely to have low plasma renin). If the target blood pressure is not achieved but the drug is well tolerated, then a drug of the other group or a thiazide diuretic is added. It is best not to increase the dose of any one drug excessively, as this often causes adverse effects and engages homeostatic control mechanisms (e.g. renin release by a diuretic) that limit efficacy.

Table 21.3

ACE, Angiotensin-converting enzyme; *AT* $_{1,}$ angiotensin II type 1 receptor

[a] ± indicates that the adverse effect occurs in special circumstances only (e.g. postural hypotension occurs with a thiazide diuretic only if the patient is dehydrated for some other reason, is taking some additional drug or suffers from some additional disorder).

β-Adrenoceptor antagonists are less well tolerated than ACEIs or ARBs, and the evidence supporting their routine use is less strong than for other classes of antihypertensive drugs. They are useful for hypertensive patients with some additional indication for β blockade, such as angina or heart failure.

Addition of a third or fourth drug (e.g. to ARB/calcium antagonist combination) is often needed, and a long-acting α_1-adrenoceptor antagonist (see **Ch. 15**) such as once-daily **doxazosin** is one option in this setting. The α_1 antagonists additionally improve symptoms of prostatic hyperplasia (also known as benign prostatic hypertrophy) (Chs **15**, **29** and **35**), which is common in older men, albeit at the risk of postural hypotension, which is the main unwanted effect of these agents. **Spironolactone**, whose active metabolite canrenone is a competitive antagonist of aldosterone (see **Ch. 29**), has staged something of a comeback as an additional agent in treating severe hypertension. Careful monitoring of plasma K^+ concentration is required, because spironolactone inhibits urinary K^+ excretion as well as causing oestrogen-related adverse effects, but it is usually well tolerated in low doses. **Methyldopa** is now used mainly for hypertension during pregnancy because of the lack of documented

adverse effects on the baby (in contrast to ACEIs, ARBs and standard β-adrenoceptor antagonists, which are contraindicated during pregnancy and therefore often avoided in women of child-bearing potential). **Clonidine** (a centrally acting α_2 agonist) is now seldom used. **Moxonidine**, a centrally acting agonist at imidazoline I_1 receptors that causes less drowsiness than α_2 agonists, is licensed for mild or moderate hypertension, but there is little evidence from clinical end-point trials to support its wider use. **Minoxidil**, combined with a diuretic and β-adrenoceptor antagonist, is sometimes effective where other drugs have failed in severe hypertension resistant to other drugs. **Fenoldopam**, a selective dopamine D_1 receptor agonist, is approved in the United States for the short-term in-hospital management of severe hypertension. Its effect is similar in magnitude to that of intravenous nitroprusside, but it lacks thiocyanate-associated toxicity and is slower in onset and offset.

Commonly used antihypertensive drugs and their main adverse effects are summarised in **Table 21.3**.

Heart Failure

Heart failure is a clinical syndrome characterised by symptoms of breathlessness and/or fatigue, usually with signs of fluid overload (oedema, raised venous pressure and crackles heard when listening to the chest). The underlying physiological abnormality (see also **Ch. 20**) is a cardiac output that is inadequate to meet the metabolic demands of the body, initially during exercise but, as the syndrome progresses, also at rest. It may be caused by direct damage to the myocardium itself (most commonly secondary to coronary artery

disease but also other pathologies including cardiotoxic drugs such as **doxorubicin** and **trastuzumab** – see **Ch. 57**), or by circulatory factors such as volume overload (e.g. leaky valves, or arteriovenous shunts caused by congenital defects) or pressure overload (e.g. stenosed – i.e. narrowed – valves, systemic or pulmonary hypertension). Some of these underlying causes are surgically correctable, and in some, either the underlying disease (e.g. hyperthyroidism; see **Ch. 34**) or an aggravating factor, such as anaemia (see **Ch. 24**) or atrial fibrillation (see **Ch. 20**), is treatable with drugs. Here, we focus on drugs used to treat heart failure per se, irrespective of the underlying cause.

When cardiac output is insufficient to meet metabolic demand, an increase in fluid volume occurs, partly because increased venous pressure increases capillary pressure and hence formation of tissue fluid, and partly because reduced renal blood flow activates the RAAS, causing Na^+ and water retention. Irrespective of the cause, and despite major recent advances in pharmacotherapy, the outlook for adults with cardiac failure remains of concern, with up to 50% mortality after 5 years. Non-drug measures, including dietary salt restriction and exercise training in mildly affected patients, [11] are important, but drugs are needed to improve symptoms of oedema, fatigue and breathlessness, and to improve prognosis.

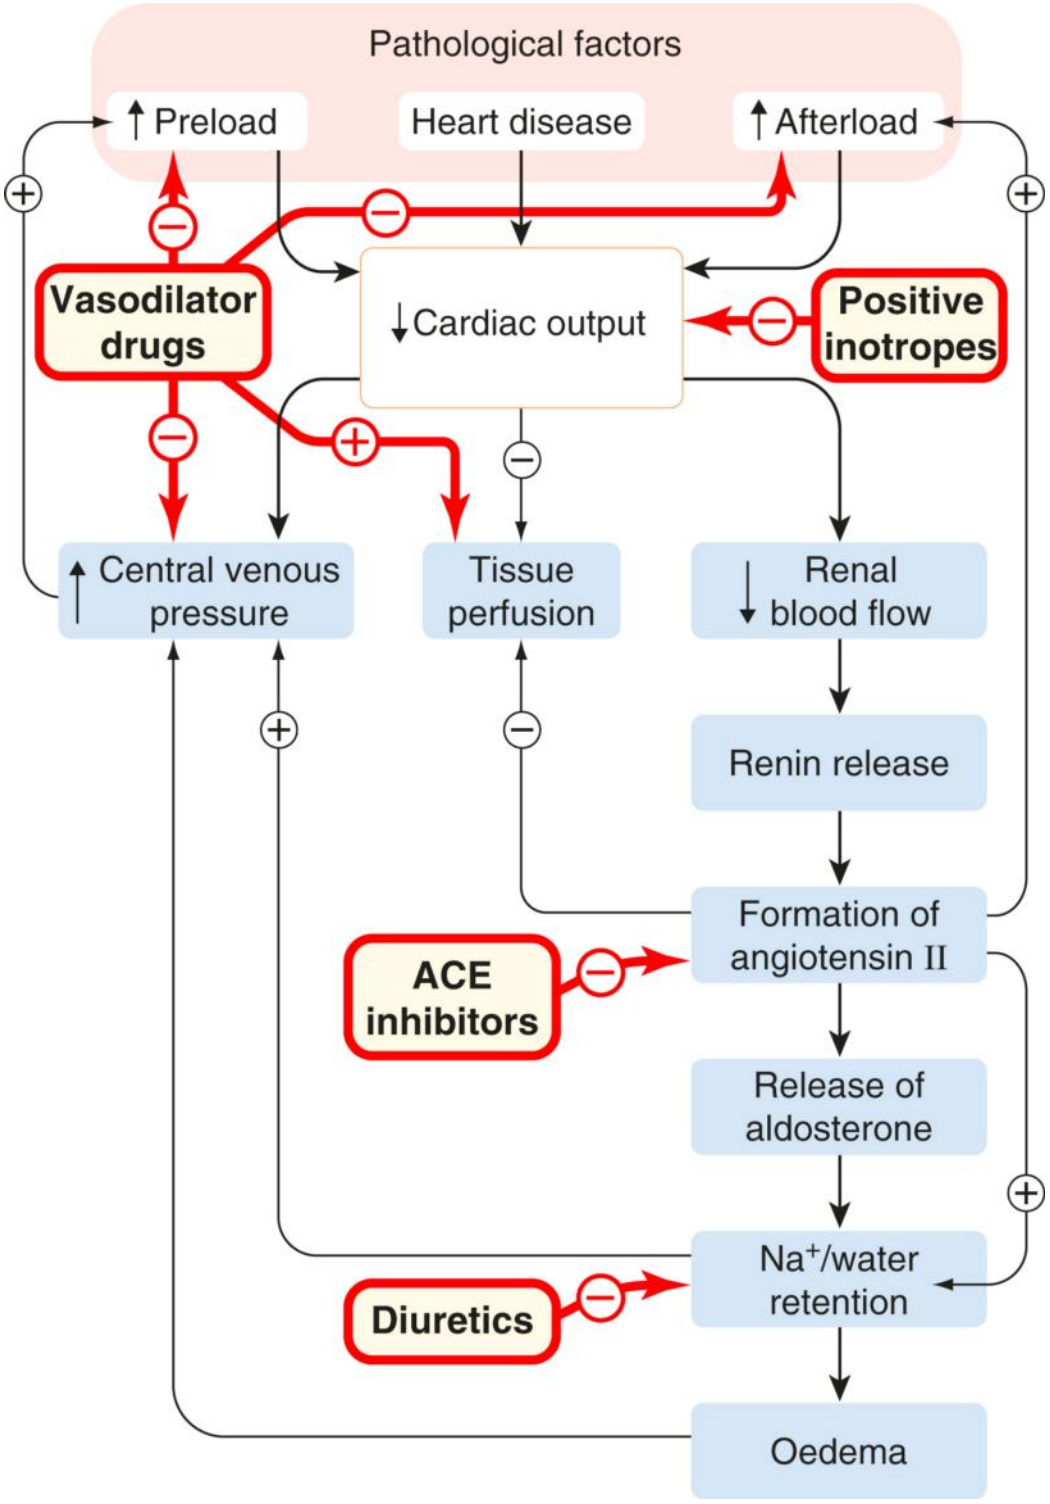

FIG. 21.8 Simplified scheme showing the pathogenesis of heart failure, and the sites of action of some of the drugs used to treat it.The

symptoms of heart failure are produced by reduced tissue perfusion, oedema and increased central venous pressure. *ACE,* Angiotensin-converting enzyme.

A simplified diagram of the sequence of events is shown in **Fig. 21.8**. A common theme is that several of the feedbacks that are activated are 'counter-regulatory' – that is, they make the situation worse not better. This occurs because the body fails to distinguish the haemodynamic state of heart failure from haemorrhage, in which release of vasoconstrictors such as angiotensin II and ADH would be appropriate. [12] ACEIs and ARBs, β-adrenoceptor and aldosterone antagonists interrupt these counter-regulatory neurohormonal mechanisms and have each been shown to prolong life in heart failure.

Drugs used to treat heart failure act in various complementary ways to do the following.

Increase natriuresis

Diuretics, especially loop diuretics (see **Ch. 29**), are important in increasing salt and water excretion, especially if there is pulmonary oedema. In chronic heart failure, drugs that have been shown to improve survival were studied mainly in patients treated with diuretics.

Sodium glucose co-transporter-2 inhibitors are used in treatment of diabetes mellitus (see **Ch. 31**) but have also been found to reduce heart failure hospital admissions, even in patients who do not have diabetes. Several mechanisms (natriuresis, lowering of blood pressure, weight loss, post-glomerular and coronary vasodilation)

have been proposed for this beneficial effect but further research is ongoing into direct action on cardiac remodelling, myocardial calcium handling and amelioration of endothelial cell dysfunction.

Inhibit the renin–angiotensin–aldosterone system/potentiate NEP

The RAAS is inappropriately activated in patients with cardiac failure, especially when they are treated with diuretics. The β-adrenoceptor antagonists inhibit renin secretion and are used as first-line agents in clinically stable patients with chronic heart failure (see clinical box). ACEIs and ARBs block the formation of angiotensin II and inhibit its action, respectively, thereby reducing vascular resistance, improving tissue perfusion and reducing cardiac afterload. They also cause natriuresis by inhibiting secretion of aldosterone and by reducing the direct stimulatory effect of angiotensin II on reabsorption of Na^+ and HCO_3^- in the early part of the proximal convoluted tubule. Most important of all, they prolong life.

Differences in the pharmacology of ACEIs and ARBs led to the hypothesis that co-administration of these drugs ('dual blockade') could confer additional benefit over increasing the dose of either given as a single agent. However, clinical trials comparing ACEI or ARB monotherapy against combined therapy found that the combined treatment had more adverse effects attributable to hypotension, and no survival benefit compared with monotherapy in patients after acute myocardial infarction.

In contrast to the disappointing experience of combining ARBs with ACEI, a fixed combination of sacubitril with valsartan is used

in patients symptomatic with chronic heart failure and reduced cardiac ejection. In comparison to an ACEI (enalapril), sacubitril/valsartan usefully reduced cardiac and all-cause mortality in such patients and **Jhund and McMurray (2016)** argue that this combination should therefore replace an ACEI as the foundation of treatment of symptomatic heart failure.

The choice of valsartan as ARB in this combination is supported by its pharmacokinetic similarity to sacubitril. Sacubitril, sacubitrilat and valsartan are highly bound to plasma proteins (94%–97%) but sacubitril does cross the blood–brain barrier to a limited extent (0.28%). Cerebrospinal fluid (CSF) Aβ clearance in young cynomolgus monkeys is reduced by sacubitril/valsartan. Administration of the combination for 2 weeks to healthy subjects increased CSF Aβ1-38 without change in Aβ1-40 and 1-42. However, pharmacoepidemiological data have not confirmed any definitive effect on cognition thus far, and the product is subject to ongoing safety monitoring in large clinical trials.

Adverse effects and drug interactions observed during treatment with valsartan/sacubitril are in line with those of its two components. Hypotension, hyperkalaemia and renal impairment are the commonest observed adverse effects. Angioedema occurred during the pivotal controlled trial in 0.5% of patients treated with the combination, compared with 0.2% of patients treated with enalapril. Concomitant use of sacubitril with ACEIs is contraindicated since, consistent with the experience with omapatrilat mentioned earlier, the concomitant inhibition of NEP and ACE increases the risk of angioedema. PDE5 inhibitors (see **Ch.**

20), including sildenafil, which work through cGMP signalling are potentiated by sacubitril.

Angiotensin II is not the only stimulus to aldosterone secretion, and during chronic treatment with ACEIs, circulating aldosterone concentrations return towards pretreatment values (a phenomenon known as 'aldosterone escape'). This provides a rationale for combining **spironolactone** (an aldosterone antagonist; see **Ch. 33**) with ACEI treatment, which further reduces mortality. **Eplerenone** is an aldosterone antagonist with less oestrogen-like adverse effects than spironolactone; it too has been shown to improve survival in patients with heart failure when added to conventional therapy. Patients with impaired renal function were excluded from these trials, and careful monitoring of plasma K^+ concentration is important when they are treated with an ACEI or an ARB in combination with an aldosterone antagonist.

Block β adrenoceptors

Heart failure is accompanied by potentially harmful activation of the sympathetic nervous system as well as of the renin–angiotensin system, providing a rationale for using β-adrenoceptor antagonists. Most clinicians were very wary of this approach because of the negative inotropic action of these drugs, but when started in low doses that are increased slowly, **metoprolol**, **carvedilol, nebivolol** and **bisoprolol** each improve survival when added to optimal treatment in clinically stable patients with chronic heart failure.

Vasodilators.

Glyceryl trinitrate (see **Ch. 20**) is infused intravenously to treat acute cardiac failure. Its venodilator effect reduces venous pressure, and its effects on arterial compliance and wave reflection further reduce cardiac work. The combination of hydralazine (to reduce afterload) with a long-acting organic nitrate (to reduce preload) in patients with chronic heart failure improved survival in a North American randomised controlled trial, but the results suggested that the benefit was restricted to patients of African origin. This ethnic group is genetically very heterogeneous, and it is unknown what other groups will benefit from such treatment. The future role of hydralazine/nitrate in targeting specific ethnic groups is now uncertain given that sacubitril/valsartan and sodium glucose co-transporter-2 inhibitors have demonstrable efficacy for heart failure in both White and non-White populations.

Vericiguat is an oral guanylyl cyclase stimulator that has recently received positive regulatory opinion on reduction of heart failure hospitalisations for patients with reduced ejection fraction.

Increase the force of cardiac contraction

Cardiac glycosides (see **Ch. 20**) are used either in patients with heart failure who also have chronic rapid atrial fibrillation (in whom it improves cardiac function by slowing ventricular rate and hence ventricular filling in addition to any benefit from its positive inotropic action) or in patients who remain symptomatic despite treatment with a diuretic and ACEI. **Digoxin** does not reduce mortality in heart failure patients in sinus rhythm who are otherwise optimally treated but does improve symptoms and reduce the need for hospital admission. In contrast, PDE inhibitors (see

Ch. 20) increase cardiac output, but increase mortality in heart failure, probably through cardiac dysrhythmias. **Dobutamine** (a β_1-selective adrenoceptor agonist; see **Ch. 20**) is used intravenously when a rapid response is needed in the short term, for example following heart surgery. Omecamtiv, a cardiac myosin activator, is currently being evaluated for treatment of heart failure (see **Ch. 20**).

Drugs used in chronic heart failure

- Loop diuretics, for example **furosemide** (see **Ch. 29**).
- ACEIs (e.g. **ramipril**) are a first-line option.
- Angiotensin II subtype 1 receptor antagonists (e.g. **valsartan**, **candesartan**) alone or, increasingly, in combination with an NEP inhibitor (**valsartan/sacubitril**).
- β-Adrenoceptor antagonists (e.g. **metoprolol**, **bisoprolol**, **carvedilol**), introduced in low dose in stable patients, are also first-line options.
- Aldosterone-receptor antagonists (e.g. **spironolactone**, see **Ch. 33**; and **eplerenone**).
- **Digoxin** (see **Ch. 20**), especially for heart failure associated with established rapid atrial fibrillation. It is also indicated in patients who remain symptomatic despite optimal treatment.
- Organic nitrates (e.g. **isosorbide mononitrate**) reduce preload, and **hydralazine** reduces afterload. Used in combination, these prolong life in African-Americans with heart failure.

- Vericiguat is an option in symptomatic patients who have recently recovered from acute decompensated heart failure.

Vasodilatory Shock and Hypotensive States

Shock is a medical emergency characterised by inadequate perfusion of vital organs, usually because of a very low arterial blood pressure. This leads to anaerobic metabolism and hence to increased lactate production. Mortality is very high, even with optimal treatment in an intensive care unit. Shock can be caused by various insults, including haemorrhage, burns, bacterial infections, anaphylaxis and myocardial infarction (**Fig. 21.9**). The common factor is reduced effective circulating blood volume (hypovolaemia) caused directly either by bleeding or by movement of fluid from the plasma to the gut lumen or extracellular fluid. The physiological (homeostatic) response to this is complex: vasodilatation in a vital organ (e.g. brain, heart or kidney) favours perfusion of that organ, but at the expense of a further reduction in blood pressure, which leads to reduced perfusion of other organs. Survival depends on a balance between vasoconstriction in non-essential vascular beds and vasodilatation in vital ones. The dividing line between the normal physiological response to blood loss and clinical shock is that in shock, tissue hypoxia produces secondary effects that magnify rather than correct the primary disturbance. Patients with established shock have profound and inappropriate vasodilatation in non-essential organs, and this is difficult to correct with vasoconstrictor drugs. The release of mediators (e.g. histamine, 5-HT, bradykinin, prostaglandins, cytokines including interleukins

and tumour necrosis factor, NO and undoubtedly many more as-yet-unidentified substances) that cause capillary dilatation and leakiness is the opposite of what is required to improve function in this setting. Mediators promoting vasodilatation in shock converge on two main mechanisms:

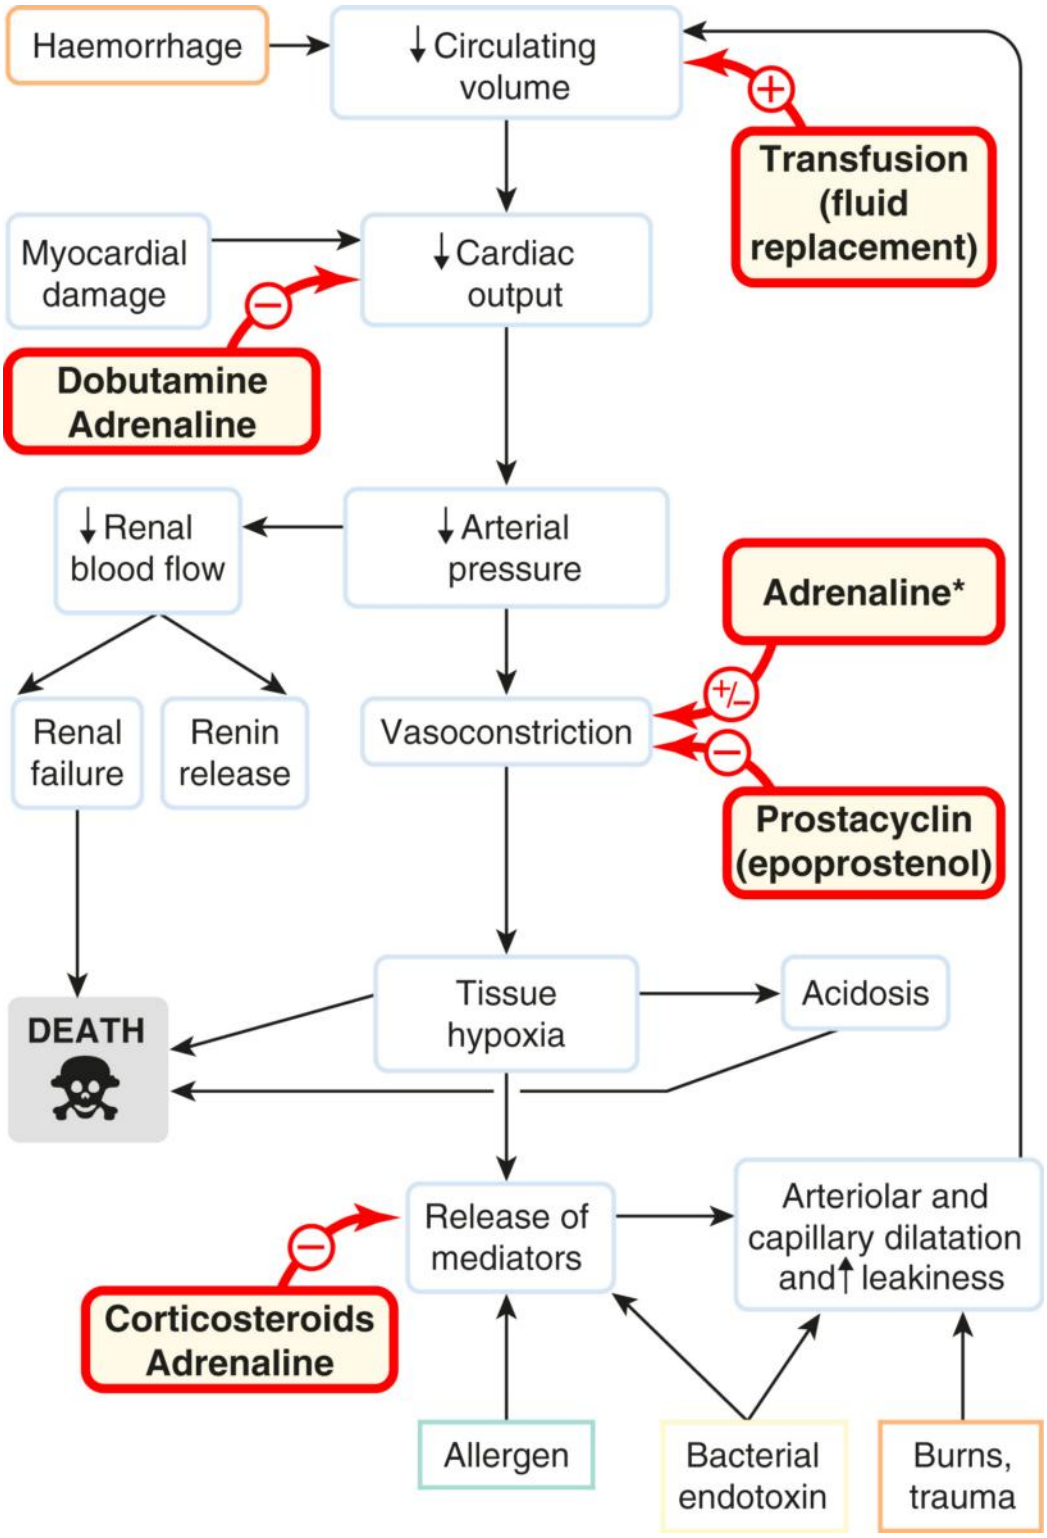

FIG. 21.9 Simplified scheme showing the pathogenesis of hypovolaemic shock.∗Adrenaline

causes vasodilatation in some vascular beds, vasoconstriction in others.

Activation of ATP-sensitive potassium channels in vascular smooth muscle by reduced cytoplasmic ATP and increased lactate and protons.

Increased synthesis of NO, which activates myosin light-chain phosphatase and activates K_{Ca} channels.

A third important mechanism seems to be a relative *deficiency* of ADH, which is secreted acutely in response to haemorrhage but subsequently declines, probably because of depletion within the neurohypophysis (see **Ch. 33**).

Patients with shock are not a homogeneous population, making it hard to perform valid clinical trials, and in contrast to hypertension and heart failure there is very little evidence to support treatment strategies based on hard clinical end points (such as improved survival). *Volume replacement* is of benefit if there is hypovolaemia; *antibiotics* are essential if there is persistent bacterial infection; **adrenaline** can be life-saving in anaphylactic shock and is also used by intensivists in managing circulatory shock of other aetiologies. Hypoperfusion leads to multiple organ failure (including renal failure), and intensive therapy specialists spend much effort supporting the circulations of such patients with cocktails of vasoactive drugs in attempts to optimise flow to vital organs. Trials of antagonists designed to block or neutralise endotoxin, interleukins, tumour necrosis factor and the inducible form of NO synthase and of recombinant human protein C have shown them to be ineffective or actually harmful. **Vasopressin** or angiotensin II may increase blood pressure even when there is

resistance to adrenaline. *Corticosteroids* suppress the formation of NO and of prostaglandins but are not of proven benefit once shock is established; positive inotropic agents, including adrenaline, noradrenaline and **dobutamine**, may be used to increase blood pressure in individual patients.

Peripheral Vascular Disease

When atheroma involves peripheral arteries, the first symptom is usually pain in the calves on walking (claudication), followed by pain at rest, and in severe cases gangrene of the feet or legs. Other vascular beds (e.g. coronary, cerebral and renal) are often also affected by atheromatous disease in patients with peripheral vascular disease. Treatment is mainly mechanical (open surgery or endovascular procedures to open the stenosed artery), combined with drugs that reduce the risk of ischaemic heart disease and strokes. Drug treatment includes antiplatelet drugs (e.g. **aspirin**, **clopidogrel**; see **Ch. 23**), a statin (e.g. **simvastatin**; see **Ch. 22**) and an ACEI (e.g. **ramipril**).

Raynaud's Disease

Inappropriate vasoconstriction of small arteries and arterioles gives rise to Raynaud's phenomenon (blanching of the fingers during vasoconstriction, followed by blueness owing to deoxygenation of the static blood and redness from reactive hyperaemia following return of blood flow). This can be mild, but if severe causes ulceration and gangrene of the fingers. It can occur in isolation (Raynaud's disease) or in association with a number of other diseases, including several so-called connective tissue diseases (e.g.

systemic sclerosis, SLE). Treatment of Raynaud's phenomenon hinges on stopping smoking (crucially) and on avoiding the cold; β-adrenoceptor antagonists are contraindicated. Vasodilators (e.g. **nifedipine**; see **Ch. 20**) are of some benefit in severe cases, and evidence from several small studies suggests sildenafil is helpful, as well as other vasodilators (e.g. PGI_2, calcitonin gene-related peptide [CGRP]) which can have surprisingly prolonged effects long outlasting their presence in the circulation, but are difficult to administer.

Pulmonary Hypertension

After birth, pulmonary vascular resistance becomes much lower than systemic vascular resistance, and systolic pulmonary artery pressure in adults is normally approximately 20 mm Hg. [13]

Pulmonary artery pressure is much less easy to estimate than systemic pressure, requiring echocardiography and/or cardiac catheterisation, so only more severe and symptomatic pulmonary hypertension tends to be diagnosed. Pulmonary hypertension usually causes some regurgitation of blood from the right ventricle to the right atrium. This tricuspid regurgitation can be used to estimate the pulmonary artery pressure indirectly by ultrasonography. Pulmonary hypertension may rarely be *idiopathic* (i.e. of unknown cause, a severe and progressive form), but is more commonly associated with some other disease (typically involving underlying pulmonary pathology). It can result from an increased cardiac output (such as occurs, for example, in patients with hepatic cirrhosis – where vasodilatation may accompany intermittent subclinical exposure to bacterial endotoxin – or in patients with

congenital connections between the systemic and pulmonary circulations). Vasoconstriction and/or structural narrowing of the pulmonary resistance arteries increase pulmonary arterial pressure, even if cardiac output is normal. In some situations, both increased cardiac output and increased pulmonary vascular resistance are present.

Endothelial dysfunction (Chs **22** and **23**) is implicated in the aetiology of pulmonary hypertension. Drugs (e.g. anorexic drugs including **dexfenfluramine**, now withdrawn) and toxins (e.g. *monocrotaline*) can cause pulmonary hypertension. Occlusion of the pulmonary arteries, for example with *recurrent pulmonary emboli* (see **Ch. 23**), is a further primary cause or exacerbating factor, and *anticoagulation* (see **Ch. 23**) is an important part of treatment. Aggregates of deformed red cells in patients with *sickle cell anaemia* (see **Ch. 24**) can occlude small pulmonary arteries.

Increased pulmonary vascular resistance may, alternatively, result from vasoconstriction (e.g. due to persistent hypoxia in chronic lung disease) and/or structural changes in the walls of pulmonary resistance arteries. Many of the diseases (e.g. systemic sclerosis) associated with Raynaud's phenomenon mentioned in the previous section are also associated with pulmonary hypertension. Vasoconstriction may precede cellular proliferation and medial hypertrophy which causes wall thickening in the pulmonary vasculature. Calcium antagonists (e.g. nifedipine) are used, but benefit is limited. Vasodilators with an antiproliferative action (e.g. epoprostenol, **Fig. 21.10**), drugs that potentiate NO such as **riociguat**, an allosteric activator of soluble guanylyl cyclase (see earlier and **Ch. 19**), approved for this indication in Europe and the

United States, or antagonise ET – for example bosentan and **ambrisentan** – are considered to yield greater benefit.

Drugs used in treating pulmonary arterial hypertension and clinical disorders for which vasoactive drugs are important are shown in the clinical boxes.

Drugs used in pulmonary arterial hypertension

Drugs are used where indicated to treat any underlying cause. The specific aims of treatment include supportive background therapy to manage symptoms, as well targeted agents to reduce disease progression.

Management of symptoms and complications is usually achieved with:

- Oral anticoagulants (see **Ch. 23**)
- Diuretics (see **Ch. 29**)
- **Oxygen**
- **Digoxin** (see **Ch. 20**)

Targeted treatment to reduce pulmonary arterial pressure and progression of disease usually involves a variety of agents, including:

- Calcium-channel blockers.
- ET receptor antagonists (e.g. **bosentan**, **ambrisentan**, **sitaxentan**) by mouth for less severe stages of disease, in combination with PDE V inhibitors, **sildenafil** or **tadalafil.**

- Prostanoid analogues (**iloprost**, **treprostinil**, **beraprost**), subcutaneous or inhaled, are used for more severe stages of disease.
- **Epoprostenol** (see **Ch. 17**) is given as a long-term intravenous infusion and improves survival (see **Fig. 23.10**).
- Inhaled **NO** is administered in intensive care, for example for pulmonary hypertensive crises in newborn babies.
- Riociguat (activator of guanylyl cyclase).

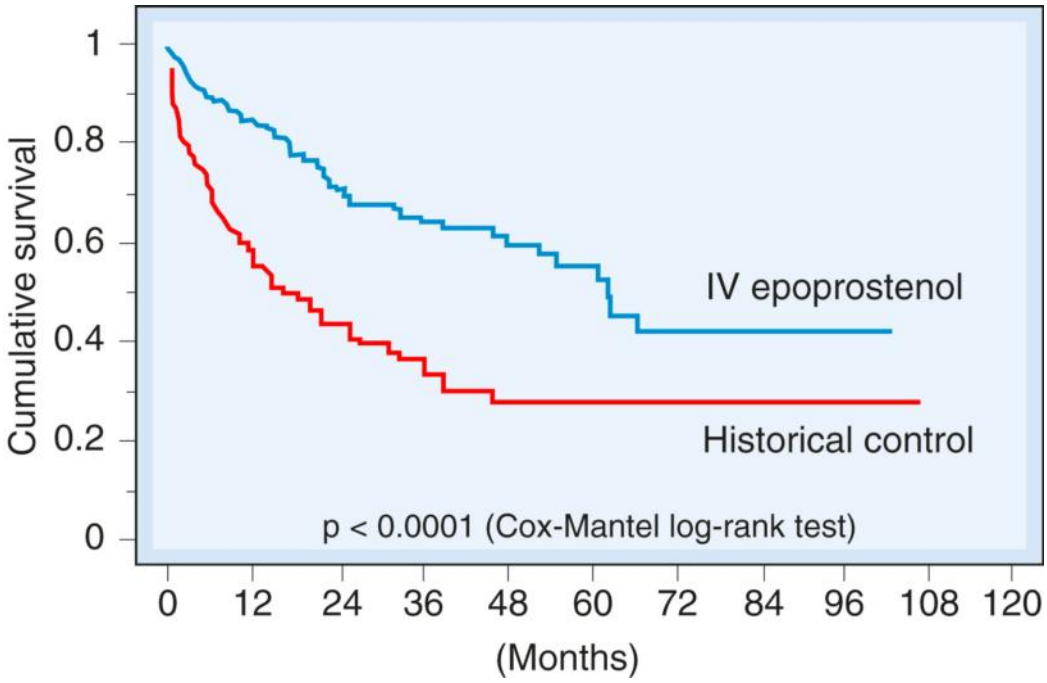

FIG. 21.10 Survival in primary pulmonary hypertension.Survival in 178 patients treated with intravenous epoprostenol versus a historical control group of 135 patients matched for disease severity. Adapted from Sitbon, O., et al., 2002. Prog. Cardiovasc. Dis. 45, 115.

QUESTIONS

QUESTION 21.1

Vascular endothelium acts as a barrier between plasma and extracellular fluid and is also responsible for the release of several vasoactive peptides that regulate vascular function and tone.

Which of the following statements about endothelial mediators is incorrect?

OPTIONS:

A. PGI_2 (prostacyclin) relaxes smooth muscle and inhibits platelet aggregation.

B. Endothelial cells synthesise PGE_2, which is a vasodilator.

C. Nitric oxide (NO) causes relaxation of vascular smooth muscle.

D. Adrenomedullin activates cAMP to cause vasodilation.

E. Endothelium-derived hyperpolarisation factors (EDHFs) mediate relaxation through cGMP.

QUESTION 21.2

The renin–angiotensin system plays an important regulatory role in the control of Na^+ excretion, fluid volume and vascular tone.

Which of the following statements about the renin–angiotensin system is incorrect?

OPTIONS:

A. Atrial natriuretic peptide (ANP) decreases renin release.

B. Angiotensin-converting enzyme (ACE) is an endothelial, membrane-bound enzyme involved in the conversion of angiotensinogen to angiotensin I.

C. PGI_2 can mediate vasoconstriction through the stimulation of renin release.

D. ACE2 reduces blood pressure through a reduction in angiotensin II.

E. Increased noradrenaline release is mediated via angiotensin II binding to angiotensin$_1$ (AT_1) receptors.

QUESTION 21.3

Vasodilator drugs play a major role in the treatment of cardiac disorders and hypertension.

Which of the following statements about the mechanism of action of the vasodilator drugs is incorrect?

OPTIONS:

A. Nifedipine is an L-type calcium channel antagonist that acts preferentially to relax vascular smooth muscle.

B. Nicorandil activates hyperpolarising K_{ATP} channels and contributes to NO donor activity.

C. Captopril inhibits renin release, causing a decrease in angiotensin-mediated vasoconstriction in hypertensive patients.

D. Valsartan is an AT_1-receptor antagonist.

E. Hydralazine blocks the action of IP_3-mediated calcium release from the sarcoplasmic reticulum.

ANSWERS

ANSWER 21.1

RATIONALE:

A. PGI_2 (prostacyclin) acting on IP receptors relaxes smooth muscle and inhibits platelet aggregation by activating adenylyl cyclase.

B. Endothelial cells from microvessels synthesise PGE_2, which is a direct vasodilator and additionally inhibits noradrenaline release from sympathetic nerve terminals.

C. NO acts via cGMP to cause relaxation of vascular smooth muscle.

D. Adrenomedullin activates cAMP to cause relaxation of vascular smooth muscle.

E.

CORRECT ANSWER WITH EXPLANATION:

E. EDHFs mediate relaxation through cGMP.

EDHFs cause hyperpolarisation by the activation of Ca^{2+}-dependent K^+ channels on endothelial cells.

ANSWER 21.2

RATIONALE:

A. ANP acts to inhibit renin release, so promoting Na^+ excretion.

B.

C. Although PGI_2 can have a direct effect to relax vascular smooth muscle, this action is kept in balance by its ability to increase renin secretion.

D. ACE2, a homologue of ACE, converts angiotensin II to angiotensin 1–7 which opposes the effects of angiotensin II. ACE2 potentially protects against heart failure by breaking down angiotensin II, thus reducing blood pressure and inflammatory cardiac damage.

E. Activation of AT_1 receptors by angiotensin II enhances sympathetic activity by increasing noradrenaline release from nerve terminals.

CORRECT ANSWER WITH EXPLANATION:

B. ACE is an endothelial membrane-bound enzyme involved in the conversion of angiotensinogen to angiotensin I.

ACE mediates the conversion of the inactive precursor angiotensin I to the active peptide angiotensin II.

ANSWER 21.3

RATIONALE:

A. Nifedipine causes arterial vasodilatation by inhibiting Ca^{2+} entry through voltage-gated calcium channels in vascular smooth muscle.

B. Nicorandil relaxes smooth muscle by opening K_{ATP} channels but has secondary activity as an NO donor.

C.

D. Valsartan is an angiotensin-receptor blocker used in the treatment of hypertension and heart failure.

E. Hydralazine acts on arteries and arterioles to reduce vasoconstriction via its action on calcium release from the sarcoplasmic reticulum.

CORRECT ANSWER WITH EXPLANATION:

C. Captopril inhibits renin release, causing a decrease in angiotensin-mediated vasoconstriction in hypertensive patients.

Captopril is an angiotensin converting enzyme inhibitor and so blocks the generation and downstream effects of angiotensin II.

[1] William Harvey (physician to King Charles I) inferred the circulation of the blood on the basis of superbly elegant quantitative experiments long before the invention of the microscope enabled visual confirmation of the tiny vessels he had predicted. This intellectual triumph did his medical standing no good at all, and

Aubrey wrote that ‘he fell mightily in his practice’, and was regarded by the vulgar as ‘crack-brained’. *Plus ça change*…

2 This cushioning action is called the ‘Windkessel’ effect. The same principle was used to deliver a steady rather than intermittent flow from old-fashioned fire pumps.

3 Think of the waves in your bath as you sit up: down the tub, a splash down the overflow but most comes back as reflections from the foot end under the taps and interferes with the forward waves.

4 Subsequently, an 11–amino acid peptide (*urotensin*) was isolated from the brains of bony fish and found to be 50–100 times more potent than ET in some blood vessels. It and its receptor are expressed in human tissue but its function, if any, in man remains enigmatic.

5 Approximately that of a football field.

6 These effects are initiated by the G protein–coupled AT_1 receptor acting via the same intracellular tyrosine phosphorylation pathways as are used by cytokines, for example, the Jak/Stat pathway (Ch. 3).

7 An autoimmune disease affecting one or more tissues, including joints, kidneys, brain, blood platelets, skin and pleural membranes (Ch. 25). Patients with hydralazine-induced lupus commonly have symptoms mimicking lupus, e.g. fever, joint pains and weight loss, with positive tests for antinuclear antibodies, but the triggering mechanism is incompletely understood.

8 The lead compound was a nonapeptide derived from the venom of *Bothrops jararaca* – a South American snake. It was originally

characterised as a bradykinin-potentiating peptide (ACE inactivates bradykinin; see Ch. 17).

[9] Severe narrowing of the renal artery caused, for example, by atheroma.

[10] Catecholamine-secreting tumours of chromaffin tissue, usually the adrenal medulla (Ch. 33).

[11] Bed rest used to be recommended but results in deconditioning, and regular exercise has been shown to be beneficial in patients who can tolerate it.

[12] Natural selection presumably favoured mechanisms that would benefit young hunter–gatherers at risk of haemorrhage; middle-aged or elderly people at high risk of heart failure are past their reproductive prime.

[13] In fetal life, pulmonary vascular resistance is high; failure to adapt appropriately at birth is associated with prematurity, lack of pulmonary surfactant and hypoxaemia. The resulting pulmonary hypertension is treated by paediatric intensive care specialists with measures including replacement of surfactant and ventilatory support, sometimes including inhaled NO – see Chapter 19.

22: Atherosclerosis and lipoprotein metabolism

OVERVIEW

Atheromatous disease is ubiquitous and underlies the commonest causes of death (myocardial infarction caused by thrombosis – **Ch. 23** – on ruptured atheromatous plaque in a coronary artery) and disability (stroke, heart failure) in industrial societies. Hypertension is one of the most important risk factors for atheroma, and is discussed in **Chapter 21**. Here, we consider other risk factors, especially dyslipidaemia, [1] which, like hypertension, is amenable to drug therapy. We describe briefly the processes of atherogenesis and of lipid transport as a basis for understanding the actions of lipid-lowering drugs. Agents employed therapeutically (statins, inhibitors of PCSK9, [2] fibrates and cholesterol absorption inhibitors) are described, with emphasis on the statins which, in selected patients, reduce the incidence of arterial disease and prolong life.

Introduction

In this chapter we summarise the pathological process of atherogenesis and approaches to the prevention of atherosclerotic disease. Lipoprotein transport forms the basis for understanding drugs used to treat dyslipidaemia. We emphasise the **statins**, which

have been a major success story, not only lowering plasma cholesterol but also reducing cardiovascular events by approximately 25%–50% and prolonging life in people at increased risk of vascular disease. However, some patients do not tolerate them, and others fail to respond. Evidence that other drugs that influence dyslipidaemia improve clinical outcomes is less secure than for the statins, and there have been setbacks, described later, that call into question the universal reliability of changes in circulating lipid concentrations in response to drugs as surrogates predicting clinical improvement. Other classes of lipid-lowering drugs currently remain second line to statins whilst we await robust outcome data from large long-term randomised clinical trials.

Atherogenesis

Atheroma is a focal disease of the intima of large and medium-sized arteries. Lesions evolve over decades, during most of which time they are clinically silent, the occurrence of symptoms signalling advanced disease. Presymptomatic lesions are often difficult to detect non-invasively, although ultrasound is useful in accessible arteries (e.g. the carotids), and associated changes such as reduced aortic compliance and arterial calcification can be detected by measuring, respectively, aortic pulse wave velocity and coronary artery calcium score (through computed tomography scans). There were no good animal models until genetically-altered mice (see **Ch. 8**) deficient in apolipoproteins or receptors that play key roles in lipoprotein metabolism transformed the scene. Nevertheless, most of our current understanding of atherogenesis comes from human epidemiology and pathology, and from clinical investigations.

Epidemiological studies have identified numerous risk factors for atheromatous disease. Some of these cannot be altered (e.g. a family history of ischaemic heart disease [3]), but others are modifiable (**Table 22.1**) and are potential targets for therapeutic drugs. Clinical trials have shown that improving risk factors can reduce the consequences of atheromatous disease. Many risk factors (e.g. type 2 diabetes, dyslipidaemia, cigarette smoking) cause endothelial dysfunction (see **Ch. 21**), evidenced by reduced vasodilator responses to acetylcholine or to increased blood flow (so-called flow-mediated dilatation), responses that are inhibited by drugs that block nitric oxide (NO) synthesis (see **Ch. 19**). Healthy endothelium produces NO and other mediators that protect against atheroma, so it is likely that metabolic cardiovascular risk factors act by causing endothelial dysfunction.

Atherogenesis involves:

1. *Endothelial dysfunction*, with altered NO (see **Ch. 19**) biosynthesis which predisposes to atherosclerosis.
2. *Injury* of dysfunctional endothelium, which leads to expression of adhesion molecules. This encourages monocyte attachment and migration of monocytes from the lumen into the intima. Lesions have a predilection for regions of disturbed flow such as the origins of aortic branches.
3. *Low-density lipoprotein (LDL) cholesterol* transport into the vessel wall. Endothelial cells and monocytes/macrophages generate free radicals that oxidise LDL (oxLDL), resulting in lipid peroxidation.

4. *oxLDL* uptake by macrophages via ‘scavenger’ receptors. Such macrophages are called *foam cells* because of their ‘foamy’ histological appearance, resulting from accumulation of cytoplasmic lipid, and are characteristic of atheroma. Uptake of oxLDL activates macrophages which release proinflammatory cytokines.
5. Subendothelial accumulation of foam cells and T lymphocytes to form *fatty streaks*.

Table 24.1

Modifiable risk factors for atheromatous disease

Raised low-density lipoprotein cholesterol
Reduced high-density lipoprotein cholesterol
Hypertension (**Ch. 21**)
Diabetes mellitus (**Ch. 31**)
Cigarette smoking (**Ch. 50**)
Obesity (**Ch. 32**)
Physical inactivity
Raised C-reactive protein [a]
Raised coagulation factors (e.g. factor VII, fibrinogen)
Raised homocysteine
Raised lipoprotein(a)

[a] Strongly associated with atheromatous disease but not causal of it.

6. Protective mechanisms, for example cholesterol *mobilisation from the artery wall* and transport in plasma as high-density lipoprotein (HDL) cholesterol, termed *reverse cholesterol transport*.
7. Cytokine and growth factor release by activated platelets, macrophages and endothelial cells, causing proliferation of

smooth muscle and deposition of connective tissue components. This *inflammatory fibroproliferative response* leads to a dense fibrous cap overlying a lipid-rich core, the whole structure comprising the atheromatous plaque.

8. Plaque *rupture*, which provides a substrate for *thrombosis* (see **Ch. 23**, **Figs 23.1 and 23.10**). The presence of large numbers of macrophages predisposes to plaque rupture, whereas vascular smooth muscle and matrix proteins stabilise the plaque.

To understand how drugs prevent atheromatous disease, it is necessary briefly to review lipoprotein transport.

Lipoprotein Transport

Lipids and cholesterol are transported in the bloodstream as complexes of lipid and protein known as *lipoproteins*. These consist of a central core of hydrophobic lipid (including triglycerides and cholesteryl esters) encased in a hydrophilic coat of polar phospholipid, free cholesterol and *apoprotein*. There are four main classes of lipoprotein, differing in the relative proportion of the core lipids and in the type of apoprotein (various kinds of apoA and apoB). Apoproteins bind to specific receptors that mediate cellular uptake of lipoprotein particles into liver, blood or other tissues. Lipoproteins differ in size and density, and this latter property, measured originally by ultracentrifugation but now commonly estimated by simpler methods, is the basis for their classification into:

- HDL particles (contain apoA1 and apoA2), diameter 7–20 nm

- LDL particles (contain apoB-100), diameter 20–30 nm
- very-low-density lipoprotein (VLDL) particles (contain apoB-100), diameter 30–80 nm
- chylomicrons (contain apoB-48), diameter 100–1000 nm

Each class of lipoprotein has a specific role in lipid transport, and there are different pathways for exogenous and endogenous lipids, as well as a pathway for reverse cholesterol transport (**Fig. 22.1**). In the *exogenous pathway*, cholesterol and triglycerides absorbed from the ileum are transported as chylomicrons in lymph and then blood, to capillaries in muscle and adipose tissue. Here, triglycerides are hydrolysed by lipoprotein lipase, and the tissues take up the resulting free fatty acids and glycerol. The chylomicron remnants, still containing their full complement of cholesteryl esters, pass to the liver, bind to receptors on hepatocytes and undergo endocytosis. Cholesterol liberated in hepatocytes is stored, oxidised to bile acids, secreted unaltered in bile, or can enter the endogenous pathway.

In the *endogenous pathway*, cholesterol and newly synthesised triglycerides are transported from the liver as VLDL to muscle and adipose tissue, where triglyceride is hydrolysed to fatty acids and glycerol; these enter the tissues as described previously. During this process, the lipoprotein particles become smaller but retain a full complement of cholesteryl esters and become LDL particles. LDL provides the source of cholesterol for incorporation into cell membranes and for synthesis of steroids (see Chs **33** and **35**) but is also key in atherogenesis. Cells take up LDL by endocytosis via *LDL receptors* that recognise apoB-100. LDL receptors are critically important in determining the concentration of circulating LDL, and hence the development and progression of atheromatous disease;

the most widely used drugs for the prevention of such disease, the statins, act by blocking the synthesis of cholesterol within hepatocytes which respond by increasing LDL receptor expression on their surface membranes (see later). A new class of drugs, monoclonal antibodies that inhibit PCSK9, also influence LDL receptor density but by a different mechanism, namely reduced lysosomal degradation of internalised LDL receptors leading to increased recycling of functional LDL receptors to the surface membrane (see later). Alternatively, inhibition of PCSK9 can be achieved using small interfering RNA (siRNA; see **Ch. 5**); **inclisiran** is a newly approved siRNA drug that blocks PCSK9 synthesis in the liver (see later).

Cholesterol can return to plasma from the tissues in HDL particles (reverse cholesterol transport). Cholesterol is esterified with long-chain fatty acids in HDL particles, and the resulting cholesteryl esters are transferred to VLDL or LDL particles by a transfer protein present in the plasma and known as *cholesteryl ester transfer protein* (CETP). Lipoprotein(a), or Lp(a), is a species of LDL that is associated with atherosclerosis and is localised in atherosclerotic lesions. Lp(a) contains a unique apoprotein, apo(a), with structural similarities to plasminogen (see **Ch. 23**). Lp(a) competes with plasminogen for its receptor on endothelial cells. Plasminogen is the substrate for plasminogen activator, which is secreted by, and bound to, endothelial cells, generating the fibrinolytic enzyme *plasmin* (see **Fig. 23.10**). The effect of the binding of Lp(a) is that less plasmin is generated, fibrinolysis is inhibited and thrombosis promoted.

Microsomal triglyceride transport protein (MTP) is a lipid-transfer protein present in the lumen of the endoplasmic reticulum responsible for binding and transfer of lipids between membranes. The inhibition of MTP interferes with apoB secretion and LDL assembly, and **lomitapide**, one such inhibitor (see later), is used in addition to diet and other measures in homozygous familial hypercholesterolaemia (FH).

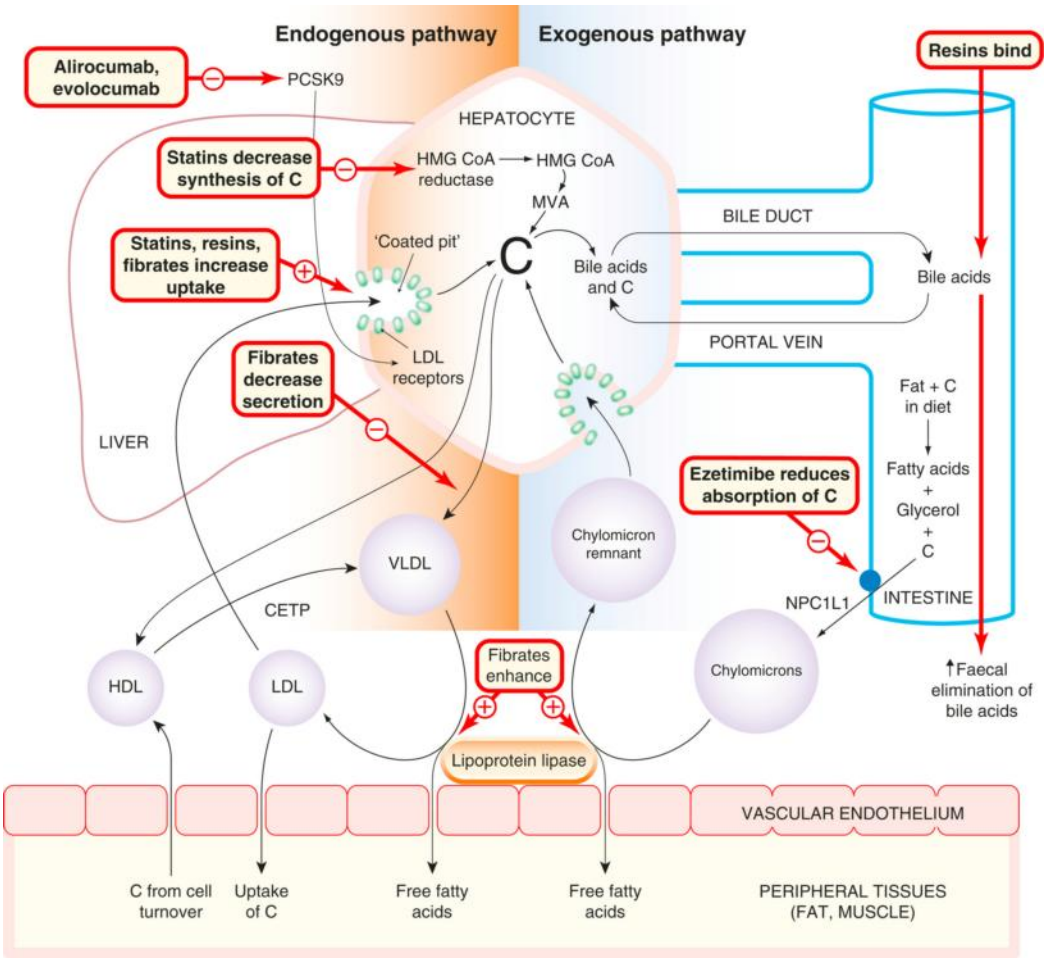

FIG. 22.1 Schematic diagram of cholesterol transport in the tissues, with sites of action of the main drugs affecting lipoprotein metabolism. *C,* Cholesterol; *CETP,* cholesteryl ester transport protein; *HDL,* high-density lipoprotein; *HMG-CoA*, 3-hydroxy-3-methylglutaryl-coenzyme A; *LDL,* low-density lipoprotein; *MVA,* mevalonate; *NPC1L1*, a cholesterol transporter in the brush border of enterocytes; *PCSK9*, proprotein convertase subtilisin/kexin 9; *VLDL,* very-low-density lipoprotein.

Dyslipidaemia

Dyslipidaemia may be primary or secondary. The *primary* forms are due to a combination of diet and genetics (often but not always polygenic). They are classified into six phenotypes (the Frederickson classification; **Table 22.2**). An especially great risk of ischaemic heart disease occurs in a subset of primary type IIa hyperlipoproteinaemia caused by single-gene defects of LDL receptors; this is known as *familial hypercholesterolaemia* (FH), and the plasma total cholesterol concentration, normally <5 mmol/L, in affected adults is typically >8 mmol/L in heterozygotes and 12–25 mmol/L in homozygotes. A study of FH enabled **Brown and Goldstein (1986)** to define the LDL receptor pathway of cholesterol homeostasis (for which they shared a Nobel Prize). Further investigation of people with very low or very high circulating LDL-cholesterol (LDL-C) concentrations led to the discovery of inactivating and gain-of-function variants of the *PCSK9* gene (see **Hall, 2013**, for a popular account, and later). Drugs used to treat primary dyslipidaemia are described later.

Secondary forms of dyslipidaemia are a consequence of other conditions, such as diabetes mellitus, alcoholism, nephrotic syndrome, chronic renal failure, hypothyroidism, liver disease and administration of drugs, for example **isotretinoin** (an isomer of vitamin A given by mouth as well as topically in the treatment of severe acne, see **Ch. 26**), **tamoxifen**, **ciclosporin-**(see **Ch. 25**) and *protease inhibitors* used to treat infection with human immunodeficiency virus (see **Ch. 53**). Secondary forms are treated where possible by correcting the underlying cause.

Table 24.2

LDL, Low-density lipoprotein; *NE,* not elevated; *PCSK9*, proprotein convertase subtilisin/kexin 9; *VLDL,* very-low-density lipoprotein; *βVLDL,* a qualitatively abnormal form of VLDL identified by its pattern on electrophoresis

+ indicates increased concentration.

Lipoprotein metabolism and dyslipidaemia

Lipids, including cholesterol and triglycerides, are transported in the plasma as lipoproteins, of which there are four classes:

- Chylomicrons transport triglycerides and cholesterol from the gastrointestinal tract to the tissues, where triglyceride is split by lipoprotein lipase, releasing free fatty acids and glycerol which are taken up in muscle and adipose tissue.
  Chylomicron remnants are taken up in the liver, where cholesterol is stored, secreted in bile, oxidised to bile acids or converted into:
  - VLDLs, which transport cholesterol and newly synthesised triglycerides to the tissues, where triglycerides are removed as before, leaving:
  - intermediate-density lipoprotein and LDL particles with a large component of cholesterol; some LDL-C is taken up by the tissues and some by the liver, by endocytosis via specific LDL receptors.
- HDL particles adsorb cholesterol derived from cell breakdown in tissues (including arteries) and transfer it to VLDL and

LDL particles via cholesterol ester transport protein (CETP).

- Dyslipidaemias can be primary, or secondary to a disease (e.g. hypothyroidism). They are classified according to which lipoprotein particle is abnormal into six phenotypes (the Frederickson classification). The higher the LDL-C and the lower the HDL cholesterol, the higher the risk of ischaemic heart disease.

Prevention of Atheromatous Disease

Drug treatment is often justified, to supplement healthy habits. Treatment of hypertension (see **Ch. 21**) and, to a lesser extent, diabetes mellitus (see **Ch. 31**) reduces the incidence of symptomatic atheromatous disease, and antithrombotic drugs (see **Ch. 23**) reduce arterial thrombosis. Reducing LDL is also effective and is the main subject of this present chapter, but steps to increase HDL have also been potential targets for pharmacological attack.

Whilst regular exercise increases circulating HDL, drug treatment to increase HDL is of uncertain benefit. Fibrates modestly increase HDL and reduce LDL and triglycerides. In subjects with low HDL, inhibition of CETP can markedly increase circulating HDL, but three such drugs have failed because of lack of clinical efficacy or adverse outcomes. Trials of a fourth, **anacetrapib,** showed that it increases HDL and lowers LDL, and is associated with a modest reduction in major coronary events. However, there was no effect on overall mortality, and its development has been discontinued. It appears that whilst low HDL may be a good risk marker in certain

ethnic groups for atherosclerosis, HDL itself may not prove to be a good pharmacological target (**Parhofer, 2015**).

Atheromatous disease

- Atheroma is a uniquely human focal disease of large- and medium-sized arteries. Atheromatous plaques occur in most people, progress insidiously over many decades and underlie the commonest causes of death (myocardial infarction) and disability (e.g. stroke) in industrialised countries.
- Fatty streaks are the earliest structurally apparent lesion and progress to fibrous and/or fatty plaques. Symptoms such as angina occur only when blood flow through the vessel is reduced below that needed to meet the metabolic demands of tissues downstream from the obstruction.
- Important modifiable risk factors include hypertension (see **Ch. 21**), dyslipidaemia (this chapter) and smoking (see **Ch. 50**).
- The pathophysiology is of chronic inflammation in response to injury. Endothelial dysfunction leads to loss of protective mechanisms, monocyte/macrophage and T-cell migration, uptake of LDL-C and its oxidation, uptake of oxidised LDL by macrophages, smooth muscle cell migration and proliferation and deposition of collagen.
- Plaque rupture leads to platelet activation and thrombosis (see **Ch. 23**) with the potential to cause downstream infarction of, for example, heart muscle or brain.

Lipid-Lowering Drugs

Several drugs decrease plasma lipoprotein concentrations. Drug therapy is used in addition to dietary measures and correction of other modifiable cardiovascular risk factors.

The main agents used clinically are:

- statins: 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors
- bempedoic acid
- PCSK9 inhibitors
- fibrates
- inhibitors of cholesterol absorption
- small molecule inhibitors

Statins: HMG-COA Reductase Inhibitors

The rate-limiting enzyme in cholesterol synthesis is HMG-CoA reductase, which catalyses the conversion of HMG-CoA to mevalonic acid (see **Fig. 22.1**). **Simvastatin, lovastatin** and **pravastatin** are specific, reversible, competitive HMG-CoA reductase inhibitors with K_i values of approximately 1 nmol/L. **Atorvastatin** and **rosuvastatin** are long-lasting inhibitors. Decreased hepatic cholesterol synthesis upregulates LDL receptor synthesis, increasing LDL clearance from plasma into liver cells. The main biochemical effect of statins is therefore to reduce plasma LDL. There is also some reduction in plasma triglyceride and increase in HDL. Several large randomised placebo-controlled trials of the effects of HMG-CoA reductase inhibitors on morbidity and mortality have been positive.

Other actions of statins

Products of the mevalonate pathway react with protein ('lipidation', which is the addition to a protein of hydrophobic groups such as prenyl or farnesyl moieties). Several important membrane-bound enzymes (e.g. endothelial NO synthase; see **Ch. 19**) are modified in this way. The fatty groups serve as anchors, localising the enzyme in organelles such as caveolae and Golgi apparatus. Consequently, there is interest in actions of statins that are unrelated, or indirectly related, to their effect on plasma LDL (sometimes referred to as *pleiotropic* effects). Some of these actions are undesirable (e.g. HMG-CoA reductase guides migrating primordial germ cells, and statin use is contraindicated during pregnancy), but some offer therapeutic promise. Such potentially beneficial actions include:

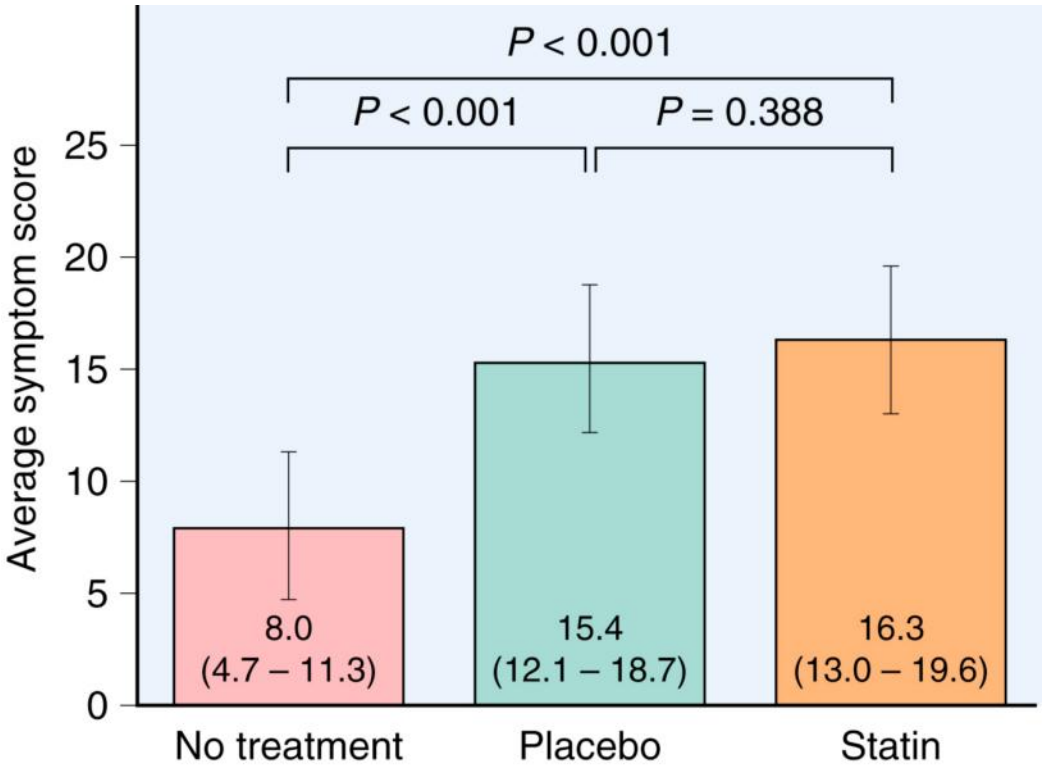

FIG. 22.2 Adverse effect symptom scores according to treatment allocation in three-way crossover trial conducted by Howard, J.P., Wood, F.A., Finegold, J.A., et al. 2021. Side effect patterns in a crossover trial of statin, placebo, and no treatment. J. Am. Coll. Cardiol. 78, 1210-1222.

- improved endothelial function
- reduced vascular inflammation
- reduced platelet aggregability
- increased neovascularisation of ischaemic tissue
- increased circulating endothelial progenitor cells
- stabilisation of atherosclerotic plaque
- antithrombotic actions

- enhanced fibrinolysis

The extent to which these effects contribute to the anti-atheromatous actions of statins is unknown.

Pharmacokinetics

Short-acting statins are given by mouth at night to reduce peak cholesterol synthesis in the early morning. They are well absorbed and extracted by the liver, their site of action, and are subject to extensive presystemic metabolism via cytochrome P450 and glucuronidation pathways. Simvastatin is an inactive lactone prodrug; it is metabolised in the liver to its active form, the corresponding β-hydroxy fatty acid.

Adverse effects

Statins are well tolerated; mild unwanted effects include muscle pain (myalgia), gastrointestinal disturbance, raised concentrations of liver enzymes in plasma, insomnia and rash. More serious adverse effects are rare but include skeletal muscle damage (myositis, which when severe is described as rhabdomyolysis) and angio-oedema. Myositis is a class effect of statins, occurring also with other lipid-lowering drugs (especially fibrates), and is dose related. [4] .However, re-instatement of statin therapy in placebo-controlled crossover trials did not find a statistically significance in symptoms with statins compared to placebo (**Fig. 22.2**). It is possible that the bulk of adverse symptoms associated with statins are due to the nocebo effect (worsening of symptoms due to sham or placebo), and that most patients who had stopped statins due to suspected adverse events can actually safely resume therapy.

Statin therapy leads to a modest increase in the long-term incidence of type 2 diabetes mellitus. The mechanism for this adverse effect is unclear, but there are suggestions that statins may accelerate progression towards hyperglycaemia, particularly in those with pre-existing risk factors for diabetes. The clinical consequences of this have not been well defined.

Clinical uses of HMG-CoA reductase inhibitors (statins, e.g. simvastatin, atorvastatin)

- Secondary prevention of myocardial infarction and stroke in patients who have symptomatic atherosclerotic disease (e.g. angina, transient ischaemic attacks, or following myocardial infarction or stroke).
- Primary prevention of arterial disease in patients who are at high risk because of elevated serum cholesterol concentration, especially if there are other risk factors for atherosclerosis such as diabetes (see **Ch. 31**) or renal failure (see **Ch. 29**). Tables (available, for example, in the British National Formulary) are used to target treatment to those at greatest risk.
- **Atorvastatin** lowers serum cholesterol in patients with homozygous FH.
- In severe drug-resistant dyslipidaemia (e.g. heterozygous FH), **ezetimibe,** which inhibits cholesterol absorption, is combined with statin treatment.
- Contraindicated in pregnancy.

Bempedoic Acid

Bempedoic acid is an inhibitor of ATP-citrate lyase, an enzyme upstream of HMG-CoA-reductase (**Fig 22.3**). It exerts its effects on the same cholesterol synthesis pathway as the statin drugs. Bempedoic acid is a dicarboxylic acid; it is a pro-drug that requires activation in the liver to a CoA thioester. There is no activation of bempedoic acid in skeletal muscle, thus potentially lowering the likelihood of myositis. Clinical trial data indicate that add-on bempedoic acid therapy can deliver further cholesterol reduction in patients who may already be on maximal statin doses. Two separate formulations are licensed, a single agent and a combination with ezetimibe (see later). Recognised adverse effects of bempedoic acid are hyperuricaemia and gout, stemming from inhibition of renal tubular organic anion transporter 2 (see **Ch. 9**).

Inhibition of PCSK9

PCSK9 is synthesised in inactive form by many tissues, including brain and liver. It is activated autocatalytically by proteolytic cleavage, which removes a section of its peptide chain that blocks its activity. When activated, it binds to LDL receptors and promotes their lysosomal degradation following LDL uptake into hepatocyte cytoplasm (see **Fig. 22.1**), thereby preventing recycling of LDL receptors to the surface membrane and diminishing their ability to sequester LDL. Family members who inherit a hyperactive form of the *PCSK9* gene suffer from severe hypercholesterolaemia; conversely individuals with inactivating mutations in this gene have low circulating LDL and a low incidence of atheromatous disease. Individuals homozygous for inactivated PCSK9 have very low

plasma concentrations of LDL and are healthy. This encouraged the development of monoclonal antibodies that block PCSK9, thereby preventing it from combining with LDL receptors and marking them down for lysosomal destruction. **Evolocumab** and **alirocumab** are now licensed for the treatment of primary hypercholesterolaemia in patients whose circulating LDL is not adequately controlled by a statin or statin/ezetimibe combination, as additional agents (or given alone to patients who do not tolerate treatment with a statin). Evolocumab is administered subcutaneously every 2–4 weeks, alirocumab every 2 weeks. Nasopharyngitis and influenza-like symptoms are common adverse effects of both agents.

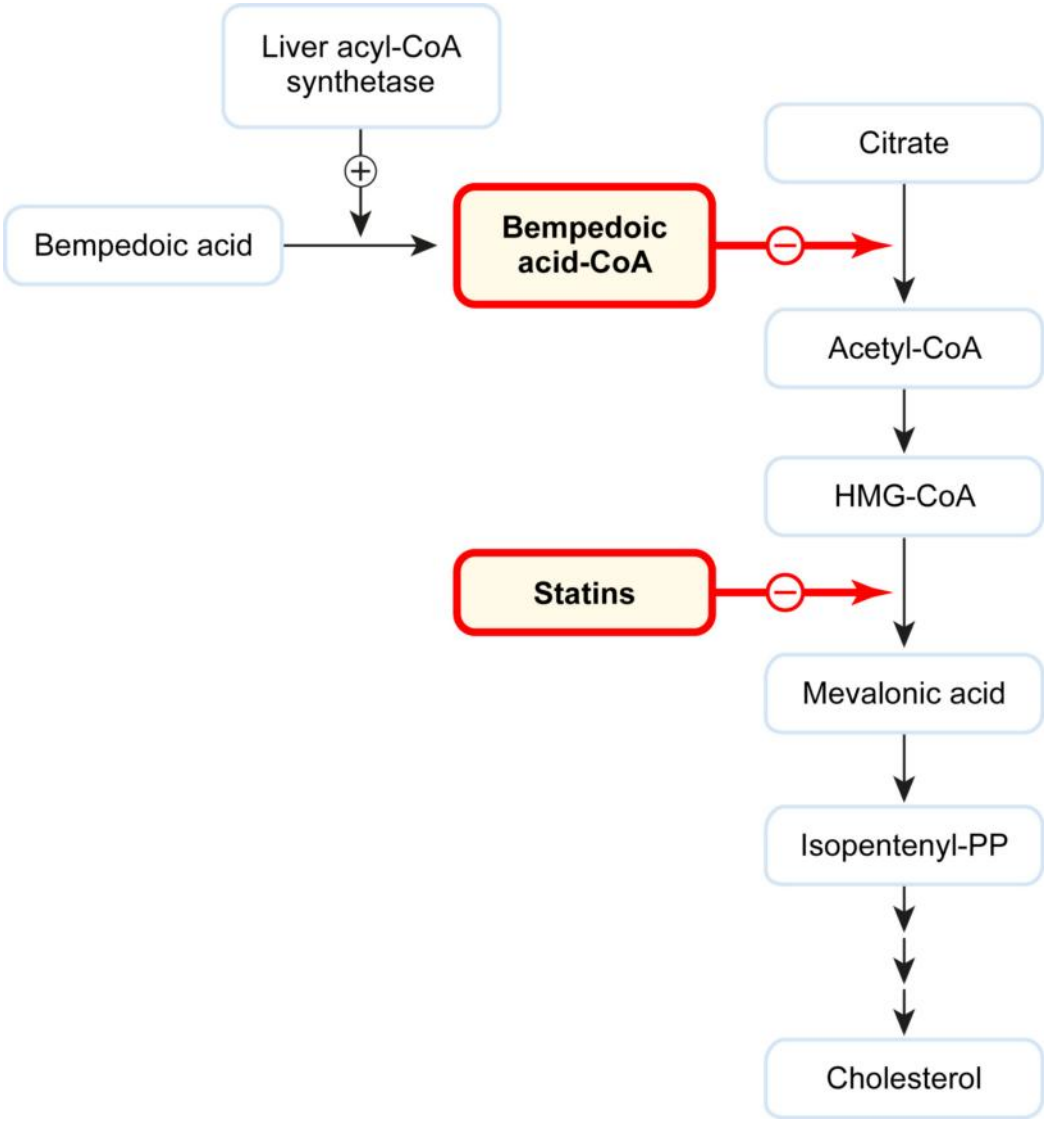

FIG. 22.3 Mechanism of action for bempedoic acid. Bempedoic acid is a pro-drug that is activated in the liver. It inhibits acetyl-CoA carboxylase and reduces subsequent production of cholesterol. *CoA*, Coenzyme A; *HMG*, 3-hydroxy-3-methylglutaryl.

Inclisiran

Inclisiran is a recently licensed double-stranded siRNA that inhibits PCSK9 synthesis. It works through RNA interference, with enhanced breakdown of mRNA relating to PCSK9. An N-acetylgalactosamine component recognised by hepatocyte receptors (see Chs **5** and **9**) is conjugated onto the sense strand so that inclisiran has high uptake and selectivity for its site of action in the liver.

It is given by subcutaneous injection twice a year, so is potentially suitable for administration in primary care centres. There are, as yet, no major safety concerns, but more robust data will emerge with longer-term experience.

Fibrates

Several fibric acid derivatives (fibrates) are available, including **bezafibrate**, **ciprofibrate**, **gemfibrozil**, **fenofibrate** and **clofibrate**. These markedly reduce circulating VLDL, and hence triglyceride, with a modest (approximately 10%) reduction in LDL and an approximately 10% increase in HDL. Their mechanism of action is complex (see **Fig. 22.1**). They are agonists at PPARα nuclear receptors [5] (see **Ch. 3**); in humans, the main effects are to increase transcription of the genes for lipoprotein lipase, apoA1 and apoA5. They increase hepatic LDL uptake. In addition to effects on lipoproteins, fibrates reduce plasma C-reactive protein and fibrinogen, improve glucose tolerance and inhibit vascular smooth muscle inflammation by inhibiting the expression of the transcription factor nuclear factor κB (see **Ch. 3**). The relative importance of these effects is uncertain, and fibrates have not been demonstrated to improve survival.

Adverse effects

Rhabdomyolysis is unusual but severe, giving rise to acute renal failure associated with excretion of muscle proteins, especially myoglobin, by the kidney. It occurs particularly in patients with renal impairment, because of reduced protein binding and impaired drug elimination. Fibrates should be avoided in such patients and also in alcoholics, who are predisposed to hypertriglyceridaemia but are at risk of severe muscle inflammation and injury. [6] Rhabdomyolysis can also be caused (rarely) by statins (see earlier), and the combined use of fibrates with this class of drugs is therefore generally inadvisable (although it is sometimes undertaken by specialists). Gastrointestinal symptoms, pruritus and rash are more common than with statins. Clofibrate predisposes to gallstones, and its use is therefore limited to patients who have had a cholecystectomy (i.e. removal of the gall bladder).

Clinical uses of fibrates (e.g. gemfibrozil, fenofibrate)

- Mixed dyslipidaemia (i.e. raised serum triglyceride as well as cholesterol), provided this is not caused by excessive alcohol consumption. **Fenofibrate** is uricosuric, which may be useful where hyperuricaemia coexists with mixed dyslipidaemia.
- Severe hypertriglyceridaemia when dietary and other measures have failed.
- Combined with other lipid-lowering drugs in patients with severe treatment-resistant dyslipidaemia. This may, however,

increase the risk of rhabdomyolysis.

Drugs that Inhibit Cholesterol Absorption

Historically, bile acid-binding resins (e.g. **colestyramine**, **colestipol**) were the only agents available to reduce cholesterol absorption and were among the few means to lower plasma cholesterol. Taken by mouth they sequester bile acids in the intestine and prevent their reabsorption and enterohepatic recirculation (see **Fig. 22.1**). The concentration of HDL is unchanged, and they cause an unwanted increase in triglycerides.

Decreased absorption of exogenous cholesterol and increased metabolism of endogenous cholesterol into bile acids in the liver lead to increased expression of LDL receptors on hepatocytes, and hence to increased clearance of LDL from the blood and a reduced concentration of LDL in plasma. Resins are bulky, unpalatable and often cause diarrhoea. They interfere with the absorption of fat-soluble vitamins, and of thiazide diuretics (see **Ch. 29**), digoxin (see **Ch. 20**) and warfarin (see **Ch. 23**), which should therefore be taken at least 1 h before or 4–6 h after the resin. With the introduction of statins, their use in treating dyslipidaemia was relegated largely to additional treatment in patients with severe disease, and (a separate use) treating bile salt-associated symptoms of pruritus (itch) and diarrhoea – see clinical box later.

Colesevelam is available in tablet form and is less bulky (daily dose up to 4 g compared with a dose up to 36 g for colestyramine) but more expensive. Subsequently, plant sterols and stanols have been marketed; these are isolated from wood pulp and used to make

margarines or yoghurts. They reduce plasma cholesterol to a small extent and are tastier than resins. Phytosterol and phytostanol esters interfere with the micellar presentation of sterols to the enterocyte surface, reducing cholesterol absorption and hence the exogenous pathway.

Ezetimibe

Ezetimibe is one of a group of azetidinone cholesterol absorption inhibitors and is used as an adjunct to diet and statins in hypercholesterolaemia. It inhibits absorption of cholesterol (and of plant stanols) from the duodenum by blocking a transport protein (NPC1L1) in the brush border of enterocytes, without affecting the absorption of fat-soluble vitamins, triglycerides or bile acids. Because of its high potency compared with resins (a daily dose of 10 mg), it represents a useful advance as a substitute for resins as supplementary treatment to statins in patients with severe dyslipidaemia.

Ezetimibe is administered by mouth and is absorbed into intestinal epithelial cells, where it localises to the brush border, which is its presumed site of action. It is also extensively (>80%) metabolised to an active metabolite. Enterohepatic recycling results in slow elimination. The terminal half-life is approximately 22 h. It enters milk (at least in animal studies) and is contraindicated for women who are breastfeeding. It is generally well tolerated but can cause diarrhoea, abdominal pain or headache; rash and angio-oedema have been reported.

Clinical use of drugs that reduce cholesterol absorption: ezetimibe or bile acid-binding

resins (e.g. colestyramine, colesevelam)

- As an addition to a statin when response has been inadequate (**ezetimibe**).
- For hypercholesterolaemia when a statin is contraindicated.
- Uses unrelated to atherosclerosis, include:
  - pruritus in patients with partial biliary obstruction (bile acid-binding resin)
  - bile acid diarrhoea, for example, caused by diabetic neuropathy (bile acid-binding resin).

Microsomal Triglyceride Transport Protein (MTP) Inhibitors

Lomitapide

Lomitapide is a small molecule inhibitor of MTP that has recently been approved as an adjunct to other treatment for homozygous FH. MTP plays a key role in the assembly and release of apoB-containing lipoproteins into the circulation, and inhibition of this protein significantly lowers plasma lipid levels. This action contrasts with other lipid-lowering drugs, which mainly work by increasing LDL uptake rather than by reducing hepatic lipoprotein secretion. Lomitapide is administered orally once a day and the dose is individualised according to how it is tolerated. Gastrointestinal disturbances are common.

Antisense Oligonucleotides

Mipomersen, the first single-stranded antisense oligonucleotide to be marketed, blocks synthesis of apoB100 and was licensed for use in patients with homozygous FH. However it was withdrawn because of hepatotoxicity.

Volanesorsen is an antisense oligonucleotide that inhibits the production of apoC-III. It is a single-stranded molecule (unlike inclisiran – see earlier). Volanesorsen binds selectively, within the 3' untranslated region, to the apoC-III mRNA, leading to breakdown of the mRNA. In the liver, apoC-III has a role in triglyceride metabolism and inhibits the clearance of chylomicrons and lipoproteins. Decreased production of apoC-III has the beneficial effect of taking away its inhibitory effects on triglyceride clearance. Volanesorsen has been found in clinical trials to significantly reduce apoC-III and serum triglycerides, and is approved for treatment of familial chylomicron syndrome, an autosomal recessive disorder of the gene coding lipoprotein lipase with an incidence of approximately 1 per million. Thrombocytopenia is a potentially serious adverse effect.

Drugs in dyslipidaemia

The main drugs used in patients with dyslipidaemias are:

- HMG-CoA reductase inhibitors (statins, e.g. **simvastatin**): inhibit synthesis of cholesterol, increasing the expression of LDL receptors on hepatocytes and hence increasing hepatic LDL-C uptake. They reduce cardiovascular events and prolong life in people at risk, and clinically are the most important class of drugs used in dyslipidaemias. Adverse

effects include myalgias (rarely, severe muscle damage) and raised liver enzymes.

Agents that target PCSK9 (alirocumab, evolocumab, inclisiran), or bempedoic acid, are used when there is inadequate response to statins, or where statins are contraindicated or not tolerated.

- Fibrates (e.g. **gemfibrozil**): activate PPARα receptors, increase the activity of lipoprotein lipase, decrease hepatic VLDL production and enhance clearance of LDL by the liver. They markedly lower serum triglycerides, and modestly increase HDL cholesterol. Adverse effects include muscle damage.
- Agents that interfere with cholesterol absorption, usually as an adjunct to diet plus statin:
  - **ezetimibe**
  - stanol-enriched foods
  - bile acid–binding resins (e.g. colestyramine, colesevelam).
- **Lomitapide** blocks MTP and is used to treat patients with homozygous FH.
- Voranesorsen is a single-stranded antisense drug that blocks the synthesis of apoC-III. It is used to treat familial chylomicron syndrome.

QUESTIONS

QUESTION 22.1

Atherogenesis involves changes to endothelial and immune cell function.

Which of the following would not contribute to the generation of an atheroma?

OPTIONS:

A. Oxidation of low-density lipoprotein (LDL)

B. Scavenging of oxy LDL by macrophages

C. Migration of monocytes into the intima

D. Increase in NO synthesis in endothelium

E. Smooth muscle cell proliferation

QUESTION 22.2

Dyslipidaemia has been shown to be a risk factor for the development of atheromatous disease.

Which of the following changes in lipid pathways would lead to an increased risk of a patient developing atheromatous disease?

OPTIONS:

A. An increase in lipoprotein(a)

B. Up-regulation of the exogenous pathway

C. An increase in LDL receptor expression

D. An increase in circulating apoA containing lipoprotein particles

E. An inactivating mutation in PCSK9

QUESTION 22.3

Reducing circulating LDL levels has been shown to be effective in reducing risk of atheromatous disease.

Which would be the best choice therapy for a patient with familial hypercholesterolaemia (FH) with renal impairment who has become pregnant?

OPTIONS:

A. Ezetimibe

B. Simvastatin

C. Bempedoic acid

D. Evolocumab

E. Bezafibrate

ANSWERS

ANSWER 22.1

RATIONALE:

A. Endothelial cells and monocytes/macrophages generate free radicals that oxidise LDL (oxy LDL), resulting in lipid

peroxidation.

B. Scavenging of oxy LDL by macrophages – uptake of oxy LDL activates macrophages which release proinflammatory cytokines.

C. Migration of monocytes into the intima contributes to the accumulation of activated pro-inflammatory cells in the tissue.

D.

E. Smooth muscle proliferation – caused by cytokine and growth factor release by activated platelets, macrophages and endothelial cells. Leads to an inflammatory fibroproliferative response and formation of the atheromatous plaque.

CORRECT ANSWER WITH EXPLANATION:

D. Increase in NO synthesis in endothelium

NO causes vasodilatation and reduces cell proliferation and so has protective mechanisms.

ANSWER 22.2

RATIONALE:

A.

B. Up-regulation of the exogenous pathway – this involves sequestering the cholesterol into chylomicron particles which are taken up by the liver and so reduce circulating cholesterol levels.

C. An increase in LDL receptor expression – this would promote uptake of LDL into cells and reduce circulating LDL levels so reducing risk.

D. An increase in circulating apoA containing lipoprotein particles – these are high-density lipoprotein (HDL) particles which are

protective against atheromatous disease.

E. Inactivating mutation in PCSK9 – PCSK9 leads to lysosomal degradation of cellular LDL receptors and so a reduction would increase LDL uptake.

CORRECT ANSWER WITH EXPLANATION:

A. An increase in lipoprotein(a)

Circulating LDL lipoprotein(a) displaces plasminogen leading to a decrease in plasmin and fibrinolysis so increasing the development of atheroma plaques.

ANSWER 22.3

RATIONALE:

A. Ezetimibe inhibits absorption of cholesterol from the duodenum by blocking a transport protein (NPC1L1). Enters breast milk and so is contraindicated for women who are breastfeeding.

B. Simvastatin decreases hepatic cholesterol synthesis, up-regulates LDL receptor synthesis, increasing LDL clearance from plasma into liver cells. The main biochemical effect of statins is therefore to reduce plasma LDL. Contraindicated in pregnancy due to 3-hydroxy-3-methylglutaryl-coenzyme (HMG-CoA) reductase guiding migrating primordial germ cells.

C. Bempedoic acid is an inhibitor of ATP-citrate lyase, an enzyme upstream of HMG-CoA reductase. It exerts its effects on the same cholesterol synthesis pathway as the statin drugs. Contraindicated in pregnancy due to HMG-CoA reductase guiding migrating primordial germ cells.

D.

E. Bezafibrate is an agonist at peroxisome proliferator-activated receptor-α (PPARα) nuclear receptors – increases transcription of the genes for lipoprotein lipase, apoA1 and apoA and hence they increase hepatic LDL uptake. Also reduces plasma C-reactive protein and fibrinogen, improves glucose tolerance and inhibits vascular smooth muscle inflammation.
Contraindicated in patients with renal impairment.

CORRECT ANSWER WITH EXPLANATION:

D. Evolocumab

Evolocumab blocks PCSK9, thereby preventing it from combining with LDL receptors and marking them down for lysosomal destruction. It is effective in patients with hyperactive PCSK9 which can lead to hypercholesterolaemia.

[1] The term *dyslipidaemia* is preferred to *hyperlipidaemia* because a low plasma concentration of high-density lipoprotein cholesterol is a risk factor for atheromatous disease.

[2] PCSK9 stands for proprotein convertase subtilisin/kexin type 9.

[5] Standing for peroxisome proliferator-activated receptors – don't ask! (Peroxisomes are organelles that are not present in human cells, so something of a misnomer!) Thiazolidinedione drugs used in treating diabetes act on related PPAR? receptors (see Ch. 31).

[6] For several reasons, including a tendency to lie immobile for prolonged periods followed by generalised convulsions – 'rum fits' – and delirium tremens..

23: Haemostasis and thrombosis

OVERVIEW

This chapter summarises the main features of blood coagulation, platelet function and fibrinolysis. These processes underlie haemostasis and thrombosis and provide a basis for understanding haemorrhagic disorders (e.g. haemophilia) and thrombotic diseases of both arteries (e.g. thrombotic stroke, myocardial infarction) and veins (e.g. deep vein thrombosis, pulmonary embolism). Anticoagulants, antiplatelet drugs and fibrinolytic drugs are especially important because of the prevalence of thrombotic disease.

Introduction

Haemostasis is the arrest of blood loss from damaged blood vessels, an essential survival mechanism for complex organisms in a hazardous environment. A wound causes vasoconstriction, accompanied by:

- adhesion and activation of platelets
- formation of fibrin

Platelet activation leads to the formation of a haemostatic plug, which stops the bleeding and is subsequently reinforced by fibrin.

The relative importance of each process depends on the type of vessel (arterial, venous or capillary) that has been injured.

Thrombosis is the pathological formation of a 'haemostatic' plug within the vasculature in the absence of bleeding ('haemostasis in the wrong place'). Over a century ago, Rudolph Virchow defined three predisposing factors – 'Virchow's triad': *injury to the vessel wall* – for example, when an atheromatous plaque ruptures or becomes eroded; *altered blood flow* – for example, in the left atrial appendage of the heart during atrial fibrillation, or in the veins of the legs while sitting awkwardly on a long journey; and *abnormal 'coagulability'* of the blood – as occurs, for example, in the later stages of pregnancy or during treatment with certain oral contraceptives (see **Ch. 35**). Increased coagulability of the blood can be inherited and is referred to as *thrombophilia*. A *thrombus*, which forms in vivo, should be distinguished from a *clot*, which forms in blood in vitro (for example in a glass tube). Clots are amorphous, consisting of a diffuse fibrin meshwork in which red and white blood cells are trapped indiscriminately. By contrast, arterial and venous thrombi each have a distinct structure.

An *arterial thrombus* (**Fig. 23.1**) is composed of so-called white thrombus consisting mainly of platelets in a fibrin mesh. It is usually associated with atherosclerosis and can interrupt blood flow, causing ischaemia or death of tissue (infarction) downstream. Venous thrombus is composed of 'red thrombus' and consists of a small white head and a large jelly-like red tail, similar in composition to a blood clot, which streams away in the flow. Thrombus can break away from its attachment and float through the circulation, forming an embolus; venous emboli usually lodge in

a pulmonary artery ('pulmonary embolism'), while a thrombus that embolises from the left heart or a carotid artery usually lodges in an artery in the brain or other organs, causing death, stroke or other disaster.

Drug therapy to promote haemostasis (e.g. antifibrinolytic and haemostatic drugs; see later) is indicated when this essential process is defective (e.g. defective or missing coagulation factors in haemophilia or following excessive anticoagulant therapy), or when it proves difficult to staunch haemorrhage following surgery or for menorrhagia (heavy menstrual periods). Drug therapy to treat or prevent thrombosis or thromboembolism is extensively used because such diseases are common as well as serious. Drugs affect haemostasis and thrombosis in three distinct ways, by influencing:

- blood coagulation (fibrin formation)
- platelet function
- fibrin removal (fibrinolysis)

Blood Coagulation

Coagulation Cascade

Blood coagulation means the conversion of liquid blood to a clot. The main event is the conversion by thrombin of soluble *fibrinogen* to insoluble strands of *fibrin*, the last step in a complex enzyme cascade. The components (called factors) are present in blood as inactive precursors (zymogens) of proteolytic enzymes and co-factors. They are activated by proteolysis, the 'active' forms being designated by the suffix 'a'. Factors XIIa, XIa, Xa, IXa and thrombin (IIa) are all serine proteases. Activation of a small amount of one

factor catalyses the formation of larger amounts of the next factor, which catalyses the formation of still larger amounts of the next, and so on; consequently, the cascade provides a mechanism of amplification. [1] As might be expected, this accelerating enzyme cascade has to be controlled by inhibitors, because otherwise all the blood in the body would solidify within minutes of the initiation of haemostasis. One of the most important inhibitors is *antithrombin III*, which neutralises all the serine proteases in the cascade. Vascular endothelium also actively limits thrombus extension (see later).

Two pathways of fibrin formation were described traditionally (termed *intrinsic* – because all the components are present in the blood – and *extrinsic* – because some components come from outside the blood). The intrinsic or 'contact' pathway is activated when shed blood comes into contact with an artificial surface such as glass, but physiologically the system functions as a single in vivo *pathway* (**Fig. 23.2**). Tissue damage exposes blood to *tissue factor*, initiating the process and leading to production of a small amount of thrombin. This acts through several positive feedbacks (on Va, VIIIa and on platelets) that amplify and propagate the process with production of more thrombin.

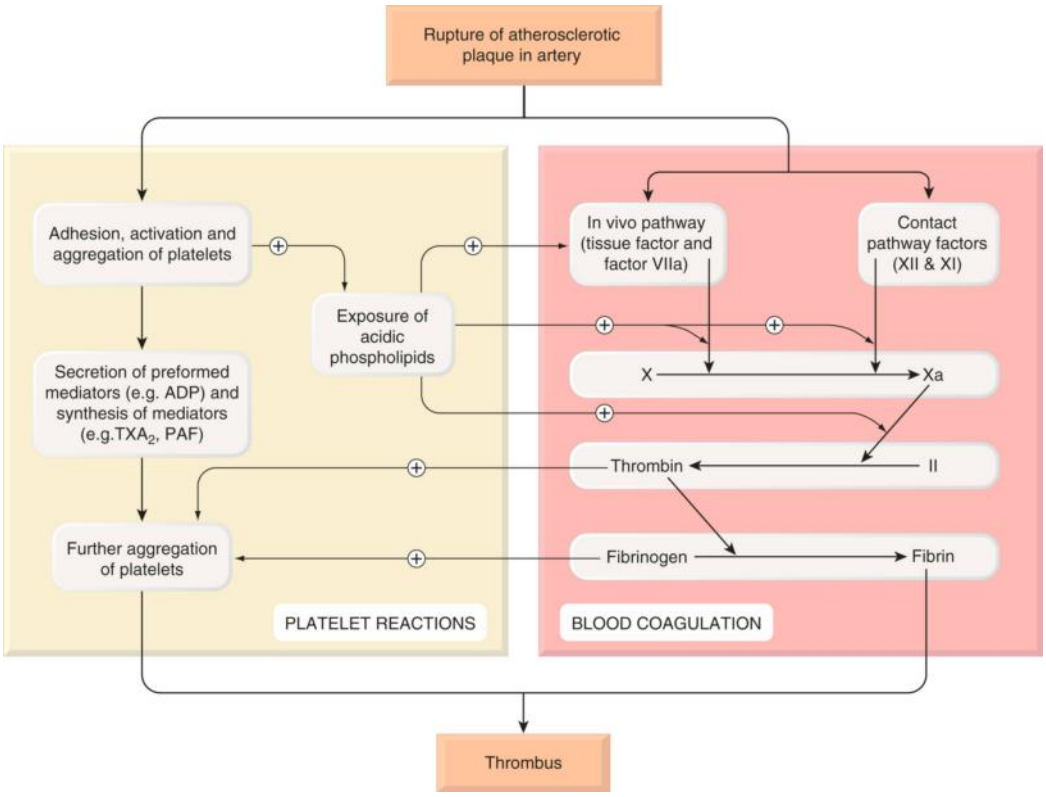

FIG. 23.1 The main events in the formation of an arterial thrombus. Exposure of acidic PLs during platelet activation provides a surface on which factors IXa and VIIa interact with factor X; factor Xa then interacts with factor II, as illustrated in more detail in Fig. 23.4. Activation of factor XII also initiates the fibrinolytic pathway, which is shown in Fig. 23.9. (A similar series of events occurs when there is vascular damage, leading to haemostasis.) *PAF,* Platelet-activating factor; *TXA_2*, thromboxane A_2.

'Tissue factor' is the cellular receptor for factor VII, which, in the presence of Ca^{2+}, undergoes an active site transition. This results in rapid autocatalytic activation of factor VII to VIIa. The tissue

factor–VIIa complex activates factors IX and X. Acidic phospholipids (PLs) function as *surface catalysts*. They are provided during platelet activation, which exposes acidic PLs (especially phosphatidylserine), on the platelets' outwardly facing membranes, and these activate various clotting factors, closely juxtaposing them in functional complexes. Platelets also contribute by secreting coagulation factors, including factor Va and fibrinogen. Coagulation is sustained by further generation of factor Xa by IXa–VIIIa–Ca^{2+}–PL complex. This is needed because the tissue factor–VIIa complex is rapidly inactivated in plasma by tissue factor pathway inhibitor and by antithrombin III. Factor Xa, in the presence of Ca^{2+}, PL and factor Va, activates prothrombin to thrombin, the main enzyme of the cascade. The *contact* (intrinsic) pathway commences when factor XII (Hageman factor) adheres to a negatively charged surface and converges with the in vivo pathway at the stage of factor X activation (see **Fig. 23.2**). The proximal part of this pathway is not crucial for blood coagulation in vivo. [2] The two pathways are not entirely separate even before they converge, and various positive feedbacks promote coagulation.

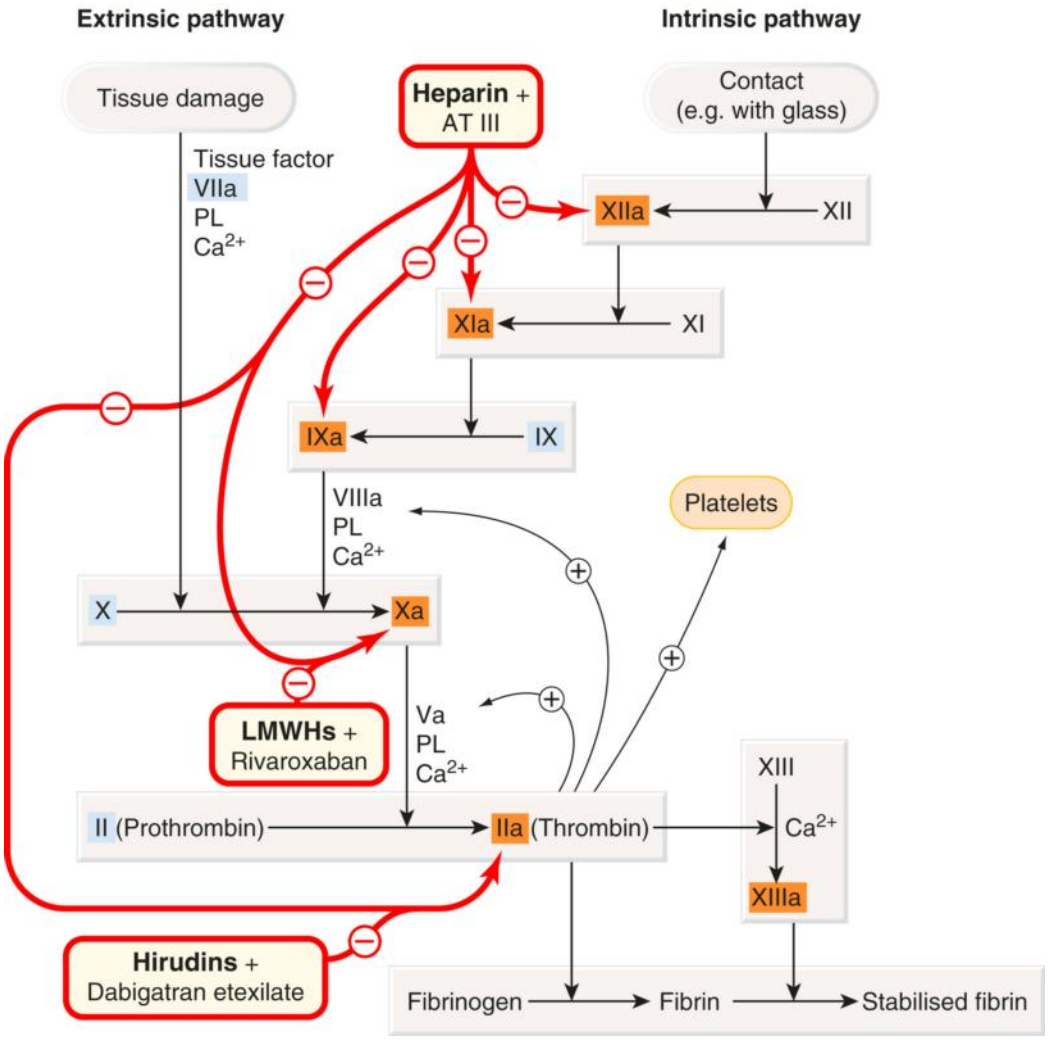

FIG. 23.2 The coagulation cascade: sites of action of anticoagulant drugs. Oral anticoagulants that inhibit vitamin K synthesis interfere with post-translational g-carboxylation of factors II, VII, IX and X *(shown in blue boxes)*; see Fig. 23.4. Heparins activate antithrombin III. *AT III,* Antithrombin III; *LMWHs,* low-molecular-weight heparins; *PL,* negatively charged PL supplied by activated platelets.

Haemostasis and thrombosis

- Haemostasis is the arrest of blood loss from damaged vessels and is essential to survival. The main phenomena are:
  - platelet adhesion and activation
  - blood coagulation (fibrin formation)
- Thrombosis is a pathological condition resulting from inappropriate activation of haemostatic mechanisms:
  - venous thrombosis is usually associated with stasis of blood; a venous thrombus has a small platelet component and a large component of fibrin;
  - arterial thrombosis is usually associated with atherosclerosis, and the thrombus has a large platelet component.
- A portion of a thrombus may break away, travel as an embolus and lodge downstream, causing ischaemia and/or infarction.

The Role of Thrombin

Thrombin (factor IIa) enzymatically cleaves fibrinogen, producing fragments that polymerise to form fibrin. It also activates factor XIII, a *fibrinoligase*, which strengthens fibrin-to-fibrin links, thereby stabilising the coagulum. In addition to coagulation, thrombin also causes platelet aggregation, stimulates cell proliferation and modulates smooth muscle contraction. Paradoxically, it can inhibit as well as promote coagulation (see later). The effects of thrombin on platelets and smooth muscle are initiated by an interaction with specific protease-activated receptors

(PARs; see **Ch. 3**), which belong to the superfamily of G protein–coupled receptors. PARs initiate cellular responses that contribute not only to haemostasis and thrombosis, but also to inflammation and perhaps angiogenesis. Receptor activation requires cleavage by thrombin of the extracellular N-terminal domain of the receptor, revealing a new N-terminal sequence that acts as a 'tethered agonist' (see **Fig. 3.8**), an unusual mechanism.

Vascular Endothelium in Haemostasis and Thrombosis

Vascular endothelium, the container of the circulating blood, can change focally from a non-thrombogenic to a thrombogenic structure in response to different demands. Normally, it provides a non-thrombogenic surface by virtue of membrane *heparan sulfate*, a glycosaminoglycan related to the endogenous anticoagulant heparin (see later), which is, like heparin, a co-factor for antithrombin III. Endothelium thus plays an essential role in preventing intravascular platelet activation and coagulation. However, it also plays an active part in haemostasis, synthesising and storing several key haemostatic components; von Willebrand factor, [3] tissue factor and plasminogen activator inhibitor (PAI)-1 are particularly important. PAI-1 is secreted in response to *angiotensin IV*, receptors for which are present on endothelial cells, providing a link between the renin–angiotensin system (see **Ch. 21**) and thrombosis. These prothrombotic factors are involved, respectively, in platelet adhesion and in coagulation and clot stabilisation. However, the endothelium is also implicated in thrombus limitation. Thus it generates anti-aggregatory

prostaglandin (PG) I_2 (prostacyclin; see **Ch. 17**) and nitric oxide (NO; see **Ch. 19**); converts adenosine diphosphate (ADP), which causes platelet aggregation, to adenosine, which inhibits it (see **Ch. 17**); synthesises *tissue plasminogen activator* (tPA; see later); and expresses *thrombomodulin*, a receptor for thrombin. After combination with thrombomodulin, thrombin activates an anticoagulant, *protein C*. Activated protein C, helped by its co-factor protein S, inactivates factors Va and VIIa. This is functionally important, because a naturally occurring mutation of the gene coding for factor V (factor V Leiden), which confers resistance to activated protein C, results in the commonest recognised form of inherited thrombophilia.

Endotoxin and some cytokines (see **Ch. 7**), including tumour necrosis factor, tilt the balance of prothrombotic and antithrombotic endothelial functions towards thrombosis by causing loss of heparan (see earlier) and increased expression of tissue factor, and alter endothelial NO function. If other mechanisms limiting coagulation are also faulty or become exhausted, *disseminated intravascular coagulation*, a serious complication of sepsis and of certain malignancies, can result.

Blood coagulation (fibrin formation)

The clotting system consists of a cascade of proteolytic enzymes and co-factors.

- Inactive precursors are activated sequentially in an amplifying cascade.

- The last enzyme, thrombin, derived from prothrombin (II), converts soluble fibrinogen (I) to an insoluble meshwork of fibrin in which blood cells are trapped, forming the clot.
- There are two limbs in the cascade:
  - the in vivo (extrinsic) pathway
  - the contact (intrinsic) pathway
- Both pathways result in activation of factor X to Xa, which converts prothrombin to thrombin.
- Calcium ions and a negatively charged PL are essential for three steps, namely the actions of:
  - factor IXa on X
  - factor VIIa on X
  - factor Xa on II
- PL is provided by activated platelets adhering to the damaged vessel.
- Some factors promote coagulation by binding to PL and a serine protease factor; for example, factor Va in the activation of II by Xa, or VIIIa in the activation of X by IXa.
- Blood coagulation is controlled by:
  - enzyme inhibitors (e.g. antithrombin III)
  - fibrinolysis

Drugs that Act on the Coagulation Cascade

Drugs are used to correct a defect in coagulation or when there is an increased risk of unwanted coagulation, or actual thrombotic disease.

Coagulation Defects

Genetically determined deficiencies of clotting factors are not common. Examples are classic haemophilia, caused by lack of factor VIII, and an even rarer form of haemophilia (haemophilia B) caused by lack of factor IX. Intravenous factor replacement using recombinant human factor VIII or IX is given by specialists to prevent or to limit bleeding in such patients. Some patients develop antibodies that act as factor inhibitors, and their management is particularly demanding (involving, for example, induction of immune tolerance, see **Ch. 7**).

Acquired clotting defects are more common than hereditary ones. The causes include liver disease (many coagulation factors are synthesised in the liver), vitamin K deficiency (universal in neonates who are routinely given vitamin K prophylactically) and excessive **warfarin** therapy (see later), each of which may require treatment with vitamin K.

A human recombinant form of factor VIIa is available to treat bleeding in patients with severe bleeding disorders but can cause intravascular coagulation.

Vitamin K

Vitamin K (for *Koagulation* in German) is a fat-soluble vitamin (**Fig. 23.3**) occurring naturally in plants (vitamin K_1) and as a series of bacterial menaquinones (vitamin K_2) formed in the gut (see **Shearer and Newman, 2008**, for a review). It is needed for the formation of clotting factors II, VII, IX and X, which are glycoproteins (GPs) with γ-carboxyglutamic acid (Gla) residues. The interaction of factors Xa and prothrombin (factor II) with Ca^{2+} and

PL is shown in **Fig. 23.4**. g-Carboxylation occurs after the synthesis of the amino acid chain, and the carboxylase enzyme requires reduced vitamin K as a co-factor (**Fig. 23.5**). Binding does not occur in the absence of g-carboxylation. Similar considerations apply to the proteolytic activation of factor X by IXa and by VIIa (see **Fig. 23.2**).

There are several other vitamin K–dependent Gla proteins, including proteins C and S (mentioned earlier) and osteocalcin in bone (see **Ch. 36**).

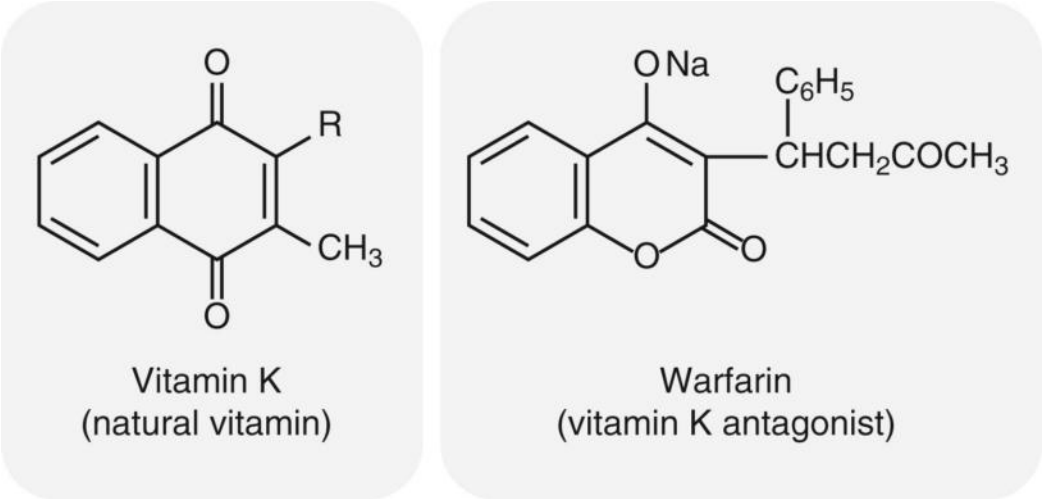

FIG. 23.3 Vitamin K and warfarin. Warfarin, a vitamin K antagonist, is an oral anticoagulant. It competes with vitamin K (note the similarity in their structures) for the reductase enzyme (vitamin K epoxide reductase component 1 [VKORC1]) that activates vitamin K and is the site of its action (see Fig. 23.5).

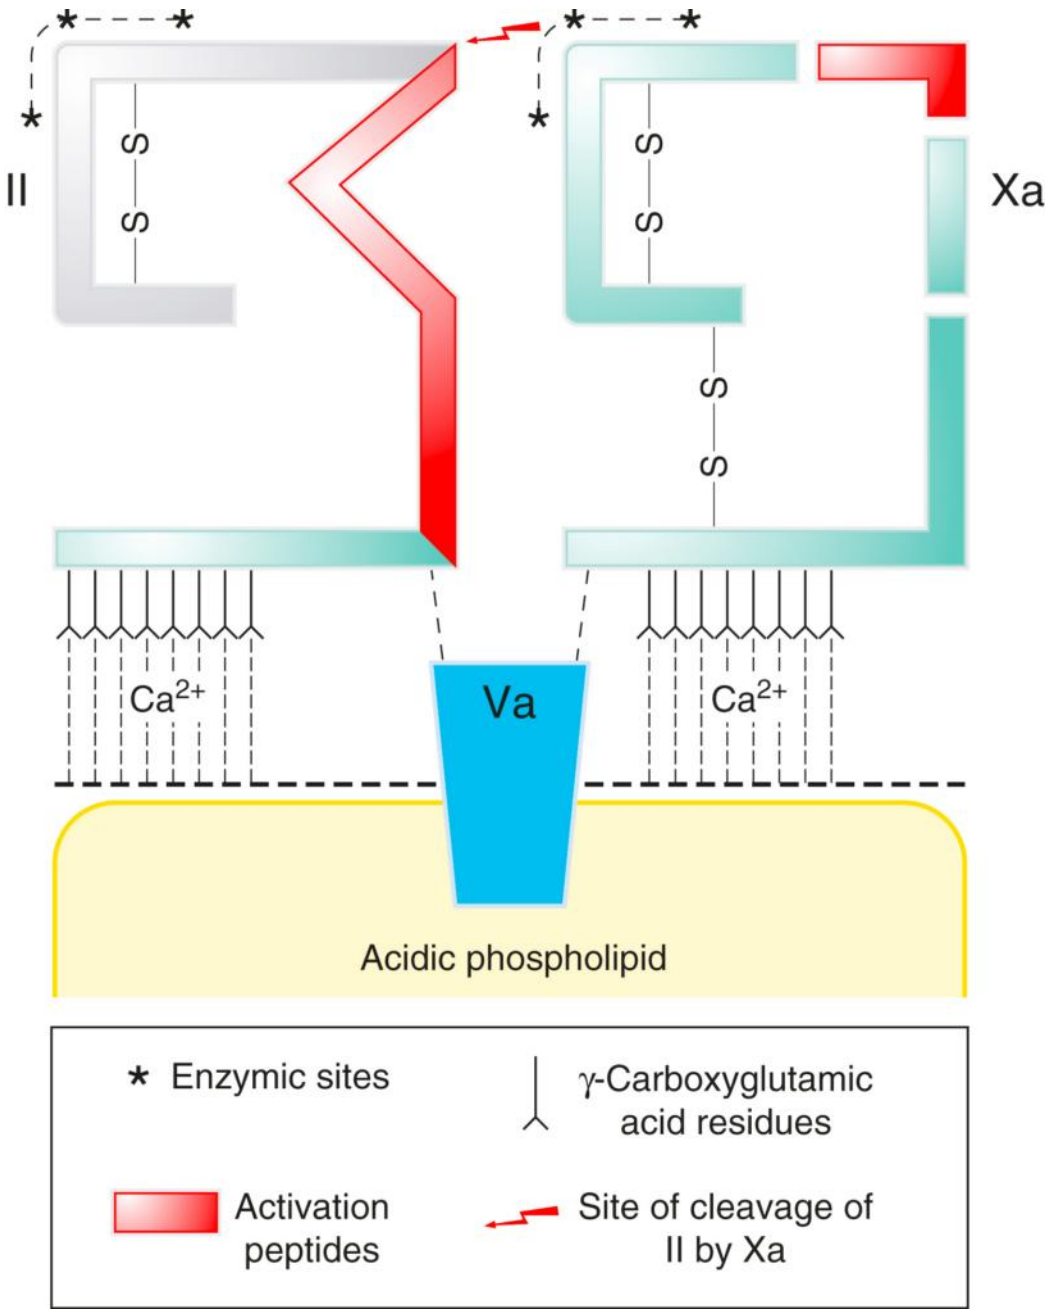

FIG. 23.4 Activation of prothrombin (factor II) by factor Xa. The complex of factor Va with a negatively charged PL surface (supplied by aggregating platelets) forms a binding site for factor Xa and prothrombin (II), which have peptide chains *(shown schematically)* that are

similar to one another. Platelets thus serve as a localising focus. Calcium ions are essential for binding. Xa activates prothrombin, liberating thrombin *(shown in grey)*. Modified from Jackson, C.M., 1978. Br. J. Haematol. 39, 1.

Administration and pharmacokinetic aspects

Natural vitamin K_1 (**phytomenadione**) may be given orally or by injection. If given by mouth, it requires bile salts for absorption, and this occurs by a saturable energy-requiring process in the proximal small intestine. A synthetic preparation, **menadiol sodium phosphate**, is also available. It is water soluble and does not require bile salts for its absorption. This synthetic compound takes longer to act than phytomenadione. There is very little storage of vitamin K in the body. It is metabolised to more polar substances that are excreted in the urine and the bile.

Clinical uses of vitamin K are summarised in the clinical box.

Clinical uses of vitamin K

- Treatment and/or prevention of bleeding:
  - from excessive oral anticoagulation (e.g. by **warfarin**)
  - in babies: to prevent *haemorrhagic disease of the newborn*
- For vitamin K deficiencies in adults:
  - sprue, coeliac disease, steatorrhoea (excessively fatty faeces)

– lack of bile (e.g. with obstructive jaundice)

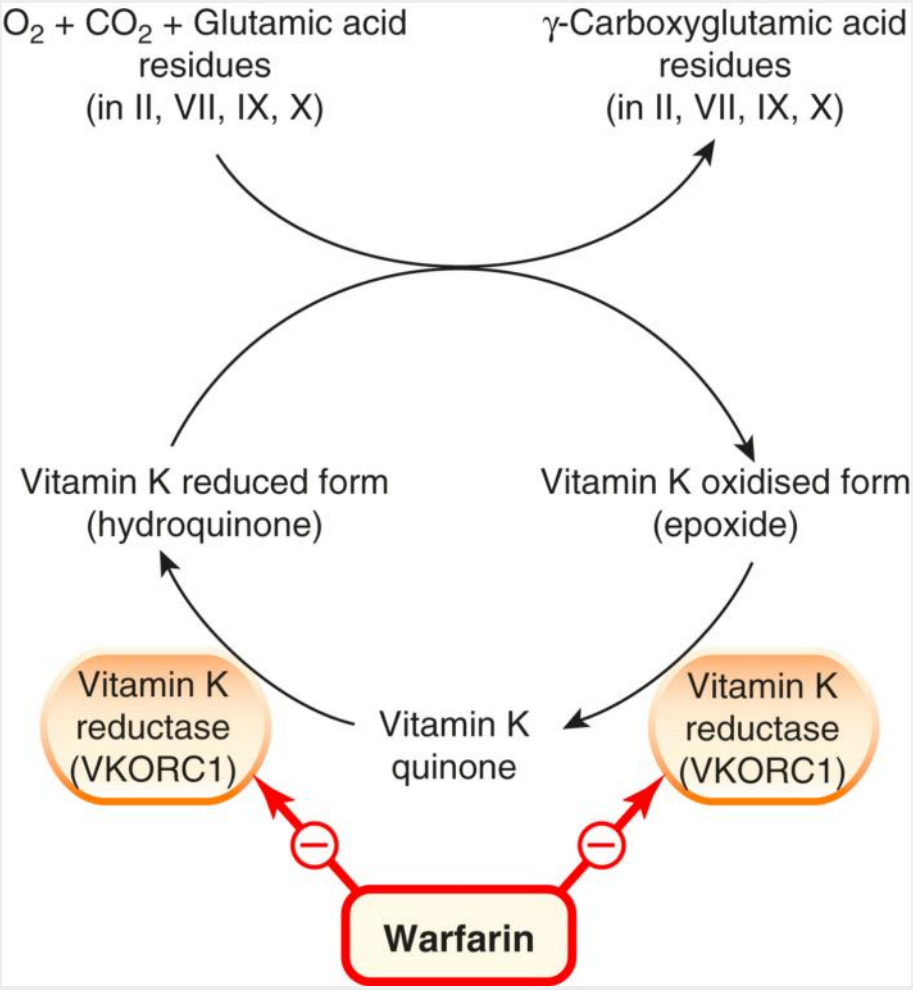

FIG. 23.5 Mechanism of vitamin K and of warfarin. After the peptide chains in clotting factors II, VII, IX and X have been synthesised, reduced vitamin K (the hydroquinone) acts as a co-factor in the conversion of glutamic acid to γ-carboxyglutamic acid. During this reaction, the reduced form of vitamin K is converted to the epoxide, which in turn is reduced to quinone and then hydroquinone by vitamin K epoxide reductase component 1 (VKORC1), the site of action of warfarin.

Thrombosis

Thrombotic and thromboembolic disease is common and has severe consequences, including myocardial infarction, stroke, deep vein thrombosis and pulmonary embolus. The main drugs used for prophylaxis of platelet-rich 'white' arterial thrombi are the antiplatelet drugs; fibrinolytic drugs are used in addition to antiplatelet drugs for treatment of acute thrombotic events if mechanical methods of emergency opening of the artery are not available. The main drugs used to prevent or treat 'red' venous thrombi are:

- injectable anticoagulants (**heparin** and newer thrombin inhibitors);
- oral anticoagulants: direct oral anticoagulants (DOACs) are inhibitors of thrombin or of factor Xa. These have largely supplanted **warfarin** and related compounds that work indirectly by antagonising vitamin K.

Heparins and DOACs act immediately, whereas warfarin and other vitamin K antagonists take several days to exert their effect due to the presence of circulating preformed coagulation factors at the start of treatment.

Heparin (Including Low-Molecular-Weight Heparins)

Heparin was discovered in 1916 by a second-year medical student at Johns Hopkins Hospital. He was attempting to extract coagulant substances from various tissues during a vacation project but found instead a powerful anticoagulant activity. [4] This was named heparin, because it was first extracted from liver.

Heparin is not a single substance but a family of sulfated glycosaminoglycans (mucopolysaccharides). It is present together with histamine in the granules of mast cells. Commercial preparations are extracted from beef lung or hog intestine and, because preparations differ in potency, assayed biologically against an agreed international standard: doses are specified in units of activity rather than of mass.

Heparin fragments (e.g. **enoxaparin, dalteparin**), referred to as low-molecular-weight heparins (LMWHs), or a synthetic pentasaccharide that inhibits factor Xa (**fondaparinux**), are longer acting than unfractionated heparin (UFH) and are usually preferred, the unfractionated product being reserved for special situations such as patients with renal failure in whom LMWHs are contraindicated.

Mechanism of action

Heparin inhibits coagulation, both in vivo and in vitro, by activating antithrombin III. Antithrombin III inhibits thrombin and other serine proteases by binding to the active site. Heparin modifies this interaction by binding, via a unique pentasaccharide sequence, to antithrombin III, changing its conformation and increasing its affinity for serine proteases.

To inhibit thrombin, it is necessary for heparin to bind to the enzyme as well as to antithrombin III; to inhibit factor Xa, it is necessary only for heparin to bind to antithrombin III. Consequently, the LMWHs increase the action of antithrombin III on factor Xa but not its action on thrombin, because the molecules are too small to bind to both enzyme and inhibitor (see **Fig. 23.6**).

Antithrombin III deficiency is very rare but can cause thrombophilia and unresponsiveness to heparin therapy.

Administration and pharmacokinetic aspects

Heparin is not absorbed from the gut because of its charge and high molecular weight, and it is therefore given intravenously or subcutaneously (intramuscular injections would cause haematomas).

After intravenous injection of a bolus dose, there is a phase of rapid redistribution followed by slower elimination caused by a combination of saturable processes involving binding to sites on endothelial cells and macrophages and slower non-saturable processes including renal excretion. As a result, the plasma concentration increases disproportionately with increasing dose (saturation kinetics; see **Ch. 11**).

Heparin acts immediately following intravenous administration, but the onset is delayed by up to 60 min when it is given subcutaneously. The elimination half-life is approximately 40–90 min. In urgent situations, it is therefore usual to start treatment with a bolus intravenous dose, followed by a constant-rate infusion. The *activated partial thromboplastin time* (APTT), or some other clotting test, is measured and the dose of heparin adjusted to achieve a value within a target range (e.g. 1.5–2.5 times control).

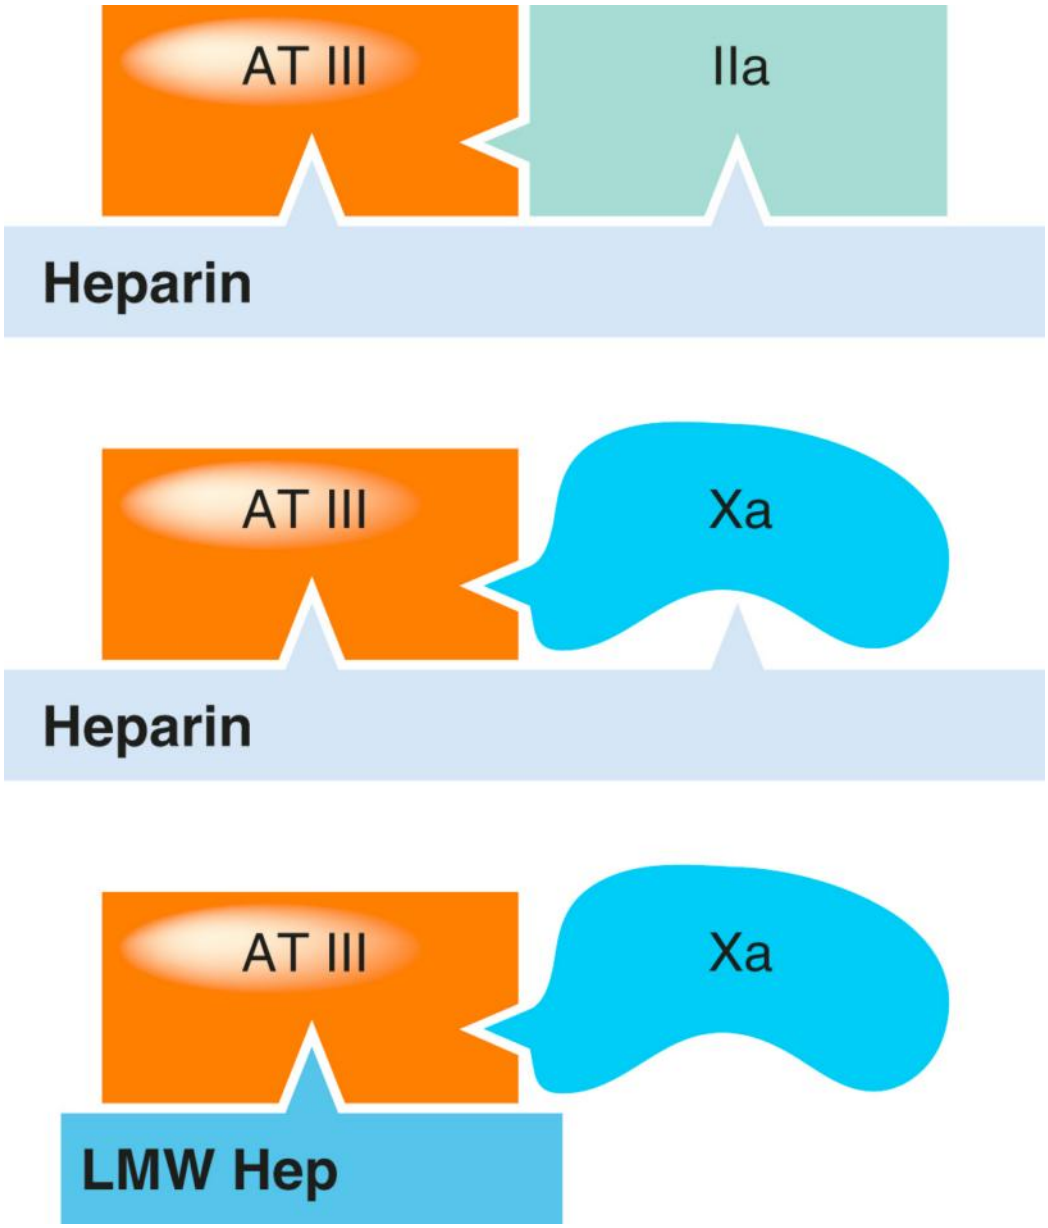

FIG. 23.6 Action of heparins. The schematic shows interactions of heparins, antithrombin III (AT III) and clotting factors. To increase the inactivation of thrombin (IIa) by AT III, heparin needs to interact with both substances *(top)*, but to speed up its effect on factor Xa it needs only to interact with AT III *(middle)*. Low-molecular-weight heparins (LMW Hep) increase the action

of AT III on factor Xa *(bottom)*, but cannot increase the action of AT III on thrombin because they cannot bind both simultaneously.

LMWHs are given subcutaneously. They have a longer elimination half-life than UFH, and this is independent of dose (first-order kinetics), so the effects are more predictable and dosing less frequent (once or twice a day). LMWHs do not prolong the APTT. Unlike UFH, the effect of a standard dose is sufficiently predictable that monitoring is not required routinely. LMWHs are eliminated mainly by renal excretion, and UFH is indicated in renal failure, but with this exception LMWHs are at least as safe and effective as UFH and are more convenient to use, because patients can be taught to inject themselves at home and there is generally no need for blood tests and dose adjustment.

Unwanted effects

Haemorrhage

The main hazard is haemorrhage, which is treated by stopping therapy and, if necessary, giving **protamine sulfate**. This heparin antagonist is a strongly basic protein that forms an inactive complex with heparin; it is given intravenously. The dose of protamine is estimated from the dose of heparin that has been administered recently, and it is important not to give too much, as this can itself cause bleeding. If necessary, an in vitro neutralisation test is performed first on a sample of blood from the patient to provide a more precise indication of the required dose.

Thrombosis

This is an uncommon but serious adverse effect of heparin and, as with warfarin necrosis (see below), may be misattributed to the natural history of the disease for which heparin is being administered.

Paradoxically, it is associated with a low blood platelet count: *heparin-induced thrombocytopenia* (HIT). A transitory early decrease in platelet numbers is not uncommon after initiating heparin treatment and is not clinically important. More serious thrombocytopenia that occurs 2–14 days after the start of therapy is uncommon and is referred to as type II HIT. This is caused by IgM or IgG antibodies against complexes of heparin and a platelet-derived chemokine, platelet factor 4. Circulating immune complexes bind to circulating platelets, and cause thrombocytopenia. Antibody also binds to platelet factor 4 attached to the surface of endothelial cells, leading to immune injury of the vessel wall, thrombosis and disseminated intravascular coagulation.

A similar mechanism is believed to underlie the thrombocytopenia and thrombosis that can, rarely, complicate immunisation against SARS COV-2 (see Chs **5** and **53**; **Scully et al., 2021**) – heparin treatment is avoided in such patients. LMWHs are less likely than UFH to cause thrombocytopenia and thrombosis by this mechanism. HIT is usually treated by substituting **danaparoid** or a direct thrombin inhibitor such as **lepirudin** instead of the heparin preparation that caused the problem. Danaparoid is a low-molecular-weight heparinoid consisting of a mixture of heparan, dermatan and chondroitin sulfates, with well-established antithrombotic activity.

Osteoporosis with spontaneous fractures has been reported with long-term (6 months or more) treatment with heparin. Its mechanism is unknown.

Hypoaldosteronism (with consequent hyperkalaemia) is uncommon but can occur with prolonged treatment. It is recommended to check plasma K^+ concentration if treatment is to be continued for >7 days.

Hypersensitivity reactions to heparin are rare.

Direct Thrombin and Xa Inhibitors

The current generation of direct thrombin inhibitors descend from *hirudins*, polypeptides from the anticoagulant present in saliva from the medicinal leech (*Hirudo medicinalis*). Unlike the heparins, they do not depend on the activation of antithrombin. The early successes, still used therapeutically, require parenteral administration. **Lepirudin** is a recombinant hirudin that binds irreversibly to both the fibrin-binding and catalytic sites on thrombin and is used for thromboembolic disease in patients with type II HIT. It is administered intravenously, the dose being adjusted depending on the APTT, and can cause bleeding or hypersensitivity reactions (rash or fever). **Bivalirudin**, another hirudin analogue, is used in combination with **aspirin** and **clopidogrel** (see later) in patients undergoing percutaneous coronary artery surgery. Treatment is initiated with an intravenous bolus followed by an infusion during and up to 4 h after the procedure. It can cause bleeding and hypersensitivity reactions.

DOACs and DOAC-reversal agents

The field of direct-acting oral anticoagulants (DOAC) had more than one false dawn, but the current agents have largely replaced warfarin in the prevention of thrombotic diseases such as deep vein thrombosis following orthopaedic surgery and embolic stroke in patients with atrial fibrillation, as well as in the treatment of thrombotic disease. These drugs do not require repeated blood testing to monitor their effect, and are less prone to interactions with other drugs or dietary constituents than is warfarin but are not suitable for patients with severe renal impairment.

Dabigatran is a synthetic serine protease inhibitor; **dabigatran etexilate**, a prodrug with a hydrophobic tail, is orally active and is licensed for prevention of venous thromboembolism following hip or knee replacement and for the prevention of stroke and systemic embolism in atrial fibrillation (see **Ch. 20**). It works rapidly and is administered 1–4 h after surgery and then once daily for up to a month (depending on the type of surgery), or twice daily indefinitely for the prevention of stroke. The dose is reduced in patients aged over 75 or receiving concomitant verapamil or amiodarone. **Rivaroxaban** is an orally active direct inhibitor of factor Xa rather than of thrombin. **Apixaban** and **edoxaban** are similar to rivaroxaban. Their commonest adverse effects are predictable (bleeding, anaemia). When these drugs were first introduced there was concern at the lack of specific treatments to neutralise their effects in patients who experienced severe bleeding, in contrast to the older agents such as heparin and warfarin. These concerns have now, at least partly, been met. **Idarucizumab** is a humanised monoclonal antibody fragment that binds dabigatran and its metabolites, blocking its effect, and is licensed for

emergency procedures or severe bleeding caused by dabigatran. **Andexanet alpha** is a modified human factor Xa which binds rivaroxaban and apixaban, reducing their anticoagulant effect. It is used in severe bleeding caused by these agents. Whilst these approaches are highly effective, DOAC-induced severe bleeding, especially when intracerebral, continues to have a high mortality. Other adverse effects caused by DOACs include hepatotoxicity (rivaroxaban).

Warfarin

Oral anticoagulants were discovered as an indirect result of a change in agricultural policy in North America in the 1920s. Sweet clover was substituted for corn in cattle feed, and an epidemic of deaths of cattle from haemorrhage ensued. This turned out to be caused by bishydroxycoumarin in spoiled sweet clover, and it led to the discovery of warfarin (named for the Wisconsin Alumni Research Foundation). One of the first uses to which this was put was as a rat poison, but for *nearly a century* it was the standard anticoagulant for the treatment and prevention of thromboembolic disease. By 2018, however, prescription numbers in the United States for DOACs were outnumbering those for warfarin by nearly 3:2 (**https://clincalc.com/DrugStats/**), although it remains commonly prescribed in the 2020s.

Warfarin (see **Fig. 23.3**) is the most important vitamin K antagonist; alternatives with a similar mechanism of action, for example **phenindione**, are now used only in rare patients who experience idiosyncratic off-target adverse reactions to warfarin [5] (see **Ch. 12**). Warfarin and other vitamin K antagonists require

frequent blood tests to individualise dose, and are consequently inconvenient as well as having a low margin of safety.

Mechanism of action

Vitamin K antagonists act only in vivo and have no effect on clotting if added to blood in vitro. They interfere with the post-translational γ-carboxylation of glutamic acid residues in clotting factors II, VII, IX and X. They do this by inhibiting *vitamin K epoxide reductase component 1* (VKORC1), thus inhibiting the reduction of vitamin K epoxide to its active hydroquinone form (see **Fig. 23.5**). Inhibition is competitive (reflecting the structural similarity between warfarin and vitamin K; see **Fig. 23.3**). The *VKORC1* gene is polymorphic (see **Ch. 12**), and different haplotypes have different affinities for warfarin. Genotyping to determine the *VKORC1* haplotype, combined with genotyping *CYP2C9* (see later), can be used to optimise the starting dose, reducing the variability in response to warfarin by around one-third. The effect of warfarin takes several days to develop because of the time taken for degradation of preformed carboxylated clotting factors. Onset of action thus depends on the elimination half-lives of the relevant factors. Factor VII, with a half-life of approximately 6 h, is affected first, then IX, X and II, with half-lives of 24, 40 and 60 h, respectively.

Administration and pharmacokinetic aspects

Warfarin is absorbed rapidly and completely from the gut after oral administration. It has a small distribution volume, being strongly bound to plasma albumin (see **Ch. 9**). The peak concentration in the blood occurs within an hour of ingestion, but because of its mechanism of action this does not coincide with the peak

pharmacological effect, which occurs about 48 h later. The effect on prothrombin time (PT, see later) of a single dose starts after approximately 12–16 h and lasts 4–5 days. Warfarin is metabolised by CYP2C9, which is polymorphic (see **Ch. 12**). Partly in consequence of this, its half-life is very variable, being of the order of 40 h in many individuals.

Warfarin crosses the placenta and is not given in the first months of pregnancy because it is teratogenic (see **Table 58.2**), nor in the later stages because it can cause intracranial haemorrhage in the baby during delivery. It appears in milk during lactation. This could theoretically be important because newborn infants are naturally deficient in vitamin K. However, infants are routinely prescribed vitamin K to prevent haemorrhagic disease, so warfarin treatment of the mother does not generally pose a risk to the breastfed infant.

The therapeutic use of warfarin requires a careful balance between giving too little, leaving unwanted coagulation unchecked, and giving too much, thereby causing haemorrhage. Therapy is complicated not only because the effect of each dose is maximal some 2 days after its administration, but also because numerous medical and environmental conditions modify sensitivity to warfarin, including interactions with other drugs (see Chs **9**, **10** and **12**). The effect of warfarin is monitored by measuring PT, which is expressed as an *international normalised ratio* (INR).

The PT is the time taken for clotting of citrated plasma after the addition of Ca^{2+} and standardised reference thromboplastin; it is expressed as the ratio (PT ratio) of the PT of the patient to the PT of a pool of plasma from healthy subjects on no medication. Because of the variability of thromboplastins, different results are obtained

in different laboratories. To standardise PT measurements internationally, each thromboplastin is assigned an international sensitivity index (ISI), and the patient's PT is expressed as an INR, where INR = (PT ratio)^{ISI}, ensuring similar results when a patient travels from, say, Birmingham to Baltimore.

The dose of warfarin is usually adjusted to give an INR of 2–4, the precise target depending on the clinical situation. The duration of treatment also varies, but for several indications (e.g. to prevent thromboembolism in chronic atrial fibrillation), treatment is long term, with the logistical challenge of providing a worldwide network of anticoagulant clinics and demands on the patient in terms of repeat visits and blood tests. Warfarin prescriptions in the United States declined from a peak of approximately 35 million in 2010 to approximately 14.5 million in 2018 (**https://clincalc.com/DrugStats/Drugs/Warfarin**), so it remains important, at least for now.

Factors that Potentiate Warfarin

Various diseases and drugs potentiate warfarin, increasing the risk of haemorrhage.

Disease

Liver disease interferes with the synthesis of clotting factors; conditions in which there is a high metabolic rate, such as fever and thyrotoxicosis, increase the effect of anticoagulants by increasing degradation of clotting factors.

Drugs (see also Ch. 10)

Many drugs potentiate warfarin.

Agents that inhibit hepatic drug metabolism

Examples include **co-trimoxazole**, **ciprofloxacin, metronidazole, amiodarone** and many antifungal azoles. Stereoselective effects (warfarin is a racemate, and its isomers are metabolised differently from one another) are described in **Chapter 10**.

Drugs that inhibit platelet function

Aspirin increases the risk of bleeding if given during warfarin therapy, although this combination can be used safely with careful monitoring. Other non-steroidal anti-inflammatory drugs (NSAIDs) also increase the risk of bleeding, partly by their effect on platelet thromboxane synthesis (see **Ch. 25**), by causing gastrointestinal damage with bleeding and, in the case of some NSAIDs, also by inhibiting warfarin metabolism.

Drugs that displace warfarin from binding sites on plasma albumin

Some of the NSAIDs and **chloral hydrate** cause a transient increase in the concentration of free warfarin in plasma by competing with it for binding to plasma albumin. This mechanism seldom causes clinically important effects as explained in **Chapter 9**.

Drugs that inhibit reduction of vitamin K

Such drugs include the *cephalosporins*.

Drugs that decrease the availability of vitamin K

Broad-spectrum antibiotics and some *sulfonamides* (see **Ch. 51**) depress the intestinal flora that normally synthesise vitamin K_2; this has little effect unless there is concurrent dietary deficiency or fat malabsorption.

Factors that Lessen the Effect of Warfarin

Physiological state/disease

There is a decreased response to warfarin in conditions (e.g. pregnancy) where there is increased coagulation factor synthesis. Similarly, the effect of oral anticoagulants is lessened in hypothyroidism, which is associated with reduced degradation of coagulation factors.

Vitamin K

This vitamin is a component of some parenteral feeds and vitamin preparations.

Drugs that induce hepatic P450 enzymes

Enzyme induction (e.g. by **rifampicin, carbamazepine**) increases the rate of degradation of warfarin, risking under-treatment and thrombosis unless the dose of warfarin is increased. Induction wanes slowly and variably after the inducing drug is discontinued, making it difficult to adjust the warfarin dose appropriately and risking haemorrhage.

Drugs that reduce absorption

Drugs that bind warfarin in the gut, for example, **colestyramine** (see **Ch. 22**), reduce its absorption.

Drugs affecting blood coagulation

Procoagulant drugs: vitamin K

- Reduced vitamin K is a co-factor in the post-translational g-carboxylation of glutamic acid (Glu) residues in factors II, VII, IX and X. The γ-carboxylated glutamic acid (Gla) residues are essential for the interaction of these factors with Ca^{2+} and negatively charged PL.

Heparin, LMWHs, injectable anticoagulants that:

- Potentiate antithrombin III, a natural inhibitor that inactivates Xa and thrombin.
- Act both in vivo and in vitro.
- Anticoagulant activity results from a unique pentasaccharide sequence with high affinity for antithrombin III.
- **Unfractionated heparin (UFH)** therapy is monitored via APTT, and dose individualised. UFH is used for patients with impaired renal function.
- **LMWHs** have the same effect on factor X as heparin but less effect on thrombin; therapeutic efficacy is similar to **heparin** but monitoring and dose individualisation are not needed. Patients can administer them subcutaneously at home. They are preferred over UFH except for patients with impaired renal function.

Oral anticoagulants, e.g. direct oral anticoagulants (DOACs); warfarin

- Orally active direct thrombin inhibitors (e.g. **dabigatran etexilate**) or factor Xa inhibitors (e.g. **rivaroxaban**, **apixaban, edoxaban**) are used increasingly instead of warfarin and do not require laboratory monitoring/dose titration. They are licensed for preventing stroke in patients with atrial fibrillation and for preventing deep vein thrombosis after orthopaedic surgery and for the treatment of deep vein thrombosis and some cases of pulmonary embolism.
- **Warfarin** is the main vitamin K antagonist.
- Vitamin K antagonists act on VKORC1 to inhibit the reduction of vitamin K epoxide, thus inhibiting the γ-carboxylation of Glu in II, VII, IX and X.
- Vitamin K antagonists act only in vivo, and their effect is delayed until preformed clotting factors are depleted.
- Many factors modify the action of vitamin K antagonists; genetic factors (polymorphisms of *CYP2C6* and *VKORC1*) and drug interactions are especially important.
- There is wide variation in response to vitamin K antagonists; their effect is monitored by measuring the INR and the dose individualised accordingly.

Unwanted Effects of Warfarin

Haemorrhage (especially into the bowel or the brain) is the main hazard. Depending on the urgency of the situation, treatment may consist of withholding warfarin (for minor problems),

administration of vitamin K or fresh frozen plasma or prothrombin complex concentrate (for life-threatening bleeding).

Oral anticoagulants are *teratogenic*, causing disordered bone development which is believed to be related to binding to the vitamin K–dependent protein osteocalcin.

Hepatotoxicity occurs but is uncommon.

Necrosis of soft tissues (e.g. breast or buttock) owing to thrombosis in venules is a rare but serious effect that occurs shortly after starting treatment and is attributed to inhibition of biosynthesis of protein C, which has a shorter elimination half-life than do the vitamin K–dependent coagulation factors; this results in a procoagulant state soon after starting treatment. Treatment with a heparin is usually started at the same time as warfarin, avoiding this problem.

The clinical use of anticoagulants is summarised in the box.

Clinical uses of anticoagulants

Heparin (often as **LMWH**) or a direct-acting intravenous thrombin antagonist such as **lepirudin** is used acutely. A **DOAC** or **warfarin** is used for more prolonged therapy. Anticoagulants are used to prevent:

- deep vein thrombosis (e.g. perioperatively)
- extension of established deep vein thrombosis
- pulmonary embolism
- thrombosis and embolisation in patients with atrial fibrillation (see **Ch. 20**)
- thrombosis on prosthetic heart valves

- clotting in extracorporeal circulations (e.g. during haemodialysis)
- progression of myocardial damage in patients with unstable angina and during treatment of ST-elevation myocardial infarction

Platelet Adhesion and Activation

Platelets maintain the integrity of the circulation: a low platelet count results in *thrombocytopenic purpura*. [6]

When platelets are activated, they undergo a sequence of reactions that are essential for haemostasis, important for the healing of damaged blood vessels, and which also play a part in inflammation (see **Ch. 17**). Several of these reactions are redundant in the sense that if one pathway of activation is blocked another is available and many are autocatalytic providing positive feedback:

- *adhesion* following vascular damage. von Willebrand factor bridges subendothelial macromolecules and GPIb receptors on the platelet surface [7] ;
- *shape change*: from smooth discs to spiny spheres with protruding pseudopodia;
- *secretion* of the granule contents which include platelet agonists such as ADP and 5-hydroxytryptamine, and coagulation factors and growth factors, such as platelet-derived growth factor (PDGF);
- *biosynthesis of labile mediators* such as platelet-activating factor and thromboxane (TX)A_2 (see **Ch. 17** and **Fig. 23.7**);

- *aggregation*, which is promoted by various agonists, including collagen, thrombin, ADP, 5-hydroxytryptamine and TXA_2, acting on specific receptors on the platelet surface; activation by agonists leads to expression of GPIIb/IIIa receptors that bind fibrinogen, which links adjacent platelets to form aggregates;

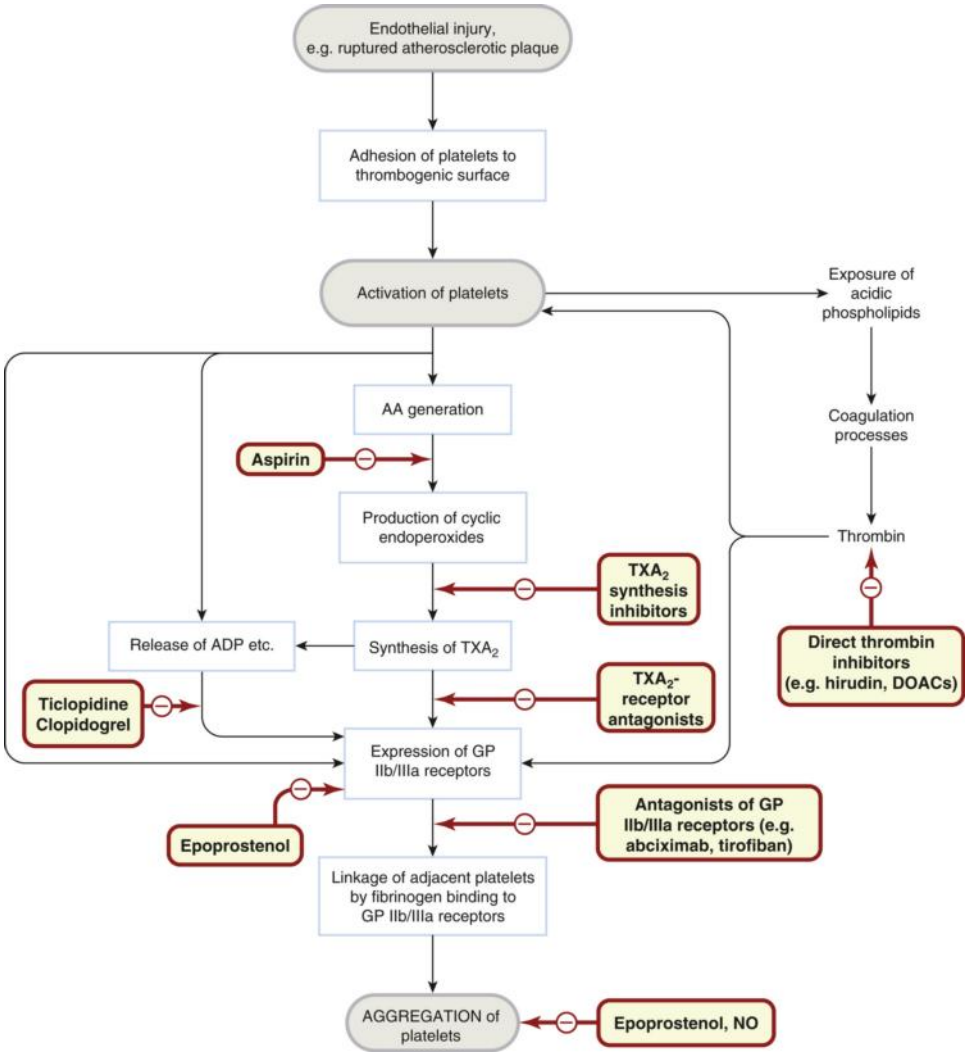

FIG. 23.7 Platelet activation. Events involved in platelet adhesion and aggregation are shown, with the sites of action of drugs and endogenous mediators. *AA,* Arachidonic acid; *ADP,* adenosine bisphosphate; *DOACs,* direct oral anticoagulants *GP,* glycoprotein; *NO,* nitric oxide; *TXA* $_2$, thromboxane A_2.

- *exposure of acidic PL* on the platelet surface, promoting thrombin formation and further platelet activation via

thrombin receptors and fibrin formation via cleavage of fibrinogen.

These processes are essential for haemostasis but may be inappropriately triggered if the artery wall is diseased, most commonly with atherosclerosis, resulting in thrombosis (see **Fig. 23.7**).

Platelet function

- Healthy vascular endothelium prevents platelet adhesion.
- Platelets adhere to diseased or damaged areas and become activated, changing shape and exposing negatively charged PLs and GPIIb/IIIa receptors, and synthesise and/or release various mediators, for example, thromboxane A_2 and ADP, which activate other platelets, causing aggregation.
- Aggregation entails fibrinogen binding to and bridging between GPIIb/IIIa receptors on adjacent platelets.
- Activated platelets constitute a focus for fibrin formation.
- Chemotactic factors (e.g. PF4) and growth factors (e.g. PDGF) necessary for repair, but also implicated in atherogenesis, are released during platelet activation.

Antiplatelet Drugs

Platelets play such a critical role in thromboembolic disease that it is no surprise that antiplatelet drugs are of great therapeutic value. Clinical trials of aspirin radically altered clinical practice, and more

recently drugs that block ADP receptors and GPIIb/IIIa have also been found to be therapeutically useful. Sites of action of antiplatelet drugs are shown in **Fig. 23.7**.

Aspirin

Low-dose aspirin (see **Ch. 25**) administered repeatedly profoundly (>95%) inhibits platelet TXA_2 synthesis, by irreversible acetylation of a serine residue in the active site of cyclo-oxygenase I (COX-1). Oral administration is relatively selective for platelets partly because of presystemic drug elimination (see **Ch. 10**). Unlike nucleated cells, platelets cannot synthesise proteins, so after administration of aspirin, TXA_2 synthesis does not recover fully until the affected cohort of platelets is replaced in 7–10 days. Clinical trials have demonstrated the efficacy of aspirin in several clinical settings (e.g. **Fig. 23.8**) and its value in the secondary prevention of cardiovascular disease is firmly established. For acute indications (progressing thrombotic stroke – so-called stroke-in-evolution – and acute myocardial infarction) treatment is started with a single dose of approximately 300 mg in order to achieve rapid substantial (>95%) inhibition of platelet thromboxane synthesis, followed by regular daily doses of 75 mg. For long-term thromboprophylaxis, a low dose (often 75 mg once daily) is used. At this dose, the risk of gastrointestinal bleeding is less than with the usual 300 mg dose given to control inflammation, but still significant, so thromboprophylaxis is reserved for people at high cardiovascular risk (e.g. survivors of myocardial infarction so-called *secondary* prevention), in whom the benefit usually outweighs the risk of gastrointestinal bleeding. Its place in *primary* prevention of

cardiovascular disease and cancer is still debated (**Patrono and Baigent, 2019**; **Ricciotti and FitzGerald, 2021**).

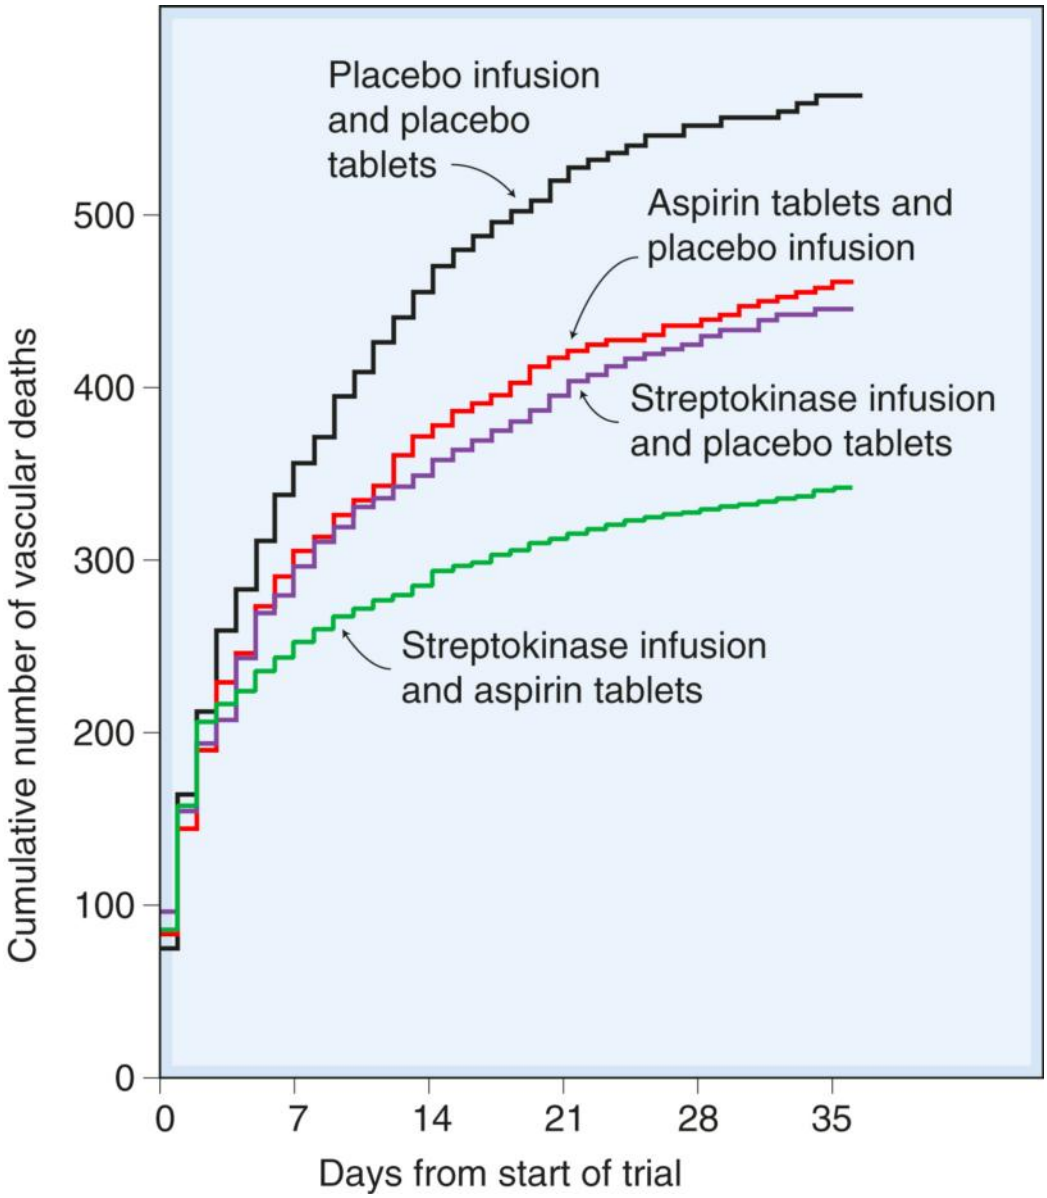

FIG. 23.8 Efficacy of aspirin and streptokinase for myocardial infarction. The curves show cumulative vascular mortality in patients treated with placebo, aspirin alone, streptokinase alone or a combined aspirin–streptokinase regimen. ISIS-2 Trial, 1988. Lancet. ii, 350–360.

Treatment failure can occur despite taking aspirin, and the possibility has been raised that some patients exhibit a syndrome of 'aspirin resistance', although the mechanism and possible importance of this remain controversial (see **Goodman et al., 2008**; **Pollack and Wang, 2021**). Other non-steroidal drugs (NSAIDs) that, like aspirin, inhibit platelet TXA_2 synthesis >95% (e.g. **sulfinpyrazone**, for which there is also supportive clinical trial evidence) may have antithrombotic effects. In contrast, where inhibition of platelet TXA_2 synthesis does not reach this threshold, NSAIDs, whether or not they are selective for COX-2, are prothrombotic and increase blood pressure. This is believed to be due to inhibition of COX enzymes leading to reduced synthesis of antiaggregatory and vasodilatory PGI_2 in blood vessels in the kidneys and elsewhere, and results in increased cardiovascular risk during chronic treatment with NSAIDs (see **Ch. 25**).

Dipyridamole

Dipyridamole inhibits platelet aggregation by several mechanisms, including inhibition of phosphodiesterase (hence potentiating mediators that inhibit platelet function by increasing cytoplasmic cAMP or cGMP), block of adenosine uptake into red cells and endothelial cells (see **Ch. 16**), potentiating this vasodilator and inhibitor of platelet aggregation. Clinical effectiveness has been uncertain, but one study showed that a modified-release form of dipyridamole reduced the risk of stroke and death in patients with transient ischaemic attacks by around 15% – similar to aspirin (25 mg twice daily). [8] The beneficial effects of aspirin and dipyridamole were additive. The main adverse effects of dipyridamole are

dizziness, headache and gastrointestinal disturbances; unlike aspirin, it does not appear to increase the risk of bleeding.

Purine ($P2Y_{12}$) Receptor Antagonists

$P2Y_{12}$ receptor antagonists (see **Ch. 16**) block the pro-aggregatory effect of ADP on platelets. **Ticlopidine** was the first to be introduced but can cause serious blood dyscrasias (neutropenia and thrombocytopenia). The main agents are currently **clopidogrel**, **prasugrel** and **ticagrelor**, each of which is combined with low-dose aspirin in patients with unstable coronary artery disease, usually for up to 1 year.

Clopidogrel and prasugrel inhibit ADP-induced platelet aggregation by irreversible inhibition of $P2Y_{12}$ receptors (see **Ch. 16**) to which they link via a disulfide bond, whereas ticagrelor is a reversible but non-competitive inhibitor of the $P2Y_{12}$ receptor.

Pharmacokinetics and unwanted effects

Clopidogrel is well absorbed when administered by mouth, and in urgent situations is given orally as a loading dose of 300 mg followed by maintenance dosing of 75 mg once daily. It is a prodrug and is converted into its active sulfhydryl metabolite by CYP enzymes in the liver including CYP2C19. Patients with variant alleles of *CYP2C19* (rapid or poor metabolisers) are at increased risk of therapeutic failure from lack of efficacy or from bleeding. There is a potential for interaction with other drugs, such as **omeprazole** (see **Ch. 30**), that are metabolised by CYP2C19 and current labelling recommends against use with proton pump inhibitors for this reason. Strong inducers such as **rifampicin** increase the concentration of active metabolite and risk of bleeding. Prasugrel

and ticagrelor are also given as a loading dose followed by maintenance once-daily dosing.

These drugs predictably increase the risk of haemorrhage over and above that caused by aspirin given alone. Clopidogrel can cause dyspepsia, rash or diarrhoea. The serious blood dyscrasias caused by ticlopidine are very rare with clopidogrel. Prasugrel can cause rash or, rarely, hypersensitivity reactions and angioedema. Ticagrelor can cause dyspnoea (perhaps related to the role of adenosine signalling in the carotid bodies, see **Ch. 28**) or, less commonly, gastrointestinal symptoms.

Clinical use

Clopidogrel was slightly more effective than aspirin as a single agent in reducing a composite outcome of ischaemic stroke, myocardial infarction or vascular death in one large trial; it can be used instead of aspirin for secondary prevention in patients with symptomatic atheromatous disease who are intolerant of aspirin. Clinical trials of adding clopidogrel to aspirin in patients with acute coronary syndromes and (in a megatrial of over 45,000 patients) in patients with acute myocardial infarction (**COMMIT Collaborative Group, 2005**) demonstrated that combined treatment reduces mortality. Treatment with clopidogrel for this indication is given for 4 weeks. Prasugrel is more effective than clopidogrel in acute coronary syndromes, but more often causes serious bleeding. Pretreatment with clopidogrel and aspirin followed by longer-term therapy is also effective in patients with ischaemic heart disease undergoing percutaneous coronary interventions. Treatment of

acute coronary syndrome with ticagrelor as compared with clopidogrel significantly reduces mortality for unknown reasons.

Glycoprotein IIB/IIIA Receptor Antagonists

Antagonists of the GPIIb/IIIa receptor have the theoretical attraction that they inhibit all pathways of platelet activation because these all converge on activation of GPIIb/IIIa receptors. A hybrid murine–human monoclonal antibody Fab fragment directed against the GPIIb/IIIa receptor, which rejoices in the catchy little name of **abciximab**, [9] is licensed for use in high-risk patients undergoing coronary angioplasty, as an adjunct to heparin and aspirin. It reduces the risk of restenosis at the expense of an increased risk of bleeding. Immunogenicity limits its use to a single administration.

Tirofiban is a synthetic non-peptide and **eptifibatide** is a cyclic peptide based on the Arg–Gly–Asp ('RGD') sequence that is common to ligands for GPIIb/IIIa receptors. Neither is absorbed if administered by mouth. Given intravenously as an adjunct to aspirin and a heparin preparation, they reduce early events in acute coronary syndrome, but long-term oral therapy with GPIIb/IIIa receptor antagonists is not effective and may be harmful. Unsurprisingly, they increase the risk of bleeding.

Other Antiplatelet Drugs

Epoprostenol (PGI_2), an agonist at prostanoid IP receptors (see **Ch. 17**), causes vasodilatation as well as inhibiting platelet aggregation. It can be added to blood entering the dialysis circuit in order to prevent thrombosis during haemodialysis, especially in patients in whom heparin is contraindicated. It is also used in

severe pulmonary hypertension (see **Ch. 21**) and circulatory shock associated with meningococcal septicaemia. It is unstable under physiological conditions and has a half-life of around 3 min, so it is administered as an intravenous infusion. A more stable analogue of PGI_2, **iloprost**, is administered by inhalation of a nebulised solution to patients with severe pulmonary artery hypertension. Adverse effects related to the vasodilator action of either of these prostanoids include flushing, headache and hypotension.

The clinical use of antiplatelet drugs is summarised in the clinical box.

Antiplatelet drugs

- **Aspirin** inhibits cyclo-oxygenase irreversibly. In chronic use, low doses (75 mg once daily) very effectively (>95%) inhibit platelet thromboxane (TX)A_2 synthesis and reduce the risk of thrombosis. Treatment is started with a single larger dose (300 mg) in acute settings in order to achieve rapid inhibition of platelet thromboxane synthesis. [10]
- ADP antagonists are combined with low-dose aspirin in treating patients with unstable coronary artery disease. **Clopidogrel** is a prodrug. Given by mouth, it irreversibly inhibits $P2Y_{12}$ receptors and thereby inhibits platelet responses to ADP. Its clinical effect is additive with **aspirin.** **Prasugrel** has a similar mechanism. **Ticagrelor** is reversible but non-competitive. **Prasugrel** and **ticagrelor** are more effective than licensed doses of **clopidogrel**, but more likely to cause haemorrhage.

- Antagonists of GPIIb/IIIa receptors include a monoclonal antibody (**abciximab**) and several synthetic molecules (e.g. **tirofiban**). They inhibit diverse agonists, for example, ADP and TXA_2, because different pathways of activation converge on GPIIb/IIIa receptors. They are administered intravenously for short-term treatment.
- **Dipyridamole** inhibits phosphodiesterase and red cell adenosine uptake. It is used in addition to aspirin in some patients with stroke or transient ischaemic attack.
- **Epoprostenol** (synthetic PGI_2) is chemically unstable. Given as an intravenous infusion, it acts on I prostanoid (IP) receptors on vascular smooth muscle and platelets (see **Ch. 17**), stimulating adenylyl cyclase and thereby causing vasodilatation and inhibiting aggregation caused by any pathway (e.g. ADP or TXA_2). It is used to prevent clotting during haemodialysis in patients who cannot be treated with heparin, and to treat pulmonary arterial hypertension (see **Ch. 21**). **Iloprost** is a less unstable analogue of PGI_2 and can be administered by inhalation of a nebulised solution to treat pulmonary hypertension.

---

[10] Its antithrombotic action is the main basis for the saying 'An aspirin a day keeps the doctor away' – although aspirin also has anticancer properties, particularly against colon cancer. However, its chronic use in primary prevention is seldom justified because of the bleeding it can cause.

Clinical uses of antiplatelet drugs

The main drug is **aspirin**. Other drugs with distinct actions (e.g. **dipyridamole**, **clopidogrel**, **ticagrelor**) can have additive effects, or be used in patients who are intolerant of **aspirin**. Uses of antiplatelet drugs relate mainly to arterial thrombosis and include:

- acute myocardial infarction
- prevention of myocardial infarction in patients at high risk, including a history of myocardial infarction, angina or intermittent claudication
- following coronary artery bypass grafting
- unstable coronary syndromes (a $P2Y_{12}$ antagonist such as **clopidogrel, prasugrel** or **ticagrelor** is added to **aspirin**)
- following coronary artery angioplasty and/or stenting. Intravenous glycoprotein IIb/IIIa antagonists, e.g. **abciximab**, are used in some patients in addition to **aspirin.**
- transient cerebral ischaemic attack ('ministrokes') or thrombotic stroke, to prevent recurrence (**dipyridamole** can be added to **aspirin**)
- atrial fibrillation, if oral anticoagulation is contraindicated; or, by specialists, in high-risk situations in combination with anticoagulant

Other antiplatelet drugs such as **epoprostenol** (PGI_2; see **Ch. 17**) have specialised clinical applications, e.g. in *haemodialysis* or

haemofiltration (see **Ch. 29**) or in *pulmonary hypertension* (see **Ch. 21**), where an analogue, **iloprost**, can be administered by inhalation of a nebulised solution.

Fibrinolysis (Thrombolysis)

When the coagulation system is activated, the fibrinolytic system is also set in motion via several endogenous *plasminogen activators*, including tPA, urokinase-type plasminogen activator, kallikrein and neutrophil elastase. tPA is inhibited by a structurally related lipoprotein, *lipoprotein(a)*, increased plasma concentrations of which constitute an independent risk factor for myocardial infarction (see **Ch. 22**). Plasminogen is deposited on the fibrin strands within a thrombus. Plasminogen activators are serine proteases and are unstable in circulating blood. They diffuse into thrombus and cleave plasminogen, a zymogen present in plasma, to release plasmin locally (**Fig. 23.9**). Plasmin is a trypsin-like protease that digests fibrin as well as fibrinogen, factors II, V and VIII and many other proteins; any plasmin that escapes into the circulation is inactivated by plasmin inhibitors, including PAI-1 (see **Ch. 21**), which protect us from digesting ourselves from within.

Drugs affect this system by increasing or inhibiting fibrinolysis (*fibrinolytic* and *antifibrinolytic* drugs, respectively).

Fibrinolytic Drugs

Fig. 23.9 summarises the interaction of the fibrinolytic system with the coagulation cascade and platelet activation, and the action of drugs that modify this. Several fibrinolytic (thrombolytic) drugs are used clinically, principally to reopen the occluded arteries in

patients with acute myocardial infarction [11] or stroke, less commonly in patients with life-threatening venous thrombosis or pulmonary embolism.

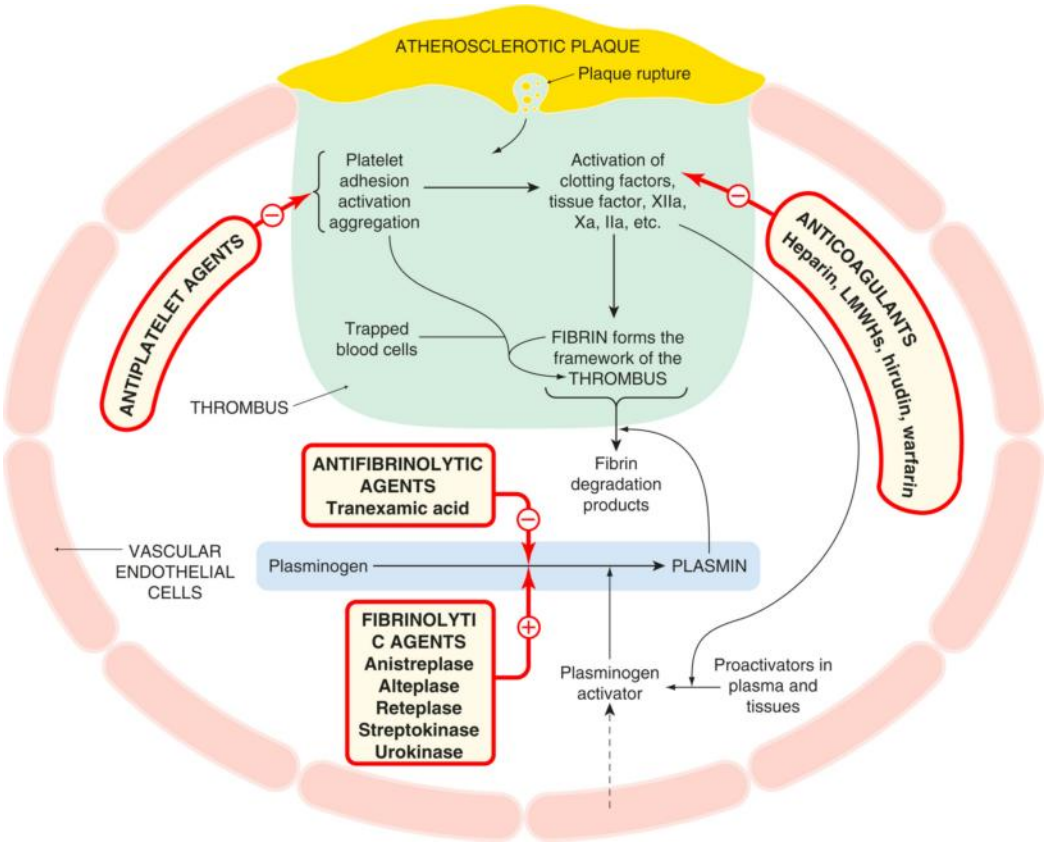

FIG. 23.9 Fibrinolytic system. The schematic shows interactions with coagulation and platelet pathways and sites of action of drugs that modify these systems. For more details of platelet activation and the coagulation cascade, refer to Figs 23.1, 23.2 and 23.7. *LMWHs,* Low-molecular-weight heparins.

Streptokinase is a plasminogen activating protein extracted from cultures of streptococci. Infused intravenously, it reduces

mortality in acute myocardial infarction, and this beneficial effect is additive with aspirin (see **Fig. 23.8**). Its action is blocked by antibodies, which appear 4 days or more after the initial dose: its use should not be repeated after this time has elapsed. [12]

Alteplase and **duteplase** are, respectively, single- and double-chain recombinant tPA. They are more active on fibrin-bound plasminogen than on plasma plasminogen and are therefore said to be 'clot selective'. Recombinant tPA is not antigenic and can be used in patients likely to have antibodies to streptokinase. Because of their short half-lives, these drugs must be given as intravenous infusions. **Reteplase** is similar but has a longer elimination half-life, allowing for bolus administration and making for simplicity of administration. It is available for clinical use in myocardial infarction.

Unwanted Effects and Contraindications

The main hazard of all fibrinolytic agents is bleeding, including gastrointestinal haemorrhage and haemorrhagic stroke. If serious, this can be treated with **tranexamic acid** (see later), fresh plasma or coagulation factors. Streptokinase can cause allergic reactions and low-grade fever. Streptokinase causes a burst of plasmin formation, generating vasodilator kinins (see **Ch. 17**), and can cause hypotension by this mechanism.

Contraindications to the use of these agents are active internal bleeding, haemorrhagic cerebrovascular disease, bleeding diatheses, pregnancy, uncontrolled hypertension, invasive procedures in which haemostasis is important and recent trauma – including vigorous cardiopulmonary resuscitation.

Clinical Use

Several large placebo-controlled studies in patients with myocardial infarction have shown convincingly that fibrinolytic drugs reduce mortality if given within 12 h of the onset of symptoms, and that the sooner they are administered the better is the result. Similar considerations apply to their use in thrombotic stroke, but with a compressed time scale of 3 h instead of 12 h. Scanning to exclude haemorrhagic stroke is advisable, although not always practicable in an emergency situation. Available fibrinolytic drugs, used in combination with aspirin, provide similar, but usually somewhat less, benefit to that obtained by mechanical (e.g. thrombectomy or angioplasty) unblocking procedures. Other uses of fibrinolytic agents are listed in the clinical box.

Fibrinolysis and drugs modifying fibrinolysis

- A fibrinolytic cascade is initiated concomitantly with the coagulation cascade, resulting in the formation within the coagulum of plasmin, an enzyme which digests fibrin.
- Various agents promote the formation of plasmin from its precursor plasminogen, for example **streptokinase**, and tPAs such as **alteplase, duteplase** and **reteplase.** Most are infused intravenously; reteplase can be given as a bolus injection.
- Some drugs (e.g. **tranexamic acid**) inhibit fibrinolysis.

Clinical uses of fibrinolytic drugs

The main drugs are tPAs, for example **alteplase**.

- The main use is in acute myocardial infarction, within 12 h of onset (the earlier the better!).
- Other uses include:
  - *acute thrombotic stroke* within 3 h of onset (tPA), in selected patients
  - clearing *thrombosed shunts* and *cannulae*
  - *acute arterial thromboembolism*
  - life-threatening *deep vein thrombosis* and *pulmonary embolism* (**streptokinase**, given promptly)

Antifibrinolytic and Haemostatic Drugs

Tranexamic acid inhibits plasminogen activation and thus prevents fibrinolysis. It can be given orally or by intravenous injection. It is used to treat various conditions in which there is bleeding or risk of bleeding, such as haemorrhage following prostatectomy or dental extraction, in menorrhagia (excessive menstrual blood loss) and for life-threatening bleeding following thrombolytic drug administration. It is also used prophylactically in patients with the rare disorder of hereditary angio-oedema (see **Ch. 21**).

QUESTIONS

QUESTION 23.1

Blood coagulation means the conversion of liquid blood to a clot and involves a complex activation cascade of zymogens and cofactors.

Which of the following statements about the intrinsic clotting cascade is incorrect?

OPTIONS:

A. It initiates with the activation of factor VII binding to tissue factor.

B. The tissue factor–VIIa complex is rapidly inactivated by antithrombin III.

C. Platelet activation results in the expression of catalytic acidic phospholipids (PLs).

D. Factor Xa, in the presence of Ca^{2+}, PL and factor Va, activates fibrinogen to fibrin.

E. The process is calcium dependent.

QUESTION 23.2

Coagulation is tightly regulated by a balance of clotting and inhibitory factors, and inherited or acquired deficiencies or mutations can lead to bleeding and clotting disorders.

Which of the following is the MOST common cause of an inherited bleeding disorder?

OPTIONS:

A. von Willebrand factor deficiency

B. Factor XII deficiency

C. Factor V mutation

D. Factor VIII deficiency

E. Vitamin K deficiency

ANSWERS

ANSWER 23.1

RATIONALE:

A. Tissue damage exposes blood to tissue factor, initiating the process and leading to production of a small amount of thrombin. 'Tissue factor' is the cellular receptor for factor VII, which, in the presence of Ca^{2+}, results in rapid autocatalytic activation of factor VII to VIIa.

B. The tissue factor–VIIa complex is rapidly inactivated in plasma by tissue factor pathway inhibitor and by antithrombin III.

C. During platelet activation, acidic PLs are exposed, on the platelets' outwardly facing membranes, and these activate various clotting factors.

D.

E. Calcium ions and a negatively charged PL are essential for the actions of factor IXa on X, factor VIIa on X and factor Xa on II.

CORRECT ANSWER WITH EXPLANATION:

D. Factor Xa, in the presence of Ca^{2+}, PL and factor Va, activates fibrinogen to fibrin.

Factor Xa, in the presence of Ca^{2+}, PL and factor Va, activates prothrombin to thrombin, the main enzyme of the cascade.

ANSWER 23.2

RATIONALE:

A.

B. The contact pathway commences when factor XII adheres to a negatively charged surface and converges with the in vivo pathway at the stage of factor X activation. This step is not crucial for blood coagulation in vivo.

C. A naturally occurring mutation of the gene coding for factor V, which confers resistance to activated protein C, results in the commonest recognised form of inherited thrombophilia (clotting).

D. Genetically determined deficiencies of clotting factors are not common. Examples are classic haemophilia, caused by lack of factor VIII.

E. Acquired vitamin K deficiency most commonly occurs in neonates or following excessive warfarin therapy.

CORRECT ANSWER WITH EXPLANATION:

A. von Willebrand factor deficiency

von Willebrand factor is a glycoprotein that is missing in a hereditary haemorrhagic disorder called von Willebrand disease, which is the most common of the inherited bleeding disorders.

---

[1] Coagulation of 100 mL of blood requires 0.2 mg of factor VIII, 2 mg of factor X, 15 mg of prothrombin and 250 mg of fibrinogen.

[2] Mr Hageman (the patient deficient in factor XII after whom it was named) died not of excessive bleeding but of a pulmonary embolism: factor XII deficiency does not give rise to a bleeding disorder.

[3] von Willebrand factor is a glycoprotein that is missing in a hereditary haemorrhagic disorder called von Willebrand disease, which is the most common of the inherited bleeding disorders. The factor is synthesised by vascular endothelial cells – indeed the presence of immunoreactive von Willebrand factor is an identifying feature of these cells in culture – and is also present in platelets.

[4] This kind of good fortune also favoured Vane and his colleagues in their discovery of PGI_2 (Ch. 17), where they were looking for one kind of biological activity and found another. More specific chemical assays (Ch. 8), for all their strengths, cannot throw up this kind of unexpected discovery.

[5] Warfarin highlights the competing philosophies of simplicity ('one size fits all') versus 'personalised medicine' or

'pharmacogenomics' (see Ch. 12). Prior to dosing with the anticoagulant, the patient can be checked by genotyping for mutations in their *VKORC1* and *CYP2C9* genes, which are involved in the coagulation cascade and metabolism of the drug. In patients possessing common mutations of these genes (particularly *VKORC1-1639G>A* and *-1173C>T*), standard doses of warfarin may cause potentially lethal bleeding or thromboembolism due to therapeutic failure. The success of the DOACs suggests that the outcome of the debate is likely to be both drug and technology dependent.

6 Purpura is a purple rash caused by multiple spontaneous bleeding points in the skin. It can be caused by disease of platelets or of the microvasculature. Bleeding can also occur into other organs, including the gut and brain.

7 Various platelet membrane glycoproteins act as receptors or binding sites for adhesive proteins such as von Willebrand factor or fibrinogen.

8 This dose regimen of aspirin is unconventional, being somewhat lower than the 75 mg once daily commonly used in thromboprophylaxis.

9 The convention for naming monoclonals is as follows: momab = -**mo**use **m**onoclonal **a**nti**b**ody; -umab = human; -zumab = humanised; -ximab = chimeric – a kind of mythical mouse–man nightmare.

11 Fibrinolytic drugs are now less widely used in acute myocardial infarction since many units throughout the world provide an emergency angioplasty service (the blocked artery is identified

angiographically, opened with a balloon catheter and, if necessary, kept open by means of a stent; see Ch. 21). The important thing is to open the thrombosed artery as swiftly as possible. If facilities are available to do this mechanically, this is at least as good as using a lytic drug. Surgical intra-arterial thrombectomy is also being introduced for acute stroke treatment.

[12] A once-in-a-lifetime drug!.

24: Haematopoietic system and treatment of anaemia

OVERVIEW

This chapter briefly reviews the haematopoietic system, emphasising the control of red cell generation ('erythropoiesis'), and summarises the different kinds of anaemia. These are caused by nutrient deficiencies, lack of bone marrow stimulation, bone marrow depression (as in aplastic anaemia) or increased red cell destruction ('haemolytic' anaemias). We then describe the main agents used to treat these and also some non-malignant diseases of white blood cells (leukocytes) and platelets. Malignant diseases of white blood cells (leukaemias) are covered in **Chapter 57**. Anti-platelet drugs are considered in **Chapter 23**. Here we describe haematopoietic growth factors and conclude by mentioning drugs used to treat sickle cell anaemia and paroxysmal nocturnal haemoglobinuria (PNH).

Introduction

In this chapter, we briefly review the haematopoietic system and different types of anaemia due to blood loss, deficiency of nutrients, lack of erythropoietin (the hormone that stimulates erythropoiesis) or increased destruction of red cells (haemolytic anaemias). Nutritional deficiencies of *iron*, *vitamin* B_{12} or *folic acid* are

common and important, and most of this chapter is devoted to these haematinic agents (i.e. nutrients needed for healthy haematopoiesis) and related drugs.

Treatment of many forms of bone marrow depression is mainly supportive for example by transfusions of red blood cells or platelets or, in patients with neutropenic sepsis, by administration of antibiotics. However, *haematopoietic growth factors* (especially *epoietins* – preparations based on the natural hormone erythropoietin) transformed the treatment of patients with chronic kidney disease who are deficient in erythropoietin which, in adults, is made and secreted mainly by the kidneys. It has also been used, notoriously, in competitive sport (see **Ch. 59**). More recently, advances in understanding of the control of erythropoietin secretion by hypoxia inducible factors (HIFs), notably by $HIF_{1\alpha}$, look set to underpin further improvements in the treatment of anaemia in patients with kidney disease and potentially of wider indications including vascular disease and, via HIF *inhibition* (e.g. **belzutifan** for the treatment of von Hippel–Lindau [VHL] syndrome), and malignant diseases (see **Ch. 57**).

Other haematopoietic factors known as *colony-stimulating factors* (CSFs) – varieties of cytokine (see **Ch. 17**) – increase the numbers of circulating white blood cells and are used therapeutically.

Finally, we mention two drugs (**hydroxycarbamide** and **crisanlizumab**) that provide mechanistic insights as well as clinical benefit in sickle cell anaemia and **eculizumab** that provides insights as well as clinical benefits in PNH. Gene editing (see **Ch. 5**) and cell-based therapies offer a glimpse of possible

future cures for sickle cell disease, the thalassaemias and related genetically determined haemoglobinopathies.

The Haematopoietic System

The main components of the haematopoietic system are the blood, bone marrow, lymph nodes and thymus, with the spleen, liver and kidneys as important accessory organs. Blood consists of formed elements (red and white blood cells and platelets) and plasma. This chapter deals mainly with red cells, which carry oxygen in the blood vessels from the lungs to the tissues, where it is needed for aerobic metabolism. Their oxygen-carrying power depends on their haemoglobin content. White blood cells are of central importance in response to infection and other danger signals (see **Ch. 7**) and platelets are essential for haemostasis (see **Ch. 23**).

Erythropoiesis and its control

The most important site of formation of red blood cells in adults is the bone marrow, whereas the spleen acts as their slaughterhouse. The lifetime of a red cell is normally about 120 days, and red cell loss in healthy adults – about 2×10^{10} cells per day – is precisely balanced by production of new cells. As mentioned previously, the kidneys (and, in fetal life, the liver) manufacture *erythropoietin*, the hormone that stimulates red cell production. In healthy individuals the anatomical site with the lowest tissue concentration of oxygen is the renal medulla which utilises anaerobic metabolism for its energy supply. The low oxygen is a consequence of the anatomical arrangement of the blood supply to the medulla via vascular loops called the vasa recta. This arrangement results in counter-current

exchange of plasma and a low blood flow to the deepest part of the medulla with a short-circuiting of extracellular fluid and oxygen between vasa recta vessels entering and leaving the medulla. This preserves the osmotic gradient that permits the kidney to excrete either a dilute or a concentrated urine (see **Ch. 29**).

The red cell content of blood is expressed as the *haematocrit*, defined as the fraction of the blood that is occupied by red cells expressed as a percentage, or as the *haemoglobin concentration* expressed nowadays (at least in European countries) in molar terms based on the molecular mass of haemoglobin and the total volume of blood in the sample – as though the haemoglobin was uniformly distributed throughout the blood sample rather than being confined within the red blood cells. The normal ranges of these measures differ between men and women, who lose blood during their reproductive years by menstruation and in childbirth.

Oxygen sensing

It has been known since early in the 20th century that the haematocrit in each sex is precisely controlled by oxygen, [1] but the details of how cells sense and respond to oxygen availability have only been worked out more recently. A transcription factor known as HIF combines with a 33–base pair chromosomal erythropoietin response element to stimulate synthesis of messenger RNA for erythropoietin synthesis. HIF is a heterodimer with α- and β-subunits, and $HIF_{1\alpha}$ plays a critical role in responsiveness to oxygen. It is synthesised in many kinds of cell – rather than just in cells that secrete erythropoietin – but in well-oxygenated cells it is rapidly oxidised by a prolyl hydroxylase domain-containing protein (PHD)

which is a dioxygenase enzyme that hydroxylates one or other of two proline residues in $HIF_{1\alpha}$ while adding the other atom of oxygen from molecular O_2 to 2-oxoglutarate (α-ketoglutarate) converting this to succinate (**Fig. 24.1**).

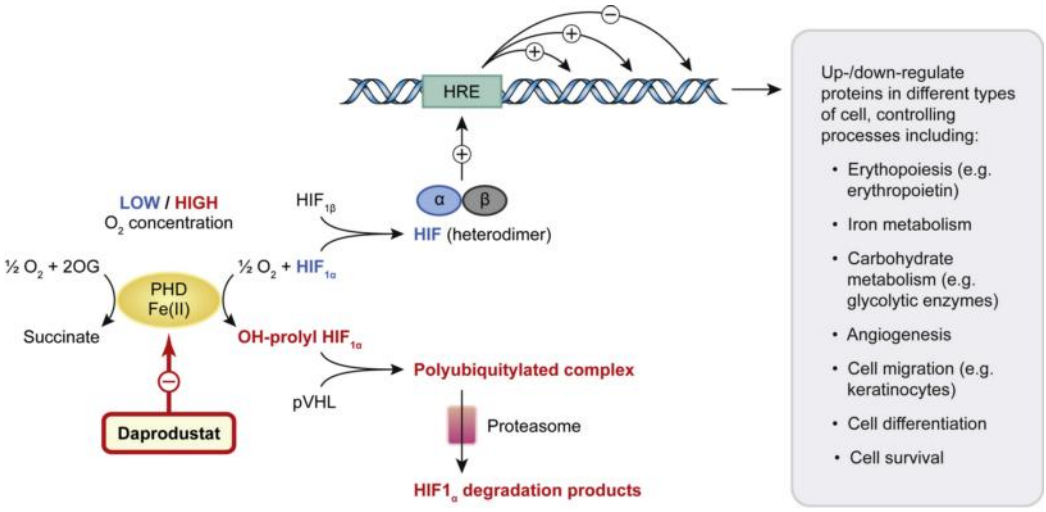

FIG 24.1 Oxygen-sensitive control of erythropoiesis by PHD/HIF.O_2 combines with Fe(II) in the active site of PHD, the oxygen sensor. At high tissue O_2 concentrations *(red)* PHD hydroxylates one or other of two prolyl residues in $HIF_{1\alpha}$ while converting 2OG to succinate. Hydroxylation of $HIF_{1\alpha}$ creates a high affinity binding site for pVHD which complexes with it and promotes polyubiquitylation, tagging the complex for destruction by proteasomes. Consequently, the concentration of $HIF_{1\alpha}$ available for combination with $HIF_{1\beta}$ to form the active HIF dimer is low when O_2 concentration is high. The affinity of PHD for O_2 is such that when the tissue O_2 concentration falls (pO_2 < 40 mm Hg – blue in the figure) there is a steep decline in the rate of hydroxylation of $HIF_{1\alpha}$, consequently $HIF_{1\alpha}$ increases, dimerises with $HIF_{1\beta}$ to form HIF which acts in the nucleus on

chromosomal HRE to control the rate of production of erythropoietin and of other proteins involved in the response to hypoxia. *2OG*, 2-Oxoglutarate; *HIF*, hypoxia inducible factor (subunits 1a and 1b); *HRE*, HIF-response element; *PHD*, prolyl hydroxylase domain-containing protein; *pVHL*, von Hippel–Lindau protein.

PHD (also known as EGLN prolyl hydroxylase because of its homology with a gene of the nematode worm *Caenorhabditis elegans*) is the oxygen sensor responsible for the integrated physiological response to tissue hypoxia which includes increased erythropoietin production. It has a non-haem Fe^{2+} atom at its active site which combines with molecular oxygen. Hydroxylation of one or both prolyl residues in $HIF_{1\alpha}$ creates a high-affinity binding site for VHL [2] protein (pVHL). pVHL acts as recognition protein for ubiquitin ligase which tags the pVHL/$HIF_{1\alpha}$ complex with ubiquitin molecules ('polyubiquitylation') for destruction by proteasomes in the cytoplasm.

PHD has an affinity for oxygen that quantitatively explains oxygen sensitivity in the physiological range of the cellular environment. It works not as a stimulus to $HIF_{1\alpha}$ synthesis in the absence of oxygen but as the means to its elimination in the presence of oxygen (**Fig 24.1**). Under conditions of low cellular oxygen concentration $HIF_{1\alpha}$ elimination is suppressed, so it accumulates, is transported to the cell nucleus, dimerises with $HIF_{1\beta}$ and the resulting HIF_1 combines with response elements that control not only erythropoietin synthesis but a very large number of

other genes (>3000) as well: it is now known that HIF is a master regulator of many integrated mechanisms including iron metabolism, anaerobic carbohydrate metabolism, cell migration and neovascularisation.

Hypoxia may be generalised (as at high altitude where the inhaled air contains only a low oxygen content or in diseases of the lungs – see **Ch. 28**) or tissue hypoxia may be limited to an anatomical region as in vasoocclusive disease (see Chs **21** and **22**) and in poorly vascularised regions of solid tumours (see **Ch. 57**) or healing wounds. There is thus therapeutic potential in either *potentiating* HIF to treat some forms of anaemia or tissue ischaemia (e.g. by blocking the degradation of $HIF_{1\alpha}$ by inhibiting PHD, see later) or in *blocking* its action, as an anti-cancer strategy (see **Ch. 57**).

Leukopoiesis and thrombopoiesis

Granulocyte-CSF (GCSF), macrophage-CSF (MCSF) and granulocyte-macrophage-CSF (GMCSF) regulate the production of leukocytes; they stimulate precursor cells in the bone marrow to divide and differentiate for release into the bloodstream. Several preparations of GCSF are used therapeutically – see later. Antagonists of GMCSF are being investigated as potential anti-inflammatory and anti-cancer agents. *Thrombopoietin*, a glycoprotein produced by the liver and kidneys, stimulates platelet formation by acting on thrombopoietin receptors on megakaryocytes, the precursors of platelets. The receptor is linked to the JAK/STAT signalling pathway (see **Ch. 3**, **Fig 3.17**) and promotes platelet generation and release into the circulation. Thrombopoietin is not used therapeutically, but other drugs that are

agonists at the thrombopoietin receptor are available for therapeutic use – see later.

Types of Anaemia

Anaemia is characterised by a reduced haemoglobin content in the blood. It may cause fatigue but, especially if it is chronic, is often surprisingly asymptomatic. The commonest cause is blood loss resulting from menstruation, drug treatment (e.g. with **aspirin** or other non-steroidal anti-inflammatory drugs; see **Ch. 25**) or pathological processes such as colonic carcinoma or (especially in developing countries) parasitic infestation (see **Ch. 56**). Pregnancy and child-bearing are important physiological drains on iron reserves. There are several different types of anaemia based on indices of red cell size and haemoglobin content and microscopical examination of a stained blood smear:

- *hypochromic, microcytic anaemia* (small red cells containing low haemoglobin concentration; caused by chronic blood loss giving rise to iron deficiency)
- *macrocytic anaemia* (large red cells, few in number)
- *normochromic normocytic anaemia* (fewer normal-sized red cells, each with a normal haemoglobin content)
- mixed pictures

Further evaluation may include determination of concentrations of ferritin, iron, vitamin B_{12} and folic acid in serum, and microscopic examination of smears of bone marrow. This leads to more precise diagnostic groupings of anaemias into:

- Deficiency of nutrients necessary for haematopoiesis, most importantly:
  - iron
  - folic acid and vitamin B_{12}
  - pyridoxine and vitamin C
- Depression of the bone marrow, commonly caused by:
  - drug toxicity (e.g. cytotoxic drugs, **clozapine**)
  - exposure to radiation, including radiotherapy
  - diseases of the bone marrow (e.g. idiopathic aplastic anaemia, leukaemias)
  - reduced production of, or responsiveness to, erythropoietin (e.g. chronic renal failure, rheumatoid arthritis, AIDS)
- Excessive destruction of red blood cells (i.e. haemolytic anaemia); this has many causes, including *haemoglobinopathies* (such as sickle cell anaemia), adverse reactions to drugs and immune reactions that have gone awry.

Haematinic Agents

The use of haematinic agents is often only an adjunct to treatment of the underlying cause of the anaemia – for example, surgery for colon cancer (a common cause of iron deficiency) or antihelminthic drugs for patients with hookworm (a frequent cause of anaemia in parts of Africa and Asia; see **Ch. 56**). Sometimes treatment consists of stopping an offending drug, for example a non-steroidal anti-inflammatory drug that is causing blood loss from the gastrointestinal tract (see **Ch. 25**).

Iron

Iron is a transition metal with two important properties relevant to its biological role, namely its ability to exist in several oxidation states and to form stable coordination complexes.

The body of a 70-kg man contains about 4 g of iron, 65% of which circulates in the blood as haemoglobin. About one-half of the remainder is stored in the liver, spleen and bone marrow, chiefly as *ferritin* and *haemosiderin*. The iron in these molecules is available for haemoglobin synthesis. The rest, which is not available for haemoglobin synthesis, is present in myoglobin, cytochromes and various enzymes.

The distribution and turnover of iron in an average adult man are shown in **Table 24.1** and **Fig. 24.2**. The corresponding values in a woman are approximately 45% less. Because most of the iron in the body is either part of – or destined to be part of – haemoglobin, the most obvious clinical result of iron deficiency is anaemia, and the only indication for therapy with iron is for treatment or prophylaxis of iron deficiency anaemia.

Haemoglobin is made up of four protein chain subunits (globins), each of which contains one haem moiety. Haem consists of a tetrapyrrole porphyrin ring containing ferrous (Fe^{2+}) iron. Each haem group can carry one oxygen molecule, which is bound reversibly to Fe^{2+} and to a histidine residue in the globin chain. This reversible binding is the basis of oxygen transport.

Iron Turnover and Balance

The normal daily requirement for iron is approximately 5 mg for men and 15 mg for growing children and for menstruating women.

A pregnant woman needs between 2 and 10 times this amount because of the demands of the fetus and increased requirements of the mother. [3] The average diet in Western Europe provides 15–20 mg of iron daily, mostly in meat. Iron in meat is generally present as haem, and about 20%–40% of haem iron is available for absorption.

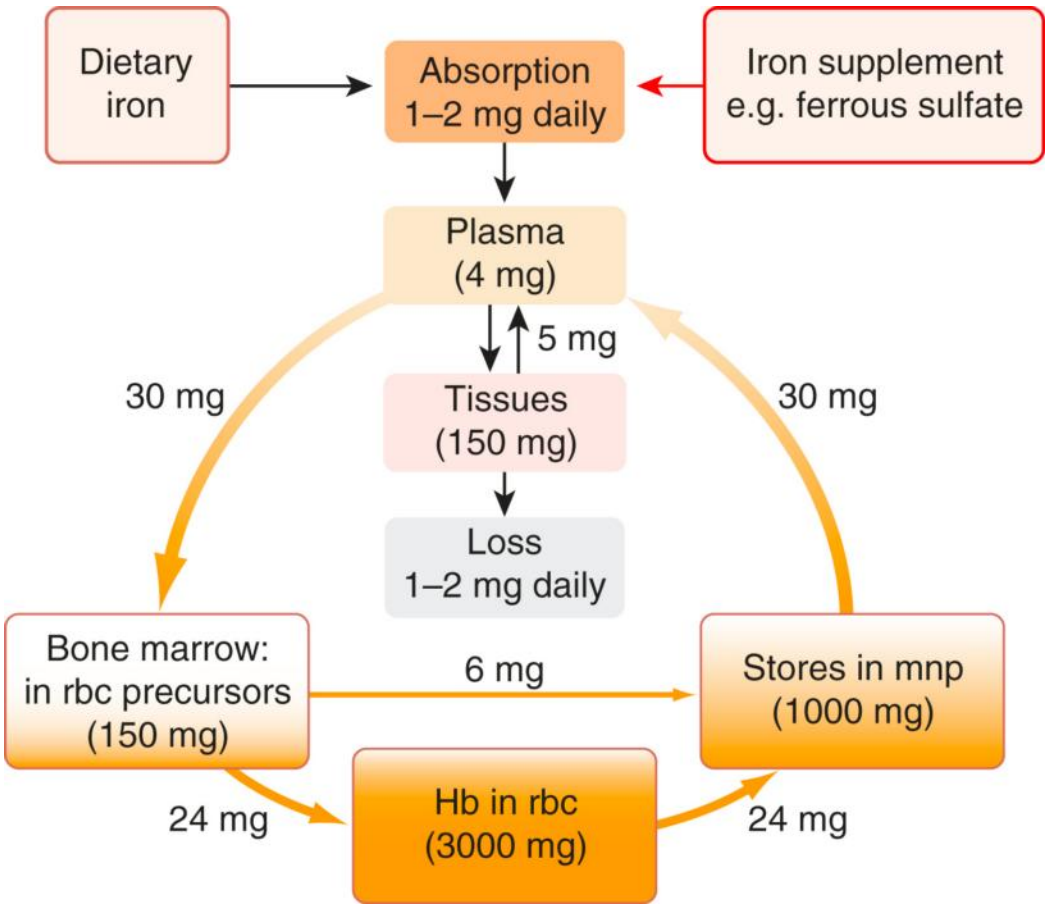

FIG. 24.2 Distribution and turnover of iron in the body.The quantities by the arrows indicate the usual amounts transferred each day. The transfer of 6 mg from red cell precursors to phagocytes represents aborted cells that fail to develop into functional red blood cells. *Hb,* Haemoglobin; *mnp,* mononuclear phagocytes (mainly in liver, spleen and bone marrow); *rbc,* red blood cells.

Table 24.1

Data from Jacobs, A., Worwood, M., 1982. Chapter 5. In: Hardisty, R.M., Weatherall, D.J. (Eds). Blood and Its Disorders. Blackwell Scientific, Oxford.

Humans are adapted to absorb haem iron. It is thought that one reason why modern humans have problems in maintaining iron balance (there are an estimated 500 million people with iron deficiency in the world) is that the change from hunting to grain cultivation 10,000 years ago led to cereals, which contain little utilisable iron, replacing meat in the diet. Non-haem iron in food is mainly in the ferric state, and this needs to be converted to ferrous iron for absorption. Iron salts have low solubility at the neutral pH of the small intestine; however, in the stomach, iron dissolves and binds to a mucoprotein carrier. In the presence of ascorbic acid, fructose and various amino acids, iron is detached from the carrier, forming soluble low-molecular-weight complexes that enable it to remain in soluble form in the intestine. Ascorbic acid stimulates iron absorption partly by forming soluble iron–ascorbate chelates and partly by reducing ferric iron to the more soluble ferrous form. **Tetracycline** (see **Ch. 52**) forms an insoluble iron chelate, impairing absorption of both substances.

The amount of iron in the diet and the various factors affecting its availability are thus important determinants in absorption, but the regulation of iron absorption is a function of the intestinal mucosa, influenced by the body's iron stores. Because there is no mechanism whereby iron excretion is regulated, the absorptive mechanism has

a central role in iron balance as it is the sole mechanism by which body iron is controlled.

Iron absorption takes place in the duodenum and upper jejunum and is a two-stage process involving uptake across the brush border into the mucosal cells, followed by transfer into the plasma. The second stage, which is rate limiting, is energy dependent. Haem iron in the diet is absorbed as intact haem, and the iron is released in the mucosal cell by the action of haem oxidase. Non-haem iron is absorbed in the ferrous state. Within the cell, ferrous iron is oxidised to ferric iron, which is bound to an intracellular carrier, a transferrin-like protein; the iron is then either held in storage in the mucosal cell as *ferritin* (if body stores of iron are high) or passed on to the plasma (if iron stores are low).

Iron is carried in the plasma bound to *transferrin*, a β-globulin with two binding sites for ferric iron. The binding sites are normally only approximately 30% saturated. Plasma contains 4 mg of iron at any one time, but the daily turnover is about 30 mg (see **Fig. 24.2**). Most of the iron that enters the plasma is derived from macrophages which have engulfed and processed time-expired erythrocytes. Intestinal absorption and mobilisation of iron from storage depots contribute only small amounts. Most of the iron that leaves the plasma each day is used for haemoglobin synthesis by red cell precursors (erythroblasts). These have receptors that bind transferrin, releasing it again when its cargo of iron has been captured.

Iron is stored in two forms: soluble ferritin and insoluble *haemosiderin*. Ferritin is present in all cells, the macrophages of liver, spleen and bone marrow containing especially high

concentrations. It is also present in plasma. The precursor of ferritin, *apoferritin*, is a protein of molecular weight 450,000, composed of 24 identical polypeptide subunits that enclose a cavity in which up to 4500 iron atoms can be stored. Apoferritin takes up ferrous iron, oxidises it and deposits the ferric iron in its core. In this form, it constitutes ferritin, the primary storage form of iron, from which the iron is most readily available. The lifespan of this iron-laden protein is only a few days. Haemosiderin is a degraded form of ferritin in which the iron cores of several ferritin molecules have aggregated, following partial disintegration of the outer protein shells.

Iron is not the most soluble of metals, hence its need to bind to transferrin (whilst transferring around the body) and ferritin for use inside cells (ferritin is found mostly inside cells but can exist in the plasma too, functioning to transport iron into cells). Ferritin in plasma contains very little iron, as two-thirds of the body's iron deposits are found within red blood cells, with more ferritin in the body than free unbound iron. The slow turnover of iron absorbed from the diet, transferred around the body by transferrin, then held in cellular storage by ferritin, means that the majority of total useful iron is held in erythrocytes, and their rapid turnover is the main source of liberated iron. Iron bound to plasma ferritin is, however, in equilibrium with the storage ferritin in cells, and its concentration in plasma (normal range 40–100 ng/mL) provides a clinically useful indicator of total body iron stores: values below 40 ng/mL despite normal haemoglobin, red cell morphology, serum iron concentration and transferrin saturation signal mild iron

deficiency, with values below 20 and 10 ng/mL signalling moderate and severe iron deficiency, respectively.

The body has no means of actively excreting iron. Small amounts leave the body through shedding of mucosal cells containing ferritin, and even smaller amounts leave in the bile, sweat and urine. A total of about 1 mg is lost daily. Control of iron balance is therefore critically dependent on the active absorption mechanism in the intestinal mucosa, which is influenced by the iron stores in the body. Iron balance is summarised in **Fig. 24.2**. Since red cells contain approximately 0.6 mg iron per mL of blood, a loss of only a few millilitres of blood per day substantially increases dietary iron requirement.

Administration of Iron

Iron is usually given orally, e.g. as **ferrous sulfate**. Other salts for oral administration are **ferrous succinate**, **gluconate** or **fumarate**.

Parenteral administration of iron (e.g. as **iron-dextran**, **iron-sucrose, ferric carboxymaltose** or **ferric derisomaltose**) by injection or intravenous infusion may be necessary in individuals who are not able to absorb oral iron because of malabsorption syndromes, or as a result of surgical procedures or inflammatory conditions involving the gastrointestinal tract. It is also used for patients who do not tolerate oral preparations, and patients with chronic renal failure or with chemotherapy-induced anaemia who are receiving treatment with erythropoietin (see later). Iron-dextran can be given by deep intramuscular injection or slow intravenous infusion; iron-sucrose is given by slow intravenous infusion. A

small initial dose is given because of the risk of anaphylactoid reaction (see **Ch. 58**). Depending on the preparation used and clinical setting it can be infused as a single total dose (e.g. ferric carboxymaltose) or in divided doses. Ongoing treatment is monitored as needed by measuring haemoglobin and serum iron concentrations.

Unwanted effects

The unwanted effects of oral iron administration are dose related and include nausea, abdominal cramps and diarrhoea. Parenteral iron can cause anaphylactoid reactions (see **Ch. 58**). Free Fe^{3+} is toxic and causes mitochondrial damage and oxidative stress. Iron is an important nutrient for several pathogens and there is concern that excessive iron could worsen the clinical course of infection. Iron treatment is usually avoided during infection for this reason.

Acute iron toxicity, usually seen in young children who have swallowed attractively coloured iron tablets in mistake for sweets, can result in severe necrotising gastritis with vomiting, haemorrhage and diarrhoea, followed by circulatory collapse.

Clinical use of iron

See clinical box.

Clinical uses of iron

To treat iron deficiency anaemia, which can be caused by:

- *chronic blood loss* (e.g. with menorrhagia, hookworm, colon cancer – the cause must be diagnosed and treated specifically in addition to iron treatment);

- *increased demand* (e.g. in pregnancy and early infancy);
- *inadequate dietary intake* (uncommon in developed countries);
- *inadequate absorption* (e.g. following gastrectomy, or in diseases such as coeliac disease, where the intestinal mucosa is damaged by an immunologically based intolerance to the wheat protein gluten).
- Prophylactic use is sometimes appropriate.
- Parenteral iron (as **iron dextran**, **iron sucrose**, **ferric carboxymaltose** or **ferric derisomaltose**) is used if oral preparations are not tolerated or unsuccessful, and is also used in conjunction with an erythropoietin preparation in the management of patients with chronic renal failure or with chemotherapy-induced anaemia (see **Ch. 57**).

Iron overload

Chronic iron toxicity or iron overload occurs in chronic haemolytic anaemias requiring frequent blood transfusions, such as the *thalassaemias* (a large group of genetic disorders of globin chain synthesis) and *haemochromatosis* (a genetic iron storage disease with increased iron absorption, resulting in damage to liver, islets of Langerhans, joints and skin). [4]

The treatment of acute and chronic iron toxicity involves the use of iron chelators such as **desferrioxamine**. These form complexes with ferric iron which are excreted in the urine. Desferrioxamine is not absorbed from the gut. For treating chronic iron overload (e.g. in thalassaemia), it must be given by slow subcutaneous infusion

several times a week. For acute iron overdose of oral iron tablets, it is given intramuscularly or intravenously as well as intragastrically to sequester unabsorbed iron. **Deferiprone** is an orally absorbed iron chelator, used as an alternative treatment for iron overload in patients with thalassaemia major who are unable to tolerate desferrioxamine. Agranulocytosis and other blood dyscrasias are serious potential adverse effects. **Deferasirox** is similar but can cause gastrointestinal bleeding.

Iron

- Iron is important for the synthesis of haemoglobin, myoglobin, cytochromes and other enzymes. Ferric iron (Fe^{3+}) must be converted to ferrous iron (Fe^{2+}) for absorption in the gastrointestinal tract.
- Absorption involves active transport into mucosal cells in the duodenum and jejunum (the upper ileum), from where it can be transported into the plasma and/or stored intracellularly as ferritin.
- Total body iron is controlled exclusively by absorption; in iron deficiency, more is transported into plasma than is stored as ferritin in jejunal mucosa.
- Iron loss occurs mainly by sloughing of ferritin-containing mucosal cells which are eliminated in the faeces.
- Iron in plasma is bound to transferrin, and most is used for erythropoiesis. Some is stored as ferritin in other tissues. Iron from time-expired erythrocytes enters the plasma for reuse.

- The main oral therapeutic preparations are **ferrous sulfate, ferrous fumarate** or **ferrous gluconate**; parenteral preparations include **iron-sucrose, iron dextran, ferric carboxymaltose** or **ferric derisomaltose.** These can be given by intravenous infusion when oral iron is not tolerated or ineffective.
- Unwanted effects include gastrointestinal disturbances. Severe toxic effects occur if large doses are ingested; such acute poisoning can be treated with **desferrioxamine**, an iron chelator, as can chronic iron overload in diseases such as thalassaemia.

Folic Acid and Vitamin B_{12}

Vitamin B_{12} and folic acid are essential constituents of the human diet, being necessary for DNA synthesis and consequently for cell proliferation. Their biochemical actions are interdependent (see 'Vitamin B_{12} and folic acid)' key point box), and treatment with folic acid corrects some, but not all, of the features of vitamin B_{12} deficiency. Deficiency of either vitamin B_{12} or folic acid affects tissues with a rapid cell turnover, particularly bone marrow, but vitamin B_{12} deficiency also causes important neuronal disorders, which are not corrected (or may even be made worse) by treatment with folic acid. Deficiency of either vitamin causes *megaloblastic haematopoiesis*, in which there is disordered erythroblast differentiation and defective erythropoiesis in the bone marrow. Large abnormal erythrocyte precursors appear in the marrow, each with a high RNA:DNA ratio as a result of decreased DNA synthesis.

The circulating abnormal erythrocytes ('macrocytes' – i.e. large red blood cells) are large fragile cells, often distorted in shape. Mild leukopenia and thrombocytopenia (i.e. low white blood cell and platelet counts) usually accompany the anaemia, and the nuclei of polymorphonuclear (PMN) leukocytes are structurally abnormal (hypersegmented – as young PMNs mature, their nuclei acquire 'lobes' in the form of discrete bulges, leading to hypersegmentation in post-mature cells. The nuclei of megaloblasts – the precursors of macrocytic red cells in patients with B_{12} or folate deficiency – are functionally asynchronous and feebly active, compared with the cells' low haemoglobin content). Neurological disorders caused by deficiency of vitamin B_{12} include peripheral neuropathy and dementia, as well as *subacute combined degeneration* [5] of the spinal cord. Folic acid deficiency is caused by dietary deficiency as in alcoholics, and especially if there is increased demand, e.g. during pregnancy – particularly important because of the link between folate deficiency and neural tube defects in the baby (see **Ch. 58**) – or because of chronic haemolysis in patients with haemoglobinopathies such as *sickle cell anaemia* (see later). Vitamin B_{12} deficiency, in contrast, is usually due to decreased absorption (see later).

Folic Acid

Some aspects of folate structure and metabolism are dealt with in **Chapters 51** and **57**, because several important antibacterial and anticancer drugs are antimetabolites that interfere with folate synthesis in microorganisms or tumour cells. Liver and green vegetables are rich sources of folate. In healthy non-pregnant

adults, the daily requirement is about 0.2 mg daily, but this is increased during pregnancy. Healthy fetal neural development in particular requires sufficient folate in the mother's diet to prevent fetal neural tube defects.

Mechanism of action

Reduction of folic acid, catalysed by *dihydrofolate reductase* in two stages, yields *dihydrofolate* (FH_2) and *tetrahydrofolate* (FH_4), co-factors which transfer methyl groups (1-carbon transfers) in several important metabolic pathways. FH_4 is essential for DNA synthesis because of its role as co-factor in the synthesis of purines and pyrimidines. It is also necessary for reactions involved in amino acid metabolism.

FH_4 is important for the conversion of deoxyuridylate monophosphate (DUMP) to deoxythymidylate monophosphate (DTMP). This reaction is rate limiting in mammalian DNA synthesis and is catalysed by thymidylate synthetase, with FH_4 acting as methyl donor (see **Fig 57.6**).

Pharmacokinetic aspects

Therapeutically, folic acid is given orally and is absorbed in the ileum. Methyl-FH_4 is the form in which folate is usually carried in blood and which enters cells. It is functionally inactive until it is demethylated in a vitamin B_{12}-dependent reaction (see later). Folate is taken up into hepatocytes and bone marrow cells by active transport. Within the cells, folic acid is reduced and formylated before being converted to the active polyglutamate form. **Folinic acid**, a synthetic FH_4, is converted much more rapidly to the polyglutamate form.

Unwanted effects

Unwanted effects do not occur even with large doses of folic acid – except in the presence of vitamin B_{12} deficiency, when administration of folic acid may improve the anaemia while possibly exacerbating the neurological degeneration. It is therefore important to determine whether a megaloblastic anaemia is caused by folate or vitamin B_{12} deficiency and treat accordingly.

Clinical uses of folic acid and vitamin B_{12} (hydroxocobalamin)

Folic acid

- Treatment of megaloblastic anaemia resulting from folate deficiency, which can be caused by:
  - *poor diet* (common in alcoholic individuals)
  - *malabsorption syndromes*
  - drugs (e.g. **phenytoin**).
- Treatment or prevention of toxicity from **methotrexate**, a folate antagonist (see Chs **25** and **57**).
- Prophylactically in individuals at hazard from developing folate deficiency, for example:
  - *pregnant women* and *before conception* (especially if there is a risk of birth defects)
  - *premature infants*
  - patients with *severe chronic haemolytic anaemias*, including haemoglobinopathies (e.g. sickle cell anaemia).

Vitamin B_{12} (hydroxocobalamin)

- Treatment of *pernicious anaemia* and other causes of vitamin B_{12} deficiency.
- Prophylactically after surgical operations that remove the site of production of intrinsic factor (the stomach) or of vitamin B_{12} absorption (the terminal ileum).

Vitamin B_{12}

Vitamin B_{12}, also called cobalamin, corrects pernicious anaemia. The vitamin B_{12} preparation used therapeutically is **hydroxocobalamin,** derived from cultured microorganisms. The principal dietary sources are meat (particularly liver, where it is stored), eggs and dairy products. For activity, cobalamins must be converted to *methylcobalamin* (methyl-B_{12}) or *5′-deoxyadenosylcobalamin* (ado-B_{12}). The average European diet contains 5–25 µg of vitamin B_{12} per day, and the daily requirement is 2–3 µg. Absorption requires *intrinsic factor* (a glycoprotein secreted by gastric parietal cells). Vitamin B_{12}, complexed with intrinsic factor, is absorbed by active transport in the terminal ileum. Healthy stomach secretes a large excess of intrinsic factor, but in patients with pernicious anaemia (an autoimmune disorder where the lining of the stomach atrophies), or following total gastrectomy, the supply of intrinsic factor is inadequate to maintain vitamin B_{12} absorption in the long term. Surgical removal of the terminal ileum, for example to treat Crohn's disease (see **Ch. 30**), can also impair B_{12} absorption.

Vitamin B_{12} is carried in the plasma by binding proteins called *transcobalamins*. It is stored in the liver, the total amount in the body being about 4 mg. This store is so large compared with the daily requirement, that if vitamin B_{12} absorption stops suddenly – as after a total gastrectomy – it takes 2–4 years for evidence of deficiency to become manifest.

Mechanism of action

Vitamin B_{12} is required for two main biochemical reactions in humans.

The conversion of methyl-FH_4 to FH_4.

The metabolic activities of vitamin B_{12} and folic acid are linked in the synthesis of DNA. It is also through this pathway that folate/vitamin B_{12} treatment can lower plasma homocysteine concentration. Because increased homocysteine concentrations may have undesirable vascular effects (see **Ch. 22**, **Table 22.1**), this has potential therapeutic and public health implications. The reaction involves conversion of both methyl-FH_4 to FH_4 and homocysteine to methionine. The enzyme that accomplishes this *(homocysteine–methionine methyltransferase)* requires vitamin B_{12} as co-factor and methyl-FH_4 as methyl donor. The methyl group from methyl-FH_4 is transferred first to B_{12}, and then to homocysteine to form methionine. Vitamin B_{12} deficiency thus traps folate in the inactive methyl-FH_4 form, thereby depleting the folate polyglutamate coenzymes needed for DNA synthesis. Vitamin B_{12}–dependent methionine synthesis additionally affects the synthesis of folate polyglutamate coenzymes because the preferred substrate for polyglutamate synthesis is formyl-FH_4, and the

conversion of FH_4 to formyl-FH_4 requires a formate donor such as methionine.

Isomerisation of methylmalonyl–coenzyme A (CoA) to succinyl-CoA

This isomerisation reaction is part of a route by which propionate is converted to succinate. Through this pathway, cholesterol, odd-chain fatty acids, some amino acids and thymine can be used for gluconeogenesis or for energy production via the tricarboxylic acid (TCA) cycle. Coenzyme B_{12} (ado-B_{12}) is an essential co-factor, so methylmalonyl-CoA accumulates in vitamin B_{12} deficiency. This distorts the pattern of fatty acid synthesis in neural tissue and may be the basis of neuropathy in vitamin B_{12} deficiency.

Administration of vitamin B_{12}

When vitamin B_{12} is used therapeutically (as **hydroxocobalamin**), it is usually given by injection [6] because, as explained earlier, vitamin B_{12} deficiency commonly results from malabsorption. Patients with pernicious anaemia require life-long therapy, with maintenance injections every 3 months following a loading dose. Replacement of hydroxocobalamin does not cause unwanted effects.

Vitamin B_{12} and folic acid

Both vitamin B_{12} and folic acid are needed for DNA synthesis. Deficiencies particularly affect erythropoiesis, causing macrocytic megaloblastic anaemia.

Folic acid (vitamin B9)

- There is active uptake of folic acid into cells and reduction to tetrahydrofolate (FH_4) by dihydrofolate reductase; extra glutamates are then added.
- Folate polyglutamate is a co-factor (a carrier of 1-carbon units) in the synthesis of purines and pyrimidines (especially thymidylate).

Vitamin B_{12} (hydroxocobalamin)

- Vitamin B_{12} needs intrinsic factor (a glycoprotein) secreted by gastric parietal cells for absorption in the terminal ileum.
- It is stored in the liver.
- It is required for:
  - conversion of methyl-FH_4 (inactive form of FH_4) to active formyl-FH_4, which, after polyglutamation, is a co-factor in the synthesis of purines and pyrimidines;
  - isomerisation of methylmalonyl-CoA to succinyl-CoA.
- Deficiency occurs most often in pernicious anaemia, which results from malabsorption caused by lack of intrinsic factor from the stomach. It causes neurological disease as well as anaemia.
- Vitamin B_{12} is given by injection every 3 months to treat pernicious anaemia.

Haematopoietic Growth Factors

Every 60 s, a human being must generate about 120 million granulocytes and 150 million erythrocytes, as well as numerous

mononuclear cells and platelets. [7] The cells responsible for this remarkable productivity are derived from a relatively small number of self-renewing, pluripotent stem cells laid down during embryogenesis. Maintenance of haematopoiesis necessitates a balance between self-renewal of the stem cells on the one hand, and differentiation into the various types of blood cell on the other. The factors involved in controlling this balance are the *haematopoietic growth factors*, which direct the division and maturation of the progeny of these cells down to eight possible lines of development (**Fig. 24.3**). These cytokine growth factors are highly potent glycoproteins, acting at concentrations of 10^{-12} to 10^{-10} mol/L. They are present in plasma at very low concentrations under basal conditions, but on stimulation their concentrations can increase within hours by 1000-fold or more. *Erythropoietin* regulates the red cell line, and the signal for its production is blood loss and/or low tissue oxygen tension (see earlier). *CSFs* regulate the myeloid divisions of the white cell line, and the main stimulus for their production is infection (see also **Ch. 7**).

Recombinant erythropoietin (**epoetin**) [8] and recombinant granulocyte CSF (**filgrastim**, **lenograstim**, **pegfilgrastim**) are used clinically (see later); *thrombopoietin* has been manufactured in recombinant form but there are concerns about effects on tumour progression (it activates a cell surface protein that is an oncogene product) and it has been associated with severe immunologically mediated adverse effects. **Romiplostim** is a fusion protein that is an agonist at the thrombopoietin receptor and licensed for use by specialists for patients with immune (idiopathic) thrombocytopenic purpura (ITP) refractory to other treatments

such as glucocorticoids, immunoglobulins and splenectomy. It is administered subcutaneously. **Eltrombopag** is a small molecule agonist at thrombopoietin receptors, given by mouth, and licensed for use under expert supervision for adult and child ITP patients. It has also been used for patients with thrombocytopenia and cirrhosis associated with hepatitis C to increase platelet count to enable antiviral treatment (**McHutchison et al., 2007**). More recently it was licensed by the FDA for patients with aplastic anaemia unresponsive to immunosuppressive treatment in whom, interestingly, it increases cell counts of red and white blood cells as well as platelets and may produce a prolonged beneficial effect (**Desmond et al., 2014**).

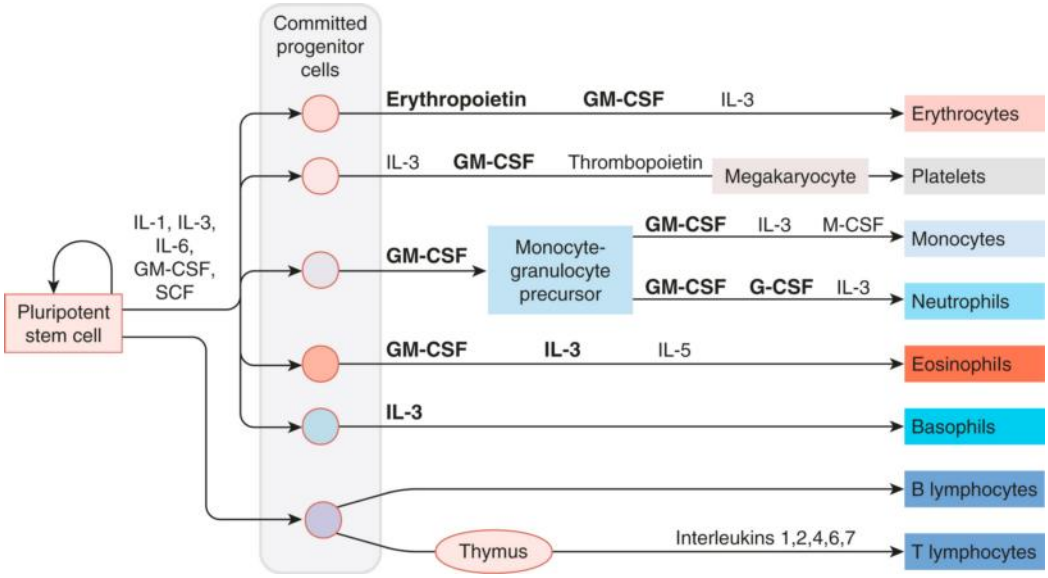

FIG. 24.3 Haematopoietic growth factors in blood cell differentiation.Various preparations of the factors shown in bold are in clinical use (see text). Most T cells generated in the thymus die by apoptosis; those that emerge are either CD4 or CD8 T cells. The colours used for the mature blood cells reflect how they appear in common staining preparations (and after which some are named). *CSF,* Colony-stimulating factor; *G-CSF,* granulocyte CSF; *GM-CSF*, granulocyte–macrophage CSF; *IL-1,* interleukin-1; *IL-3,* interleukin-3 or multi-CSF; *M-CSF,* macrophage CSF; *SCF,* stem cell factor. (See also **Ch. 7**.)

Some of the other haematopoietic growth factors (e.g. interleukin-3, interleukin-5 and various other cytokines) are covered in **Chapter 7**.

Erythropoietin

Erythropoietin is a glycoprotein produced in juxtatubular fibroblast cells in the kidney and also in macrophages; it stimulates committed erythroid progenitor cells to proliferate and generate erythrocytes (see **Fig. 24.3**). Recombinant human erythropoietins (epoietins) are made in cultured mammalian cells because their pharmacokinetic properties depend critically on the degree of glycosylation, a post-translational modification that occurs in mammalian but not so predictably in bacterial cells. They are used to treat anaemia caused by erythropoietin deficiency, for example in patients with chronic kidney disease, AIDS or cancer. Epoietins exist in several forms (alpha, beta, theta and zeta) with plasma half-lives of about 5 h. They are administered by injection three times weekly for convenience as this is the usual frequency of haemodialysis. **Darbepoetin**, a hyperglycosylated form, has a longer half-life (20–70 h) and can be administered less frequently, every 1–4 weeks; **methoxy polyethylene glycol-epoetin beta** is another preparation with an even longer half-life. Epoetin and darbepoetin are given intravenously or subcutaneously, the response being greater after subcutaneous injection and faster after intravenous injection.

Epoietins are reaching the end of patent protection and 'biosimilar' products have been licensed. Unlike the situation for small-molecule chemical entities where criteria for bioequivalence are relatively uncontroversial – see **Chapter 9** – biologically produced macromolecules may vary markedly with seemingly minor changes in manufacture and have many opportunities to form immunologically distinct products during cell culture (see **Ch. 5**).

Unwanted effects

Transient influenza-like symptoms are common. Hypertension is also common and can cause encephalopathy with headache, disorientation and sometimes convulsions. Iron deficiency can be induced because more iron is required for the enhanced erythropoiesis. Blood viscosity increases as the haematocrit rises, increasing the risk of thrombosis, especially during dialysis. While anaemia in patients with chronic renal disease is associated with an increased risk of cardiovascular events, it has not been shown that correction of renal anaemia by treatment with epoetin -alpha or -beta or with darbepoetin with iron reduces this risk, and indeed there is evidence that normalisation of haemoglobin concentration in such patients may worsen cardiovascular risk especially of stroke (**Drüeke et al., 2006**; **Pfeffer et al., 2009**; **Singh et al., 2006**).

There have been reports of a devastating chronic condition known as pure red cell aplasia (PRCA), connected with the development of neutralising antibodies directed against erythropoietin which inactivate the endogenous hormone as well as the recombinant product (**Berns, 2013**). This has been a huge concern with indirect implications for quality control between batches of biological products and, indirectly, for the licensing of biosimilar products. Before 1998, only three cases of PRCA in association with epoetin treatment had been published. In that year, in response to concerns about transmitting bovine spongiform encephalopathy (‘mad cow disease’), the formulation of the leading brand was changed, human serum albumin (used to stabilise the product) being replaced by polysorbate 80 and glycine. The incidence of PRCA increased

abruptly (**Fig 24.4**), with approximately 250 documented cases by 2002, many of whom died or became completely dependent on blood transfusions. A large proportion had been treated with the new formulation. The mechanism whereby the manufacturing change led to the change in immunogenicity remains a matter of debate (**Locatelli et al., 2007**), but the packaging and storage were changed again in 2003, since when the incidence of PRCA has declined abruptly to baseline level (**Fig. 24.4**). The moral is that immunogenicity is unpredictable and can be caused by seemingly minor changes in manufacture or storage (**Kuhlmann and Marre, 2010**).

Clinical use

Iron or folate deficiency must be corrected before starting treatment. Parenteral iron preparations are often needed (see earlier). Haemoglobin must be monitored and maintained within the range 10–12 g/dL (i.e. less than the normal range) to minimise the unwanted cardiovascular effects described earlier. The clinical use of epoetin is given in the clinical box.

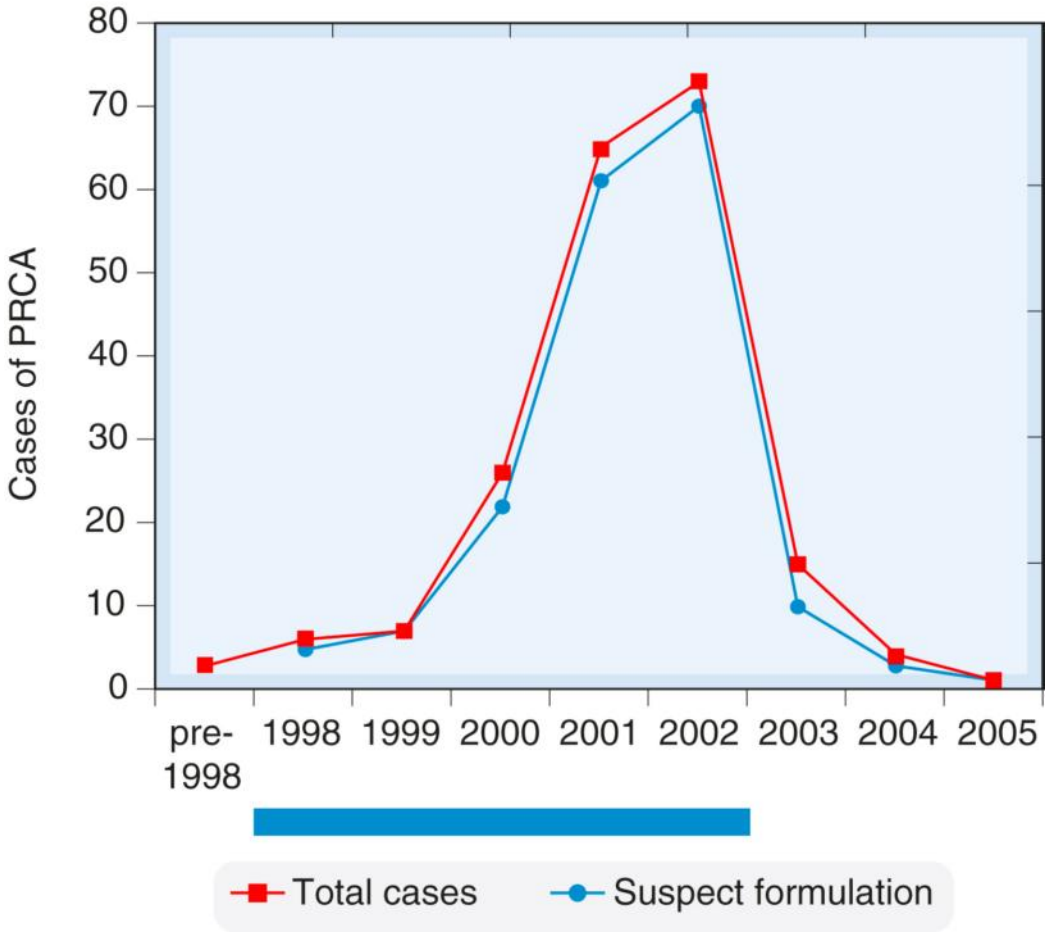

FIG. 24.4 Incidence of pure red cell aplasia (PRCA) in relation to introduction in 1998 of a changed formulation of the leading brand of epoetin.The incidence increased markedly and the suspect formulation *(blue)* accounted for almost all of the cases that were positive for anti-erythropoietin antibody *(red)*; the formulation and instructions for its administration and storage were changed again in 2003 with an abrupt subsequent decline in PRCA. The period when the suspect formulation was in use is indicated by the *blue rectangle*. Redrawn from

Kuhlmann, M., Marre, M., 2010. Lessons learned from biosimilar epoietins and insulins. Br. J. Diab. Vasc. Dis. 10, 90–97.

New directions in treating the anaemia of chronic kidney disease

As explained earlier, while epoetins with iron are very effective in increasing the haemoglobin concentration when treating the anaemia of chronic kidney disease, it is of concern that this does not correct and indeed may exacerbate the increased cardiovascular risk of such patients. This is currently mitigated by selecting a target haemoglobin below the normal range found in healthy people but achieving and maintaining this is exacting and may leave patients symptomatic. The anaemia of chronic renal disease is multifactorial with the important contribution of reduced erythropoietin combined with abnormal iron metabolism and increased iron loss particularly in patients requiring chronic haemodialysis. It is possible that potentiating HIF could favourably influence iron metabolism as well as increase endogenous erythropoietin, since HIF also controls other aspects of iron metabolism. Inhibition of PHD increases $HIF_{1\alpha}$ by reducing its degradation (**Fig 24.1**), and an oral inhibitor, daprodustat was approved in 2023 by the FDA, and is the first oral treatment for anaemia caused by chronic kidney disease. It is not yet known if its use will be associated with improved cardiovascular outcomes compared with epoietin (**Chen et al., 2019a**, **2019b**). Other HIF prolyl hydroxylase inhibitors are also undergoing phase 3 studies.

Colony-Stimulating Factors

CSFs are cytokines that stimulate the formation of maturing colonies of leukocytes, observable in tissue culture. They not only stimulate particular committed progenitor cells to proliferate (see **Fig. 24.3**) but also cause irreversible differentiation. The responding precursor cells have membrane receptors for specific CSFs and may express receptors for more than one factor, permitting collaborative interactions.

Granulocyte CSF is produced mainly by monocytes, fibroblasts and endothelial cells, and controls primarily the development of neutrophils, increasing their proliferation and maturation, stimulating their release from bone marrow storage pools and enhancing their function. Recombinant forms (**filgrastim**, which is not glycosylated, and glycosylated **lenograstim**) are used therapeutically. **Pegfilgrastim** is a derivative of filgrastim conjugated with polyethylene glycol ('pegylated') which slows its elimination, increasing its duration of action.

Thrombopoietin, made in liver and kidney, stimulates proliferation and maturation of megakaryocytes to form platelets. Recombinant thrombopoietin has been a tempting but horribly deceptive therapeutic target. Thrombocytopenia occurs in an autoimmune disorder known as immune (previously 'idiopathic') thrombocytopenic purpura (ITP) which is associated with a risk of severe spontaneous haemorrhage. Thrombocytopenia is also a predictable and limiting toxicity of many chemotherapeutic regimens in oncology (see **Ch. 57**), so a means to mitigate this would be a valuable prize. Recombinant thrombopoietin, seemingly the logical answer to this need, was manufactured and increased

platelet counts in healthy volunteers and patients with mild chemotherapy-induced thrombocytopenia. But in early trials on healthy subjects, repeated dosing of a pegylated product caused the appearance of neutralising antibodies and consequently prolonged thrombocytopenia (**Li et al., 2001**), driving home the message from experience with erythropoietin (see **Fig. 24.4**) that subtle differences between biological products and natural mediators can lead to very serious immunologically mediated adverse effects. **Eltrombopag** (a small-molecule agonist administered orally) and **romiplostim** (a dimerised fusion protein analogue) are licensed as safe and effective therapeutic options for use in ITP. They bind to and activate thrombopoietin receptors which signal via the JAK/STAT pathway. Romiplostim is administered by subcutaneous injection. Both of these agonists are approved for treatment of patients with ITP who have not responded to other treatments such as immunosuppression by glucocorticoids (see **Ch. 33**), or splenectomy; eltrombopag is also used to increase platelet counts for aplastic anaemia and increases white and red blood cell counts as well as platelets in some such patients.

Administration and unwanted effects

Filgrastim and lenograstim are given subcutaneously or by intravenous infusion. Pegfilgrastim is administered subcutaneously. Gastrointestinal effects, fever, bone pain, myalgia and rash are recognised adverse effects; less common effects include pulmonary infiltrates and enlargement of liver or spleen.

Haematopoietic growth factors

Erythropoietin

- A hormone synthesised in the kidney and deficient in chronic kidney failure.
- Stimulates red cell production via receptors on the surface of red cell precursors.
- Its synthesis is controlled by HIF, a heterodimer controlled by PHD, the physiological oxygen sensor of the oxygen concentration of tissues. HIF is a transcription factor produced in many cell types and which controls a large number of genes implicated in responses to hypoxia.
- Is available, as epoetin or as a hyperglycosylated form **darbepoetin**, to treat patients with anaemia caused by chronic renal failure. The target haemoglobin concentration is lower than the normal range in healthy individuals because full correction of anaemia in such patients increases cardiovascular risk.
- Can cause transient flu-like symptoms, hypertension, iron deficiency (via increased utilisation) and increased blood viscosity.

Granulocyte CSF

- Stimulates neutrophil progenitors.
- Is available as **filgrastim**, **pegfilgrastim** or **lenograstim**; it is given parenterally.

Clinical uses of epoetin

- Anaemia of chronic *renal failure*. Inhibition of the physiological oxygen sensor is an alternative way to treat the anaemia of renal disease. One such inhibitor, **daprodustat**, is administered orally and was licensed recently.
- Anaemia during *chemotherapy* for cancer.
- Prevention of the anaemia that occurs in *premature infants* (unpreserved formulations are used because benzyl alcohol, used as a preservative, has been associated with a fatal toxic syndrome in neonates).
- To increase the yield of autologous blood before *blood donation*.
- Anaemia of *AIDS* (exacerbated by **zidovudine** which is used as an anti-viral).

Clinical uses of the colony-stimulating factors

CSFs are used in specialist centres. Granulocyte colony stimulating factors are used:

- To reduce the severity/duration of neutropenia induced by cytotoxic drugs during:
  - intensive *chemotherapy* necessitating autologous *bone marrow rescue*
  - following *bone marrow transplant*.

- To harvest progenitor cells.
- To expand the number of harvested progenitor cells ex vivo before reinfusing them.
- For persistent neutropenia in advanced HIV infection.
- In aplastic anaemia.

Naturally occurring *thrombopoietin* stimulates megakaryocytes to produce platelets. It is not used clinically, but, as mentioned above, agonists at thrombopoietin receptors, e.g. a small molecule drug **eltrombopag** which is effective when given orally, are licensed for use in children and adults with ITP unresponsive to other treatments. Eltrombopag is also effective in some patients with aplastic anaemia increasing red and white blood cell production as well as platelet production.

Haemolytic Anaemia

Anaemia associated with increased red cell destruction can arise from genetic causes (e.g. sickle cell disease, thalassaemia, PNH) or a variety of non-genetic causes such as autoimmunity, infections and adverse drug reactions.

Sickle cell anaemia is caused by a mutation in the gene that codes the β-globin chain of adult haemoglobin (haemoglobin A), resulting in a single amino acid substitution. The abnormal haemoglobin (haemoglobin S) can polymerise when deoxygenated, changing the physical properties of the red cells (which deform to a sickle shape, hence the name) and damaging their cell membranes. P-selectin, a mediator stored in endothelial cells and platelets, is

released and interacts with P-selectin glycoprotein ligand 1 (PSGL-1), causing the cells to adhere to vessel walls. This can block the microcirculation, causing tissue hypoxia and painful vaso-occlusive crises. Haemolysis also reduces the availability of nitric oxide (see **Ch. 19**) (**Schaer et al., 2013**). Polymerisation, as well as the severity of the disease, is markedly reduced when other forms of haemoglobin (A2 or/and F) are present.

PNH is a rare and previously untreatable form of haemolytic anaemia caused by clonal expansion of haematopoietic stem cells with somatic mutations that prevent formation of glycophosphatidylinositol (GPI), which anchors many proteins to the cell surface, rendering the cell susceptible to complement-mediated haemolysis. In addition to anaemia, patients with PNH suffer from other features, including thrombosis, attacks of abdominal pain and pulmonary hypertension (see **Ch. 21**).

Drugs Used to Treat Haemolytic Anaemias

As in most forms of haemolytic anaemia, treatment is symptomatic (e.g. analgesia for painful crises in patients with sickle cell disease) and supportive, e.g. oxygen therapy, blood transfusion when essential, treatment of iron overload and provision of adequate folate to support increased red cell turnover. Haemolytic anaemia associated with autoantibodies may respond to treatment with glucocorticoids (see **Ch. 33**). Here we mention specific treatments for two haemolytic diseases, ***sickle cell anaemia*** and ***PNH*** , that are of particular clinical importance and pharmacological interest.

Hydroxycarbamide (also known as **hydroxyurea**) is a cytotoxic drug that has been used for decades to lower red cell and

platelet counts in patients with *polycythaemia rubra vera* (a myeloproliferative disorder affecting especially the red cell lineage) or to treat chronic myeloid leukaemia. It is additionally used for sickle cell disease and reduces the frequency of painful crises (**Charache et al., 1995**; **Wang et al., 2011**; **Weatherall, 2011**). Hydroxycarbamide inhibits DNA synthesis by inhibiting *ribonucleotide reductase* and is S-phase specific (see **Ch. 6**). It increases circulating haemoglobin F, while reducing haemoglobin S. Hydroxycarbamide metabolism gives rise to nitric oxide, which may contribute to its beneficial effect in sickle cell disease. Some of its beneficial effect in reducing painful crises could relate to anti-inflammatory effects secondary to its cytotoxic action. Hydroxycarbamide is administered by mouth once daily at a rather lower starting dose than is used for treating malignant disease; reduced doses are used in patients with impaired renal function. The blood count and haemoglobin F are monitored and the dose adjusted accordingly. Once stabilised, treatment may be continued indefinitely.

Myelosuppression, nausea and rashes are the commonest adverse effects. Animal studies demonstrated teratogenicity and potential adverse effects on spermatogenesis. When used to treat malignant disease there is an increased risk of second malignancy, but this has not been observed when treating patients with sickle cell disease.

Crizanlizumab is a humanised monoclonal antibody that binds to P-selectin and blocks its interaction with PSGL-1 (see earlier). Administered intravenously each month it reduces the frequency of painful vaso-occlusive crises compared with placebo among patients with sickle cell disease, regardless of concomitant use of

hydroxyurea (**Ataga et al., 2017**). A subsequent phase 3 study confirmed efficacy with an approximately 40% reduction in crises and crizanlizumab has been approved in the Unites States and Europe.

Treatment of paroxysmal nocturnal haemoglobinuria (PNH)

Eculizumab, licensed for the treatment of PNH, is a humanised monoclonal antibody that blocks the complement protein C5 (see **Ch. 7**). In a double-blind, randomised, controlled trial of 87 patients, treatment with eculizumab dramatically reduced haemolysis and transfusion requirement during 6 months of treatment (**Fig. 24.5**). Patients must be inoculated against meningococcal infection before treatment. It is administered by intravenous infusion weekly for 4 weeks and then approximately every 2 weeks. Serious adverse effects include infection, notably meningococcal infection (the complement system is important in killing *N. meningitidis* organisms which are capsulated Gram-negative diplococci – see **Ch. 52**), but are uncommon. The commonest adverse effects are headache and back pain.

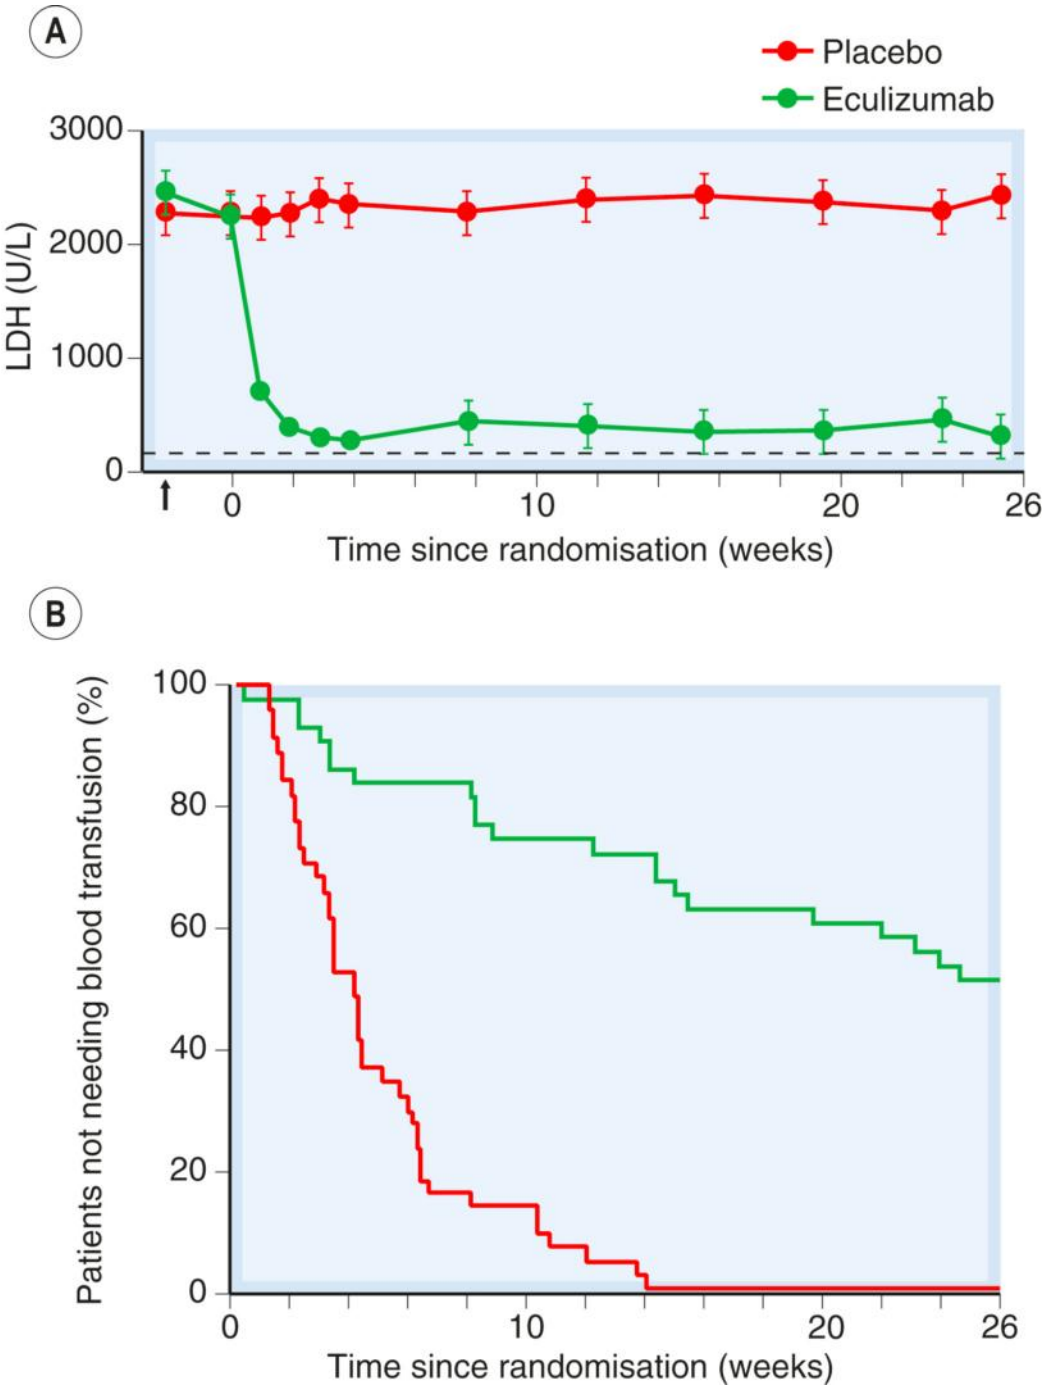

FIG. 24.5 Effect of eculizumab in patients with paroxysmal nocturnal haemoglobinuria (PNH).(A) Effect on plasma lactate dehydrogenase (LDH) activity, a measure of haemolysis. The horizontal dotted line shows the

upper limit of normal. The arrow shows the baseline level at screening (n = 44 in the placebo group, n = 43 in the eculizumab group; p < 0.001). (B) Kaplan–Meier curves for the time to first transfusion during treatment in the same patients shown in (A) (p < 0.001). Redrawn from **Hillmen, P., Young, N.S., Schubert, J., et al., 2006**. The complement inhibitor eculizumab in paroxysmal nocturnal hemoglobinuria. N. Engl. J. Med. 355, 1233–1243.

QUESTIONS

QUESTION 24.1

The haemopoietic system is responsible for the generation and maintenance of blood components.

Which of the following organs or tissues is not key component of haemopoietic system?

OPTIONS:

A. Blood

B. Bone marrow

C. Spleen

D. Lymph nodes

E. Thymus

QUESTION 24.2

The regulation of the haematocrit by erythropoietin is dependent upon transcription factors which sense and respond to oxygen availability.

Which of the following would occur in low oxygen concentrations?

OPTIONS:

A. Dimerisation of $HIF_{1\alpha}$ with $HIF_{1\beta}$

B. Oxidation of $HIF_{1\alpha}$

C. Binding of $HIF_{1\alpha}$ to von Hippel Lindau protein (pVHL)

D. Activation of prolyl hydroxylase domain-containing protein (PHD)

E. Inhibition of $HIF_{1\alpha}$-mediated gene transcription

QUESTION 24.3

Iron is a critical component of haemoglobin and regular dietary intake of iron is important in maintaining haemoglobin levels.

Which of the following statements about the uptake and transport of iron is incorrect?

OPTIONS:

A. The iron content in the body is controlled entirely by the rate of absorption.

B. Iron is required to be in the ferric form to be absorbed in the small intestine.

C. Ascorbic acid increases iron absorption through the formation of soluble chelates.

D. Iron is transported around the body bound to transferrin.

E. Iron is stored inside mononuclear phagocytes in the form of ferritin.

ANSWERS

ANSWER 24.1

RATIONALE:

A. Blood consists of formed elements (red and white blood cells and platelets) and plasma.

B. Site of formation of blood cells.

C.

D. Mature white blood cells migrate to the lymph nodes to maintain defence mechanisms against pathogens.

E. Involved in maturation and selection of T lymphocytes to maintain peripheral tolerance.

CORRECT ANSWER WITH EXPLANATION:

C. Spleen

The spleen, liver and kidneys are not part of the haemopoietic system but are important accessory organs in the production and elimination of blood cells.

ANSWER 24.2

RATIONALE:

A.

B. Oxidation of HIF provides a binding site for pVHL which leads to its degradation.

C. Hydroxylation of one or both prolyl residues in HIF_{1a} creates a high affinity binding site for pVHL which targets the complex for ubiquitination and destruction by proteosomes.

D. PHD is an oxygen sensing enzyme that, in the presence of high oxygen, oxidises HIF leading to its elimination.

E. $HIF_{1\alpha}$ is a transcription factor that drives the transcription of many genes including erythropoietin required for red blood cell production.

CORRECT ANSWER WITH EXPLANATION:

A. Dimerisation of $HIF_{1\alpha}$ with $HIF_{1\beta}$

Dimerisation of the two subunits of HIF forms an active transcription factor that can drive transcription of several genes including erythropoietin required for red blood cell production.

ANSWER 24.3

RATIONALE:

A. There is no regulated excretion mechanism for iron, so levels are largely controlled by intake and absorption.

B.

C. Ascorbic acid displaces iron from the mucoprotein carrier in the stomach to form soluble low-molecular-weight chelates which can be absorbed in the small intestine. It also reduces ferric to ferrous iron.

D. Iron is carried in the plasma bound to transferrin, a β_1-globulin with two binding sites for ferric iron.

E. Iron is stored in the body as soluble ferritin, which is found in all cells but at high concentrations in mononuclear phagocytes in the liver, spleen and bone marrow.

CORRECT ANSWER WITH EXPLANATION:

B. Iron is required to be in the ferric form to be absorbed in the small intestine.

Iron is required to be in the reduced, ferrous form to be absorbed.

---

[1] Discovered by Mabel Purefoy FitzGerald, the only woman scientist in an expedition to Pike's Peak. The men stayed in luxury in an accommodation near the summit while she was assigned to less comfortable quarters lower down, whence she studied the relationship between the altitude of various communities – the determinant of the partial pressure of oxygen in the inhaled air – and the mean haematocrit of the inhabitants. She demonstrated a very sensitive steep linear relationship within each sex. The circumstances are described by Sir Peter Ratcliffe in his 2019 Nobel lecture (https://www.youtube.com/watch?v=-Q0OGLCzKEE). He

shared the prize with Gregg L. Semenza and William Kaelin 'for their discoveries of how cells sense and adapt to oxygen availability'.

[2] VHL disease is a rare single-gene disorder in which pVHD is defective. It is characterised by vascular tumours in the retina, cerebellum, brainstem, kidneys and neuro-endocrine tissue (phaeochromocytomas; see Ch. 15) and in some patients by increased haematocrit.

[3] Each pregnancy 'costs' the mother 680 mg of iron, equivalent to 1300 mL of blood, owing to the demands of the fetus, plus requirements of the expanded blood volume and blood loss at delivery.

[4] 'Bronze diabetes' – where chronic iron overload causing dark skin and diabetes mellitus from damage to the pancreatic islets of Langerhans, is treated by repeated bleeding, one of the few modern uses of this once near-universal 'remedy'; polycythaemia vera (caused by mutations in erythroid progenitors that increase their proliferation) is another.

[5] 'Combined' because the lateral as well as the dorsal columns are involved, giving rise to motor as well as sensory symptoms.

[6] At least in Anglo-Saxon countries; in France, very large doses of vitamin B_{12} are given by mouth to achieve sufficient absorption for therapeutic efficacy despite the absence of intrinsic factor. Either method is a great improvement on eating the prodigious quantities of raw liver required by Minot and Murphy's 'liver diet' of 1925!

[7] That's your entire genome replicated faithfully for at least 200 million new blood cells every minute!

[8] One of the earliest therapeutic agents to be produced by recombinant technology, by Amgen in 1989 – a huge commercial success, heralding the emergence of the biotechnology industry – albeit with some anxious moments (see Fig. 24.4).

25: Anti-inflammatory and immunosuppressant drugs

OVERVIEW

The inflammatory response – essentially a manifestation of the immune system in action – is a protective response, but there are occasions when it is activated inappropriately or outlasts its usefulness. In such cases, we may turn to the anti-inflammatory and immunosuppressive drugs for remedial action. This chapter deals with the main groups of these drugs, together with their therapeutic uses in a range of different inflammatory and immune disorders. While generally associated with conditions such as rheumatoid arthritis, inflammation forms a significant component of many, if not most, of the diseases encountered in the clinic; consequently, anti-inflammatory drugs are extensively employed in virtually all branches of medicine. In UK alone, 1.4 billion items of this type were dispensed in 2020/21 and since some of the drugs in this category are available without prescription from pharmacy counters, the true figure is probably much higher.

Introduction

Anti-inflammatory drugs may be divided conveniently into five major groups:

- Drugs that inhibit the cyclo-oxygenase (COX) enzyme(s) – the *non-steroidal anti-inflammatory drugs* (NSAIDs) and the *coxibs*.
- Antirheumatoid drugs – the so-called *disease-modifying antirheumatic drugs* (DMARDs). This group comprises some synthetic drugs, 'synthetic (s) DMARDs', anticytokine and other biopharmaceutical agents, referred to as 'biologic (b) DMARDs'.
- The glucocorticoids.
- Drugs specifically used to control gout.
- Antihistamines used for the treatment of allergic inflammation.

In this chapter we first describe the therapeutic effects, mechanism of action and unwanted effects common to NSAIDs and then deal in a little more detail with **aspirin**, **paracetamol**, **ibuprofen** as well as drugs that are selective for COX-2. The antirheumatoid drugs comprise a varied group comprising both synthetic and biopharmaceuticals as well as immunosuppressant drugs that are also used to treat other autoimmune diseases and prevent rejection of organ transplants. The glucocorticoids are covered in **Chapters 4** and 33 but are briefly discussed in this chapter. Finally, we consider drugs that are used to control gout and the histamine H_1 receptor antagonists, which are used to treat acute allergic conditions.

Cyclo-Oxygenase Inhibitors

This group includes the ‘traditional’ (in the historical sense) NSAIDs [1] as well as the coxibs, which are more selective for COX-2. NSAIDs, sometimes called *aspirin-like drugs* or *antipyretic analgesics*, are among the most widely used of all medicines. There are now more than 50 different examples on the global market; common examples are listed in **Table 25.1** and some significant NSAID structures are depicted in **Fig. 25.1**. It has been estimated that these drugs constitute 5%–10% of all prescriptions and are taken daily by more than 30 million people worldwide (**McEvoy et al., 2021**).

NSAIDs provide symptomatic relief from fever, pain and swelling in chronic joint disease such as occurs in osteo- and rheumatoid arthritis, as well as in more acute inflammatory conditions such as fractures, sprains, sports and other soft tissue injuries. They are also useful in the treatment of postoperative, dental and menstrual pain, as well as headaches and migraine. Several NSAIDs are available over the counter and are widely used to treat minor aches and pains and other ailments and some are available in different formulations including tablets, injections and gels. Virtually all these drugs, particularly the ‘traditional’ NSAIDs, can have significant unwanted effects, especially in the elderly. Newer agents generally provoke fewer adverse effects.

While there are differences between individual NSAIDs, their primary pharmacology is related to their shared ability to inhibit the fatty acid COX enzyme(s), thereby inhibiting the biosynthesis of prostaglandins and thromboxanes. As explained in **Chapter 17**, there are two common isoforms of this enzyme, COX-1 and COX-2 (although there may be further isoforms as yet uncharacterised).

While they are closely related (>60% sequence identity) and catalyse the same reaction, there are important differences between the expression and role of these two isoforms. COX-1 is a constitutive enzyme expressed in most tissues, including blood platelets. It has a 'housekeeping' role in the body, being involved principally in tissue homeostasis. It is, for example, responsible for the production of prostaglandins involved in gastric cytoprotection (see **Ch. 30**), platelet aggregation (see **Ch. 23**), renal blood flow autoregulation (see **Ch. 29**) and the initiation of parturition (see **Ch. 35**).

In contrast, COX-2 is induced in inflammatory cells when they are activated by (for example) the inflammatory cytokines – interleukin (IL)-1 and tumour necrosis factor (TNF)-α (see **Ch. 17**). Thus, the COX-2 isoform is therefore generally considered to be mainly responsible for the production of the prostanoid mediators of inflammation (**Vane and Botting, 2001**). There are, however, some significant exceptions. COX-2 is constitutively expressed in the kidney, generating prostacyclin (prostaglandin I_2), which plays a part in renal homeostasis (see **Ch. 29**), and also in the central nervous system (CNS), where its function is not yet clear.

Table 25.1

The chemical classes of these NSAIDs are also shown because sometimes they are referred to in this manner.

AS, Ankylosing spondylitis; *COX,* cyclo-oxygenase; *CV,* cardiovascular; *D,* dysmenorrhoea; *G,* acute gout; *GI,* gastrointestinal; *H&M,* headache and migraine; *MS,* musculoskeletal injuries and pain; *NT,* not tested; *OA,* osteoarthritis; *OTC,* over-the-counter; *PO,* postoperative pain; *RA,* rheumatoid arthritis.

Data from British National Formulary, 2021, and COX selectivity data, where tested, from Warner, T.D.,et al, 1999. Proc Natl. Acad. Sci. USA 96, 7563-7568; Warner, T.D., Mitchell, J.A., 2004. FASEB J. 18, 790–804; and Warner, T.D., Mitchell, J.A., 2008. Lancet 371, 270–273.

Although NSAIDs differ in toxicity and degree of patient acceptability and tolerance, with certain provisos, their pharmacological actions are broadly similar. **Aspirin** has other qualitatively different pharmacological actions and **paracetamol** is an interesting exception to the general NSAID stereotype (see later). Some notes on the relative selectivity of several NSAIDs and coxibs are provided in **Table 25.1**.

Mechanism of Action

In 1971, Vane and his colleagues demonstrated that the NSAIDs inhibit prostaglandin biosynthesis by a direct action on the COX enzyme and established the hypothesis that this single action

explained the vast majority of their therapeutic actions and side effects. This has since been confirmed by numerous studies.

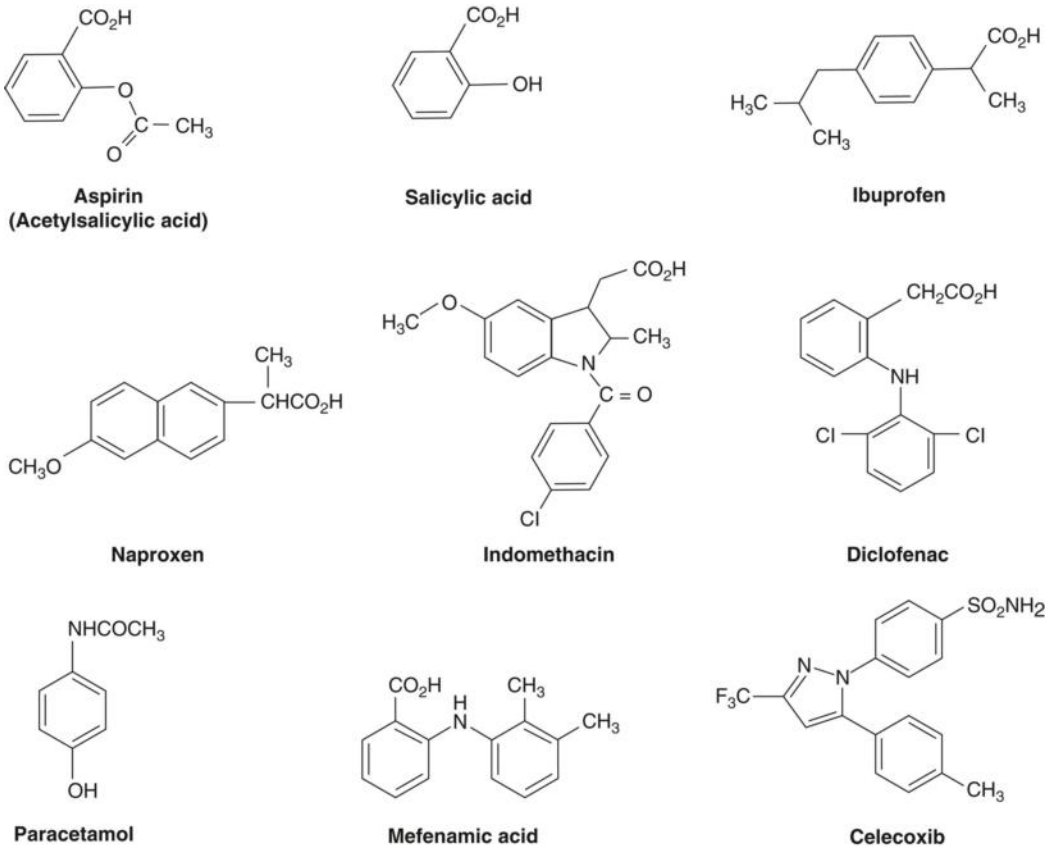

FIG. 25.1 Significant structural features of some non-steroidal anti-inflammatory drugs (NSAIDs) and coxibs. **Aspirin** contains an acetyl group that is responsible for the inactivation of the cyclo-oxygenase (COX) enzyme. **Salicylic acid** is the end product when **aspirin** is de-acetylated but oddly has anti-inflammatory activity in its own right. **Paracetamol** is a commonly used analgesic agent also of simple structure. Most 'classic' NSAIDs are carboxylic acids including **ibuprofen**. Coxibs (**celecoxib** shown here as an example), however, often contain sulfonamide or sulfone groups. These are thought to be important in determining the

selectivity of the molecule as they impede access to the hydrophobic channel in the COX-1 enzyme (see **Fig. 25.2**).

COX enzymes are bifunctional, having two distinct catalytic activities. A *dioxygenase* step is followed by a second, *peroxidase*, reaction (see **Ch. 17**). Both COX-1 and COX-2 are haem-containing enzymes that exist as homodimers attached to intracellular membranes. Interestingly, only one monomer is catalytically active at one time. Binding of NSAIDs to one COX monomer can inhibit the catalytic activity of the entire dimeric complex.

Most NSAIDs inhibit only the initial dioxygenation reaction. They are generally rapid 'competitive reversible' inhibitors of COX-1, but there are differences in their kinetics. Inhibition of COX-2 is generally more time dependent and the inhibition is often irreversible.

Structurally, COX-1 and COX-2 are very similar; both contain a hydrophobic 'channel' into which the arachidonic or other substrate fatty acids dock so that the oxygenation reaction can proceed. To block these enzymes, NSAIDs enter this channel, forming hydrogen bonds with an arginine residue at position 120, thus preventing substrate fatty acids from entering the catalytic domain. However, a single amino acid change (isoleucine to valine at position 523) in the structure of the entrance of this channel in COX-2 results in a 'bulge' in the channel that is not found in COX-1. This is important in understanding why some drugs, especially those with large sulfur-containing side groups (such as **celecoxib**), are more selective for the COX-2 isoform (**Fig. 25.2**). **Aspirin** is, however, an anomaly. It enters the active site and acetylates a serine at

position 530, irreversibly inactivating COX. This is the basis for aspirin's long-lasting effects on platelets. Interestingly, aspirin-inactivated COX-2 can still generate some hydroxyacids but is unable produce the endoperoxide intermediate required for prostanoid synthesis.

Pharmacological Actions

All the NSAIDs have actions very similar to those of **aspirin**, the archetypal NSAID which was introduced into clinical medicine in the 1890s. Their pharmacological profile is listed in the key points box.

Most traditional NSAIDs inhibit both COX-1 and COX-2, although their relative potency against the two isoforms differs. It is believed that the anti-inflammatory action (and probably most analgesic and antipyretic actions) of the NSAIDs are related to inhibition of COX-2, while their physiological effects are largely a result of their inhibition of COX-1. Unfortunately, it is the latter which are often responsible for the unwanted effects of these drugs, particularly those affecting the gastrointestinal (GI) tract. Compounds with a selective inhibitory action on COX-2 show fewer GI side effects, however are by no means as well tolerated as was once hoped.

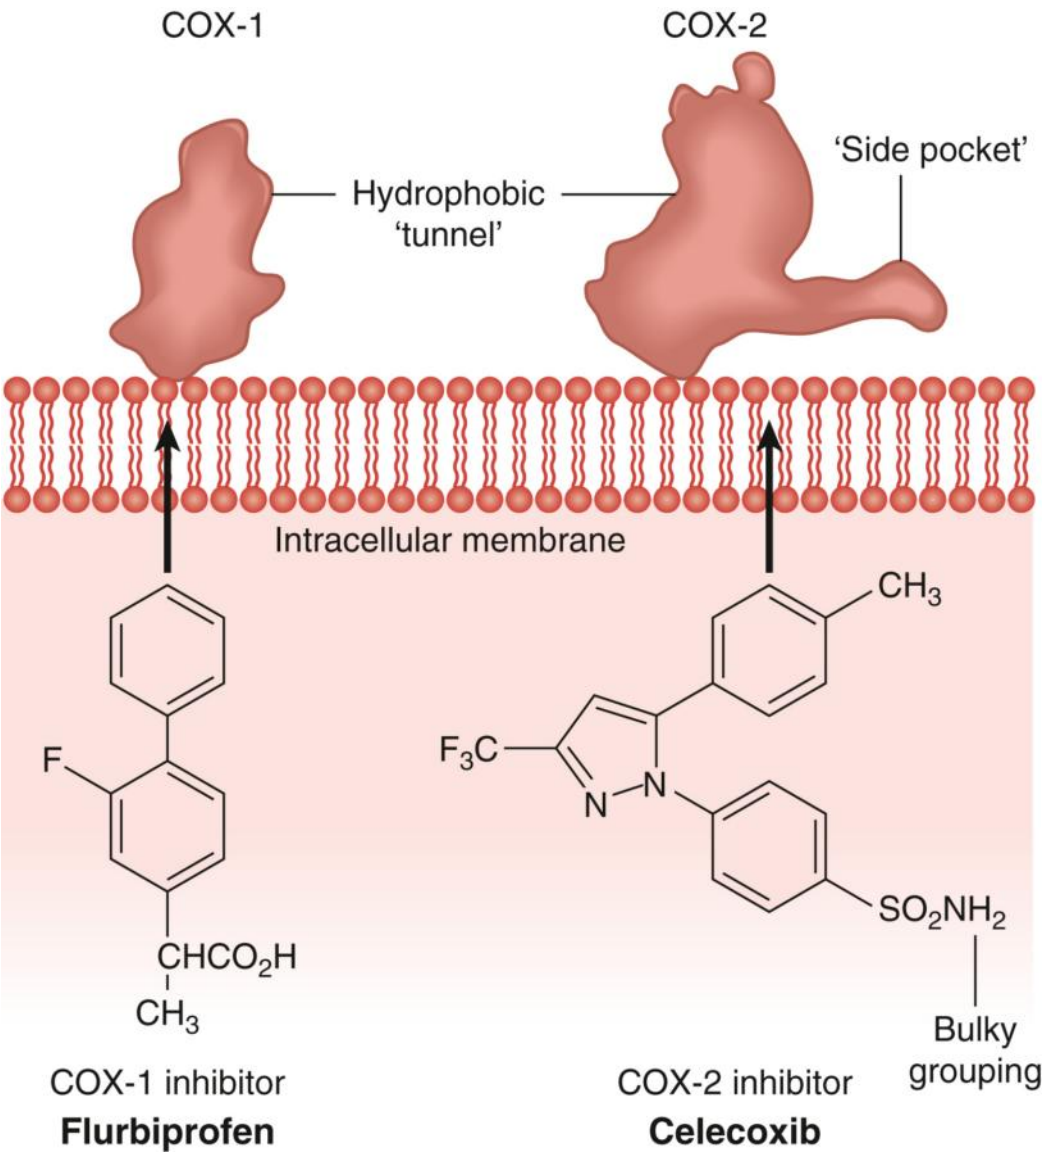

FIG. 25.2 Schematic diagram comparing the binding sites of cyclo-oxygenase (COX)-1 and COX-2.The illustration shows the differences in non-steroidal anti-inflammatory (NSAID) binding sites in the two isoforms. Note that the COX-2 binding site is characterised by a 'side pocket' that can accommodate the relatively 'bulky' groups, such as the sulfonamide moiety of **celecoxib**, which would impede its access to

the COX-1 site. Other NSAIDs, such as **flurbiprofen** (shown here), can enter the active site of either enzyme. After Luong, C., Miller, A., Barnett, J., et al., 1996. Flexibility of the NSAID binding site in the structure of human cyclooxygenase-2. Nat. Struct. Biol. 3, 927–933.

Anti-Inflammatory Effects

As described in **Chapter 17**, many mediators coordinate inflammatory and allergic reactions. The NSAIDs reduce those components in which prostaglandins, mainly derived from COX-2, play a significant part. These include not only the characteristic vasodilatation of inflammation (because of reduced synthesis of vasodilator prostaglandins) but also the oedema because vasodilatation facilitates and potentiates the action of mediators that increase the permeability of postcapillary venules, such as histamine.

Other actions besides inhibition of COX may contribute to the anti-inflammatory effects of some NSAIDs. Reactive oxygen radicals produced by neutrophils and macrophages are implicated in tissue damage in some conditions, and some NSAIDs (e.g. **sulindac**) have oxygen radical-scavenging effects as well as COX inhibitory activity, so may decrease tissue damage. **Aspirin** also inhibits expression of the transcription factor nuclear factor kappa B (NFκB) (see **Ch. 3**), which has a key role in the transcription of the genes for inflammatory mediators. Reports have also emerged of an NSAID binding site on sulfotransferase enzymes (**Wang et al., 2017**) but

the significance of this to the regulation of inflammation has yet to be established.

While NSAIDs suppress the signs and symptoms of inflammation, they have little or no action on the underlying chronic disease itself. As a class, they are generally also without direct effect on other aspects of inflammation, such as cytokine/chemokine release, leukocyte migration and lysosomal enzyme release, which contribute to tissue damage in chronic inflammatory conditions such as rheumatoid arthritis, vasculitis and nephritis. As such they are often a treatment but rarely a cure.

Antipyretic Effects

Neurons in the hypothalamus control the balance between heat production and heat loss, thereby regulating normal body temperature. Fever occurs when there is a disturbance of this hypothalamic 'thermostat', which raises body temperature. NSAIDs reset this thermostat. Once there has been a return to the normal 'set point', the temperature-regulating mechanisms (dilatation of superficial blood vessels, sweating, etc.) then operate to reduce temperature.

The NSAIDs exert their antipyretic action largely through inhibition of prostaglandin production in the hypothalamus (see **Lee and Simmons 2018**). During infection, bacterial endotoxins cause the release from macrophages of IL-1 (see **Ch. 17**). In the hypothalamus this cytokine stimulates the generation of E-type prostaglandins that, through the EP3 receptor, elevate the temperature set point. COX-2 may have a role here, because IL-1 induces this enzyme in the hypothalamic vascular endothelium.

There is some evidence that prostaglandins are not the only mediators of fever, hence NSAIDs may have an additional antipyretic effect through mechanisms as yet undiscovered. Normal body temperature in healthy humans is not affected by NSAIDs. [2]

Analgesic Effects

The NSAIDs are effective against mild or moderate pain, especially that arising from inflammation or tissue damage. Two sites of action have been identified.

Peripherally, NSAIDs decrease production of prostaglandins that sensitise nociceptors to inflammatory mediators such as bradykinin (see Chs **17** and **43**) and they are therefore effective in arthritis, bursitis, pain of muscular and vascular origin, toothache, dysmenorrhoea, the pain of postpartum states and the pain of cancer metastases in bone. All conditions are associated with increased local prostaglandin synthesis probably as a consequence of COX-2 induction. Alone, or in combination with paracetamol or opioids, they decrease postoperative pain and, in some cases, can reduce the requirement for opioids by as much as one-third (see **Thybo et al., 2019** as a recent example). Their ability to relieve headache may be related to the reduction in vasodilator prostaglandins acting on the cerebral vasculature (see **Ch. 42**).

In addition to these peripheral effects, there is a second, less well-characterised (at least in humans) central action in the spinal cord and possibly elsewhere in the CNS. Peripheral inflammatory lesions increase COX-2 expression and prostaglandin release within the cord itself, facilitating transmission from afferent pain fibres to

relay neurons in the dorsal horn (see **Ch. 43** and **Vuilleumier et al., 2018**).

Unwanted Effects

Although generally well tolerated, the overall burden of unwanted side effects from NSAIDs is high, probably reflecting the fact that they are used extensively, often for extended periods of time in an un-supervised manner (being available over the counter), and often by the more vulnerable elderly population. When used for joint diseases (which usually necessitates fairly large doses and sustained treatment), there is a high incidence of side effects – particularly related to the GI tract and cardiovascular system, but also in the liver, kidney, spleen, blood and bone marrow. They may also contribute to less organ-specific pathology such as falls in the elderly, where enhanced surveillance and protective pharmacological strategies are warranted to mitigate risk (see **Wongrakpanich et al., 2018**). The rule for prescribing NAIDS is consequently to use the lowest dose for the shortest possible period of time.

Because prostaglandins are involved in gastric cytoprotection, platelet aggregation, renal vascular autoregulation and induction of labour, all NSAIDs share a broadly similar profile of mechanism-dependent side effects on these processes, although there may be other additional unwanted effects peculiar to individual members of the group. Of note, the relative risk of given side effects (such as cardiovascular events) also appears to vary within the class: information which should influence prescription choice dependent

on the indication and recipient. COX-2-selective drugs have less, but not negligible, GI toxicity.

Therapeutic effects of COX inhibitors

Important NSAIDs include **aspirin**, **ibuprofen**, **naproxen**, **indometacin**, **piroxicam** and **paracetamol**. These drugs inhibit COX enzymes, and therefore prostanoid synthesis, in inflammatory cells. Inhibition of the COX-2 isoform is probably crucial for their therapeutic actions. Agents with more selective inhibition of COX-2 (and thus fewer adverse effects on the GI tract) include **celecoxib** and **etoricoxib**. Class effects include:

- *An anti-inflammatory action*: the decrease in prostaglandin E_2 and prostacyclin reduces vasodilatation and, indirectly, oedema. Accumulation of inflammatory cells is not directly reduced.
- *An analgesic effect*: decreased prostaglandin generation means less sensitisation of nociceptive nerve endings to inflammatory mediators such as bradykinin and 5-hydroxytryptamine. Relief of headache is probably a result of decreased prostaglandin-mediated vasodilatation.
- *An antipyretic effect*: interleukin 1 releases prostaglandins in the CNS, where they elevate the hypothalamic set point for temperature control, thus causing fever.

Gastrointestinal disturbances

Adverse GI events are the commonest unwanted effects of the NSAIDs. They are believed to result mainly from inhibition of gastric COX-1, which synthesises prostaglandins that normally inhibit acid secretion and protect the mucosa (see **Ch. 30**).

Mild symptoms of gastric discomfort ('dyspepsia') and nausea result from gastric mucosal damage, which in some cases progresses to manifest gastric bleeding, ulceration and perforation. It has been estimated that 34%–46% of users of NSAIDs will sustain some GI damage which, while it may be asymptomatic, can carry a risk of morbidity and mortality. Indeed, a recent review identified 400–1000 deaths in the UK each year as a result of this adverse drug reaction (**McEvoy et al., 2021**). Damage is seen whether the drugs are given orally or systemically. However, in some cases (aspirin being a good example), local irritation of the gastric mucosa caused directly by the drug itself may compound the damage. This may partly account for why the use of individual NSAIDs is associated with notably different rates of upper GI complications (see **Henry et al., 1996** and **Castellsague et al., 2012**). Oral administration of 'replacement' prostaglandin analogues such as **misoprostol**, or more commonly co-prescription of proton-pump inhibitors (PPI) or histamine H2-receptor antagonists (see **Ch. 30**), is now routinely employed to diminish the gastric damage produced by NSAIDs, especially in high risk individuals.

Based on extensive experimental evidence, it had been predicted that COX-2-selective agents would provide good anti-inflammatory and analgesic actions with less gastric damage compared to standard NSAIDs. Whilst borne out in large clinical trials of drugs such as celecoxib, the results have not been as clear-cut as had been hoped.

Whilst the risk is reduced it is not eliminated and the need for PPI or alternate gastro-protective strategies is not removed (see **Bakhriansyah et al., 2017**). COX-2-selective agents are also associated with an increased burden of alternate side effects (notably cardiovascular, famously leading to the withdrawal of some agents such as **rofecoxib**). The actual situation following therapy is complex because the degree to which the two COX isoforms are inhibited depends not only upon the intrinsic activity of the drug but the relative inhibitory kinetics. **Warner and Mitchell (2008)** have suggested that the degree to which NSAIDs inhibit COX-1 at the concentration at which they inhibit COX-2 by 80% is the best measure of 'selectivity'. Newer strategies to ameliorate the gastrointestinal side effects of NSAIDs include the addition of nitric oxide (NO) generating moieties (NO-NSAIDS or COX-inhibiting NO-donating drugs; CINODs) or, perhaps more promisingly, the linkage of hydrogen sulfide (H_2S) releasing molecules to NSAIDs (or their derivatives, see **Wallace et al., 2020**). None are currently on the market.

Damage to the small intestine and colon (NSAID enteropathy) may also occur following NSAID treatment, is difficult to prevent pharmacologically and can lead to significant morbidity and mortality, especially if anticoagulants are co-prescribed (**Lanas et al., 2015**). It is not clear if a COX-dependent mechanism is involved.

Hypersensitivity reactions

Approximately 5%–15% of patients exposed to NSAIDs experience hypersensitivity reactions: in fact, some authors believe that the

NSAIDs are the most significant cause of drug-induced hypersensitivity reactions surpassing the β-lactam antibiotics (**Blanca-Lopez et al., 2019**). One manifestation of this is *NSAID-sensitive asthma* or what is now described as NSAID-exacerbated respiratory disease (NERD), characterized by moderate-to-severe asthma, often in association with chronic rhinosinusitis and nasal polyps. The exact mechanism is unknown, but inhibition of COX and overproduction of cysteinyl leukotrienes is implicated (see **Ch. 28**) and pre-existing viral infections may predispose (**Woo et al., 2020**). **Aspirin** is the worst offender but in some, although not all, patients there is cross-reaction with other NSAIDs (except possibly selective COX-2 inhibitors).

Another manifestation of hypersensitivity, skin rashes, is also a common idiosyncratic unwanted effect of NSAIDs, particularly with **mefenamic acid** (10%–15% frequency) and **sulindac** (5%–10% frequency). They vary from mild erythematous, urticarial and photosensitivity reactions to more serious and potentially fatal diseases including *Stevens–Johnson syndrome* (a blistering rash that extends into the gut, see **Ch. 58**), and its more severe form, *toxic epidermal necrolysis* [3] (fortunately very rare). The mechanism is unclear. See (**Laidlaw and Cahill, 2017**) for further reading.

Adverse renal effects

Therapeutic doses of NSAIDs taken for short periods in otherwise healthy individuals pose little threat to kidney function, but in susceptible patients they cause acute renal insufficiency, which is reversible on discontinuing the drug (see **Ch. 58**). This occurs because of inhibition of the biosynthesis of PGE_2 and PGI_2

(prostacyclin) which are involved in the maintenance of renal blood flow, specifically in the PGE_2-mediated compensatory vasodilatation that occurs in response to the action of noradrenaline (norepinephrine) or angiotensin II (see **Ch. 29**). Neonates and the elderly are especially at risk, as are patients with heart, liver or kidney disease, or a reduced circulating blood volume. Concurrent use of drugs affecting the renin-angiotensin system (such as ACE-inhibitors), diuretics or calcineurin inhibitors is an additional risk factor. Whilst classically thought to be reversible on discontinuation of the drug there is now evidence that long term NSAID use may contribute to chronic renal impairment.

Prolonged NSAID consumption, especially NSAID abuse, [4] can cause analgesic nephropathy characterised by interstitial nephritis and renal papillary necrosis (see **Ch. 29**). **Phenacetin** (now withdrawn) was the main culprit; paracetamol, one of its major metabolites, is much less toxic. NSAIDs may also drive electrolyte and acid-base disorders (for instance hyperkalaemia and Type 4 renal tubular acidosis) and elicit the nephrotic syndrome. For comprehensive reviews of the effects of NSAIDs on the kidneys (see **Horl, 2010** and **Baker and Perazella, 2020**).

Cardiovascular side effects

Though aspirin is widely used clinically for its long-lasting antiplatelet action (see later) other NSAIDs lack this property, being associated with an increased rate of thrombotic cardiovascular events (stroke and myocardial infarction), even with short term use. The risk is associated with the relative degree of COX-2 versus COX-1 inhibition, with agents displaying higher COX-2 selectivity (for

instance the coxibs) being the worst offenders. The biology underlying this effect is still debated, however undoubtedly relates to disturbance of the thrombotic tone exerted by vascular endothelial cell-derived anti-thrombotic prostacyclin (generated via COX-1 and COX-2) and platelet-derived pro-thrombotic and vasoconstrictive thromboxane A2 (generated via COX-1 alone) (see **Mitchell et al., 2019**).

NSAIDS oppose the effects of some antihypertensive drugs and also raise blood pressure in patients not taking antihypertensive drugs, thus therefore predisposing to adverse cardiovascular events through a second mechanism. Astonishingly, given the fact that some of these drugs have been in use for half a century or more, this was only recognised as a serious issue during trials of the aforementioned COX-2 inhibitor **rofecoxib** in the early 2000′s. NSAID′s hypertensive effect is dose- and time-dependent and rarely occurs with short-term (i.e. days) administration. Its aetiology is multi-factorial and includes suppression of vasodilatory prostacyclin release as well as modulation of renin release, itself regulated by prostaglandins acting on cells of the macula densa region. The resultant sodium and thus water retention also explains why NSAIDs may precipitate or worsen heart failure. An additional explanation for the blood pressure rise relates to inhibition of renal COX-2 that controls the methylarginine system, itself suppressing the release of cardiotoxic asymmetrical dimethyl arginate (ADMA) by the constitutive nitric oxide synthase (NOS) enzyme (see Kirby et al., 2016 and **Ch. 19**). It is now known that (with the exception of low-dose aspirin) these effects are common to most NSAIDs, especially following prolonged use. Patients with pre-existing

cardiovascular disease are at particular risk. Some drugs (e.g. **naproxen**) appear to be better tolerated in this respect than others (e.g. **diclofenac**) (see **Schjerning et al., 2020**).

Other unwanted effects

Other, much less common, unwanted effects of NSAIDs include CNS effects, bone marrow disturbances and liver disorders, the last being more likely if there is already renal impairment. [5]

Paracetamol overdose causes liver failure. All NSAIDs (except selective COX-2 inhibitors and **paracetamol** in therapeutic doses) prevent platelet aggregation to some extent and therefore may prolong bleeding. Again, **aspirin** is the main problem in this regard and risk is significantly heightened if anti-coagulants are co-prescribed.

General unwanted effects of cyclo-oxygenase (COX) inhibitors

Unwanted effects, many stemming from inhibition of the constitutive housekeeping enzyme COX-1 isoform, are common, particularly in the elderly, and include the following:

- *Dyspepsia, nausea, vomiting* and *other GI effects*. Gastric and intestinal damage may occur with chronic use, with risk of haemorrhage, ulceration and perforation which can be life-threatening. The cause is suppression of gastroprotective prostaglandins in the gastric mucosa.
- *Adverse cardiovascular effects*. These are multi-faceted and occur with effectively all non-steroidal anti-inflammatory

drugs (NSAIDs) and coxibs. Hypertension and increased thrombotic risk drive increased rates of stroke and myocardial infarction. Heart failure is worsened.

- *Hypersensitivity reactions*. NSAIDs are now probably the leading cause of hypersensitivity reactions. Common manifestations include skin reactions and exacerbation of asthma. The mechanism(s) are not fully elucidated but probably involve increasing leukotriene production.
- *Renal effects*. Result from inhibition of prostaglandins (especially I_2/E_2) involved in regulation of renal blood flow and electrolyte resorption. Exert both direct effects (e.g. papillary necrosis) on the kidney and secondary (e.g. fluid retention, raised blood pressure).
- '*Analgesic-associated nephropathy*'. This can occur following long-term high-dose regimes of NSAIDs and is often irreversible.
- *Liver disorders, bone marrow depression*. Transient elevation of liver enzymes may occur with high doses of some NSAIDs. Bone marrow depression is relatively uncommon.

Some Important Nsaids and Coxibs

Table 25.1 lists commonly used NSAIDs, and the clinical uses of the NSAIDs are summarised in the clinical box. We now look at some of the more significant drugs in a little more detail focusing on those with unusual pharmacological properties or those which are readily available at pharmacies and thus (although unprescribed) are consumed in large quantities.

Clinical uses of non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are widely used but cause serious adverse effects (especially GI, renal, pulmonary and cardiovascular effects related to their main pharmacological actions, as well as idiosyncratic effects). Elderly patients and those with pre-existing disorders are at particular risk. The main uses are:

- *Antithrombotic*: e.g. **aspirin** (Ch. 25) for patients at high risk of arterial thrombosis (e.g. following myocardial infarction). Other NSAIDs that cause less profound inhibition of platelet thromboxane synthesis than does **aspirin** *increase* the risk of thrombosis and should be avoided in high-risk individuals if possible.
- *Analgesia* (e.g. for headache, dysmenorrhea, backache, bony metastases, postoperative pain):
  - short-term use: e.g. **aspirin**, **paracetamol**, **ibuprofen**;
  - chronic pain: more potent, longer-lasting drugs (e.g. **naproxen**, **piroxicam**) often combined with a low-potency opioid (e.g. **codeine**, **Ch. 42**);
  - to reduce the requirement for narcotic analgesics (the NSAID **ketorolac** is sometimes given postoperatively for this purpose).
- *Anti-inflammatory*: e.g. **ibuprofen**, **naproxen** for symptomatic relief in rheumatoid arthritis, gout, soft tissue disorders.
- *Antipyretic*: **paracetamol.**

Aspirin

Aspirin (acetylsalicylic acid) was among the earliest drugs to be synthesised and is still one of the most widely consumed drugs worldwide. [6] It is also a common ingredient in proprietary over-the-counter medicines (although increasingly less so). The drug itself is relatively insoluble, but its sodium and calcium salts dissolve readily in aqueous solutions.

While **aspirin** was originally an anti-inflammatory/analgesic workhorse, it is seldom used for this purpose now (except perhaps in migraine), having been supplanted by other, better tolerated, NSAIDs. Today, its main clinical use is as a cardiovascular drug because of its ability to provide a prolonged suppression of platelet COX-1 and hence reduce aggregation (see **Ch. 23**).

While inhibition of platelet function is a feature of most NSAIDs, the effect of **aspirin** is longer lasting because it irreversibly acetylates platelet COX enzymes. While these proteins can be replaced in most cells, platelets, lacking a nucleus (and hence the cellular machinery for making new proteins), are not able to do so, remaining inactivated for their lifetime (approximately 10 days). Since a proportion of platelets is replaced each day from the bone marrow, this inhibition gradually abates but a small daily dose of **aspirin** (e.g. 75 mg/day) is all that is required to suppress platelet function to levels which benefit patients at risk for myocardial infarction and other cardiovascular problems (see **Ch. 22**). The view that even patients not at risk would benefit from taking the drug prophylactically (primary prevention) was challenged in a meta-analysis (**Baigent et al., 2009**) suggesting that in the

general population, the risk from GI bleeding outweighed the protective action. The current guidance reflects this, recommending **aspirin** only as a secondary prevention treatment restricted to patients who have experienced, e.g., an ischaemic episode or who suffer from angina.

The use of **aspirin** has also been canvassed for other conditions. The most significant include:

- *Cancer* – especially colonic and rectal cancer: **aspirin** (and some COX-2 inhibitors) may reduce the incidence of several types of cancer although one always has to be aware of the GI risk (see **Wong, 2019**). Their effect may be related to their anti-inflammatory effect or their inhibitory action on platelets, which are thought to be involved in the metastasis of some cancers.
- *Alzheimer's disease* (see **Ch. 40**): epidemiological evidence suggests that **aspirin** might be beneficial in reducing the rate of cognitive decline in cases of Alzheimer's disease, but not the rate of age-related decline in normal patients (see **Weng et al., 2021**). However, other studies have been less encouraging.

Pharmacokinetic aspects

Aspirin, being a weak acid, is undissociated (i.e. not ionised) in the acid environment of the stomach, thus facilitating its passage across the mucosa. Most absorption, however, occurs in the ileum, because of the extensive surface area of the microvilli.

Aspirin is rapidly (within 30 min) hydrolysed by esterases in plasma and tissues, particularly the liver, yielding **salicylate**. This

compound itself has anti-inflammatory actions (indeed, it was the original anti-inflammatory from which **aspirin** was derived); the mechanism is not clearly understood, although it may depend upon inhibition of the NFκB system (see **Ch. 3**) and only secondarily on COX inhibition. Oral **salicylate** is no longer used for treating inflammation, although it is a component of some topical preparations. Approximately 25% of the salicylate is oxidised; some is conjugated to give the glucuronide or sulfate before excretion, and about 25% is excreted unchanged, the rate of excretion being higher in alkaline urine (see **Ch. 10**).

The plasma half-life of **aspirin** will depend on the dose, but the duration of action is not directly related to the plasma half-life because of the irreversible nature of the action of the acetylation reaction by which it inhibits COX activity.

Unwanted effects

Salicylates (e.g. **aspirin**, **diflunisal** and **sulfasalazine**) may produce both local and systemic toxic effects. In addition to the general unwanted effects of NSAIDs outlined earlier, there are certain specific unwanted effects including *Reye's syndrome*, a rare disorder of children that is characterised by hepatic encephalopathy following an acute viral illness, which carries a 20%–40% mortality. Since the withdrawal of **aspirin** for paediatric use, the incidence of this iatrogenic disease has fallen dramatically.

Salicylism, characterised by tinnitus (high pitched ringing in the ears), vertigo, decreased hearing and sometimes also nausea and vomiting, occurs with overdosage of any **salicylate,** and acute **salicylate** poisoning (which occurs mainly in children and

attempted suicides) constitutes a medical emergency. The mechanism is a major disturbance of acid–base and electrolyte balance. **Salicylates** uncouple oxidative phosphorylation (mainly in skeletal muscle), leading to hyperthermia, increased oxygen consumption and thus increased production of carbon dioxide. This stimulates respiration, which is also increased by a direct action of the drugs on the respiratory centre. The resulting hyperventilation causes a respiratory alkalosis that is normally compensated by renal mechanisms involving increased bicarbonate excretion. Larger doses actually cause a depression of the respiratory centre, less CO_2 is exhaled and therefore it increases in the blood. Because this is superimposed on a reduction in plasma bicarbonate, an uncompensated respiratory acidosis will occur. This may also be complicated by a metabolic acidosis, which results from the accumulation of metabolites of pyruvic, lactic and acetoacetic acids (an indirect consequence of uncoupled oxidative phosphorylation). Hyperthermia secondary to the increased metabolic rate is also likely to be present, and dehydration may follow repeated vomiting. In the CNS, initial stimulation with excitement is followed eventually by coma and respiratory depression. Bleeding can also occur, mainly as a result of depressed platelet aggregation.

Drug interactions

Aspirin may cause a potentially hazardous increase in the effect of **warfarin**, partly by displacing it from plasma protein binding sites (see **Ch. 11**) thereby increasing its effective concentration and partly because its effect on platelets further interferes with haemostasis (see **Ch. 23**). **Aspirin** also antagonises the effect of

some antihypertensive and uricosuric agents such as **probenecid** and **sulfinpyrazone**. Because low doses of **aspirin** may, on their own, reduce urate excretion (see **Ch. 29**), it should not be used in gout.

Aspirin

Aspirin (acetylsalicylic acid) is the oldest NSAID. It acts by irreversibly inactivating COX-1 and COX-2.

Therapeutic effects

- In addition to its anti-inflammatory actions, **aspirin** strongly inhibits platelet aggregation, and its main clinical use now is in the therapy of cardiovascular disease.
- It is given orally and is rapidly absorbed; 75% is metabolised in the liver.
- Elimination of its metabolite **salicylate** follows first-order kinetics with low doses (half-life 4 h), and saturation kinetics with high doses (half-life over 15 h).

Unwanted effects:

- With therapeutic doses: GI symptoms, often including some gastric bleeding (usually slight and asymptomatic). Hypersensitivity reactions.
- With larger doses: dizziness, deafness and tinnitus ('salicylism'); compensatory respiratory alkalosis may occur.
- With toxic doses (e.g. from self-poisoning): uncompensated metabolic acidosis may occur,

particularly in children.

- **Aspirin** has been linked with a rare but serious post-viral encephalitis (Reye's syndrome) in children and is not used in paediatric patients.
- If given concomitantly with warfarin, **aspirin** can cause a potentially hazardous increase in the risk of bleeding.

Paracetamol

Paracetamol (called **acetaminophen** in the United States) is one of the most commonly used non-narcotic analgesic–antipyretic agents and is also a component of many over-the-counter proprietary preparations. In some ways, the drug constitutes an anomaly: while it is an excellent analgesic (see Chs **42** and **43**) and antipyretic, its anti-inflammatory action is slight. It is also substantially free of the gastric and platelet side effects of the other NSAIDs. For these reasons, **paracetamol** is sometimes not classified as an NSAID at all and it's co-administration with traditional NSAIDs is both safe and effective, leading to enhanced analgesia dependent on the context of their use (see **Hyllested et al., 2002**). Paracetamol is also often combined with weak opioids such as **codeine** for the same reason.

The antipyretic and analgesic activities are still not fully understood. Multiple mechanisms have been suggested and include inhibition of prostaglandin biosynthesis in the CNS (where low peroxide concentrations allow paracetamol to act as a reducing agent on COX), activation of descending serotonergic pathways and increased cannabinoid receptor activation (see also **Ch. 43** and **Anderson, 2008**).

Pharmacokinetic aspects

Paracetamol is well absorbed when given orally, with peak plasma concentrations reached in 30–60 min. The plasma half-life of therapeutic doses is 2–4 h, but with toxic doses it may be extended to 4–8 h. **Paracetamol** is inactivated in the liver, being conjugated to give the glucuronide or sulfate. Intravenous preparations of paracetamol are now available but should largely be reserved for those who cannot take the drug orally, clinical studies repeatedly demonstrating no difference in efficacy.

Unwanted effects

With therapeutic doses, side effects are few and uncommon, although allergic skin reactions sometimes occur. It is possible that regular intake of large doses over a long period may cause kidney damage. More seriously, toxic doses (<150 mg/kg, subject to modification by other clinical features) cause potentially fatal hepatotoxicity, and nephrotoxicity. This occurs when normal conjugation reactions are saturated, and the drug is metabolised instead by mixed function oxidases. The resulting toxic metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI), is normally inactivated by conjugation with glutathione, but when this becomes depleted, the toxic intermediate accumulates in the liver and the kidney tubules and causes necrosis. Chronic, but not acute, alcohol consumption can exacerbate paracetamol toxicity by inducing the liver microsomal enzymes producing the toxic metabolite, but the situation here is complex (see **Prescott, 2000**). Paracetamol dosing should be adjusted in those weighing less than 50 kg.

The initial symptoms of acute **paracetamol** poisoning are nausea and vomiting, the hepatotoxicity being a delayed manifestation that occurs 24–72 h later. Further details of the toxic effects are given in **Chapter 58**. If the patient is seen sufficiently soon after ingestion, the liver damage can be prevented by administering agents that increase glutathione formation in the liver, principally **N-acetylcysteine** (NAC) via the intravenous route. If more than 8 h have passed since the ingestion of a large dose, then NAC, which itself can cause adverse effects (anaphylactoid reactions in 10%-50%), is less likely to be useful. Regrettably, ingestion of large amounts of **paracetamol** is a common method of suicide.

Paracetamol

Paracetamol is a commonly used drug that is widely available over the counter. It has potent analgesic and antipyretic actions but much weaker anti-inflammatory effects than other NSAIDs. Its COX inhibitory action seems to be mainly restricted to the CNS enzyme.

- It is given orally (preferentially) or intravenously and metabolised in the liver (half-life 2–4 h).
- Toxic doses cause nausea and vomiting, then, after 24–72 h, potentially fatal liver damage by saturating normal conjugating enzymes, causing the drug to be converted by mixed function oxidases to NAPQI. If not inactivated by conjugation with glutathione, this compound reacts with cellular proteins causing tissue damage.

- Agents that increase glutathione (principally intravenous **acetylcysteine**) can prevent liver damage if given early.

Ibuprofen

Ibuprofen, the 'founder' member of the proprionic acid family of drugs, was first introduced in 1969. Although it has a different type of chemical structure from the salicylates it acts in the same manner by inhibiting COX enzymes. It is a racemic compound but only the S(+) enantiomer is fully active: the R(–) enantiomer is converted to the S(+) enantiomer in the body. It is a non-selective COX inhibitor.

Because of its excellent safety record, **ibuprofen** soon became the most commonly prescribed NSAID and was eventually made available in pharmacies without prescription. It is a versatile drug, being available in various formulations including tablets, liquids, gels for topical application and sterile intravenous formulations. It is now probably the most widely consumed of all the NSAIDs and is used for many indications including dental and postoperative pain, osteo and rheumatoid arthritis, dysmenorrhea, sprains, headache and migraine.

Ibuprofen is well absorbed orally with peak serum concentrations peaking at 1–2 h after administration (cited in **Bushra and Aslam, 2010**). The plasma half-life is 1.8–2.0 h; metabolism mainly occurs in the liver by hydroxylation and carboxylation followed by conjugation and the drug is completely excreted within 24 h. Very little drug is excreted unchanged. The drug is extensively bound to plasma proteins (about 99%) but

unlike many NSAIDs does not displace **warfarin** from its biding sites, making concurrent use of the two drugs easier to manage.

Adverse effects

While considered a 'safe' NSAID, ibuprofen has fundamentally the same mechanism-dependent adverse effect profile as all the other drugs of this type, with GI effects, platelet effects and renal actions being the most prominent.

Coxibs

Coxibs are generally offered to patients for whom treatment with conventional NSAIDs would pose a high probability of serious GI side effects. However, these may still occur with coxibs, perhaps because COX-2 has been implicated in the healing of pre-existing ulcers, so inhibition could delay recovery from earlier lesions. As is the case with all NSAID treatment, cardiovascular risk should be assessed prior to long-term treatment. Several coxibs have been withdrawn following claims of cardiovascular and other toxicity, but three drugs are currently available for clinical use in the United Kingdom and others may be available elsewhere.

Celecoxib and etoricoxib

Celecoxib and **etoricoxib** are used for symptomatic relief in the treatment of osteoarthritis and rheumatoid arthritis and some other conditions.

Both are administered orally and have similar pharmacokinetic profiles, being well absorbed with peak plasma concentrations being achieved within 1–3 h. They are extensively (>99%) metabolised in the liver, and plasma protein binding is high (>90%). Common

unwanted effects may include headache, dizziness, rashes and peripheral oedema caused by fluid retention. Because of the potential role of COX-2 in the healing of ulcers, patients with pre-existing disease should avoid the drugs.

Parecoxib

Parecoxib is a prodrug of **valdecoxib**. The latter drug has now been withdrawn, but **parecoxib** is licensed for the short-term treatment of postoperative pain. It is given by intravenous or intramuscular injection and is rapidly and virtually completely (>95%) converted into the active **valdecoxib** by enzymatic hydrolysis in the liver.

Maximum blood levels are achieved within approximately 30–60 min, depending on the route of administration. Plasma protein binding is high. The active metabolite, **valdecoxib**, has a plasma half-life of about 8 h and is converted in the liver to various inactive metabolites. Skin reactions, some of them serious, have been reported with **valdecoxib**, and patients should be monitored carefully. The drug should also be given with caution to patients with impaired renal function, and renal failure has been reported in connection with this drug. Postoperative anaemia may also occur.

Antirheumatoid Drugs

Rheumatoid arthritis is one of the commonest chronic inflammatory conditions in developed countries, and a common cause of disability. [7] Affected joints become swollen, painful, deformed and immobile. One in three patients with rheumatoid arthritis is likely to become severely disabled. The disease also has

cardiovascular and other systemic manifestations which carry an increased risk of mortality. The degenerative joint changes, which are driven by an autoimmune reaction, are characterised by inflammation, proliferation of the synovium and erosion of cartilage and bone. **Davis and Matteson (2012)** have reviewed the classification and treatment of this miserable and disabling affliction.

The primary inflammatory cytokines, IL-1 and (especially) TNF-α, have a major role in the disease (see **Ch. 7**). A simplified scheme showing the development of rheumatoid arthritis and the sites of action of therapeutic drugs is given in **Fig. 25.3**.

Disease-Modifying Antirheumatic Drugs

Unlike the NSAIDs, which only reduce the symptoms of these disorders, these drugs aim to halt or reverse the underlying disease itself, hence the name 'disease-modifying antirheumatic drugs' [8] (or more conveniently, 'DMARDs'). While originally a heterologous group of synthetic drugs with different chemical structures and mechanisms of action this group has recently been expanded to include the anti-cytokine and other agents. For this reason, this group of drugs is nowadays divided into 'conventional synthetic (cs) DMARDS' and the 'biological (b) DMARDs'. We will consider these groups in turn.

Conventional Synthetic Disease-Modifying Antirheumatic Drugs

The csDMARDs (**Table 25.2**) include **chloroquine** and other antimalarials, **methotrexate**, **sulfasalazine**, **penicillamine, gold compounds**, as well as various immunosuppressant drugs

such as **leflunomide**. This group also comprises a subclass of these drugs which include the *Janus associated tyrosine kinase* (JAK) inhibitors **tofacitinib** and **baricitinib** and which are referred to as *targeted sDMARDs* (tsDMARDs) and which are discussed separately below. Glucocorticoids are also included in the sDMARD category by some reviewers but will not be considered in depth in this chapter. The reader is referred to **Chapters 3** and **33** for more information on these drugs.

Although still licensed in the UK, revision of the *European League Against Rheumatism* (EULAR) treatment guidelines in 2016 suggested that **leflunomide** and **gold compounds** should no longer be used, and so they will not be considered further here.

Despite the evident success of the newer anticytokine bDMARDs, many authors believe that there is little overall difference in efficacy between the bDMARDs and the sDMARDs although many features of their pharmacology such as their side effect profile and pharmacokinetics are evidently so different (**Chatzidionysiou et al., 2017**; **Ramiro et al., 2017**).

The antirheumatoid action of csDMARDs was discovered through a mixture of serendipity and clinical intuition. When they were introduced, nothing was known about their mechanism of action and decades of in vitro experiments have generally resulted in further bewilderment. When successful, csDMARDs generally improve symptoms and reduce disease activity in rheumatoid arthritis, as measured by reduction in the number of swollen and tender joints, pain score, disability score, X-ray appearance and serum concentration of acute-phase proteins and of *rheumatoid factor* (an immunoglobulin M (IgM) antibody against host IgG).

The csDMARDs are sometimes referred to as *second-line drugs*, with the implication that they are only resorted to when other therapies (e.g. NSAIDs) fail, but csDMARD therapy may be initiated as soon as a definite diagnosis has been reached to reduce permanent joint damage and hence future disability. Their clinical effects are usually slow (months) in onset, and it is usual to provide NSAID 'cover' during this induction phase. If therapy is successful (and the success rate is variable), concomitant NSAID (or glucocorticoid) therapy can be reduced. Some csDMARDs (e.g. **methotrexate**) have a place in the treatment of other chronic inflammatory diseases, whereas others (e.g. **penicillamine**) are not thought to have a general anti- inflammatory action. The putative mechanisms of action of csDMARDs have been reviewed by **Cutolo (2002)** and **Chandrashekara (2013)**.

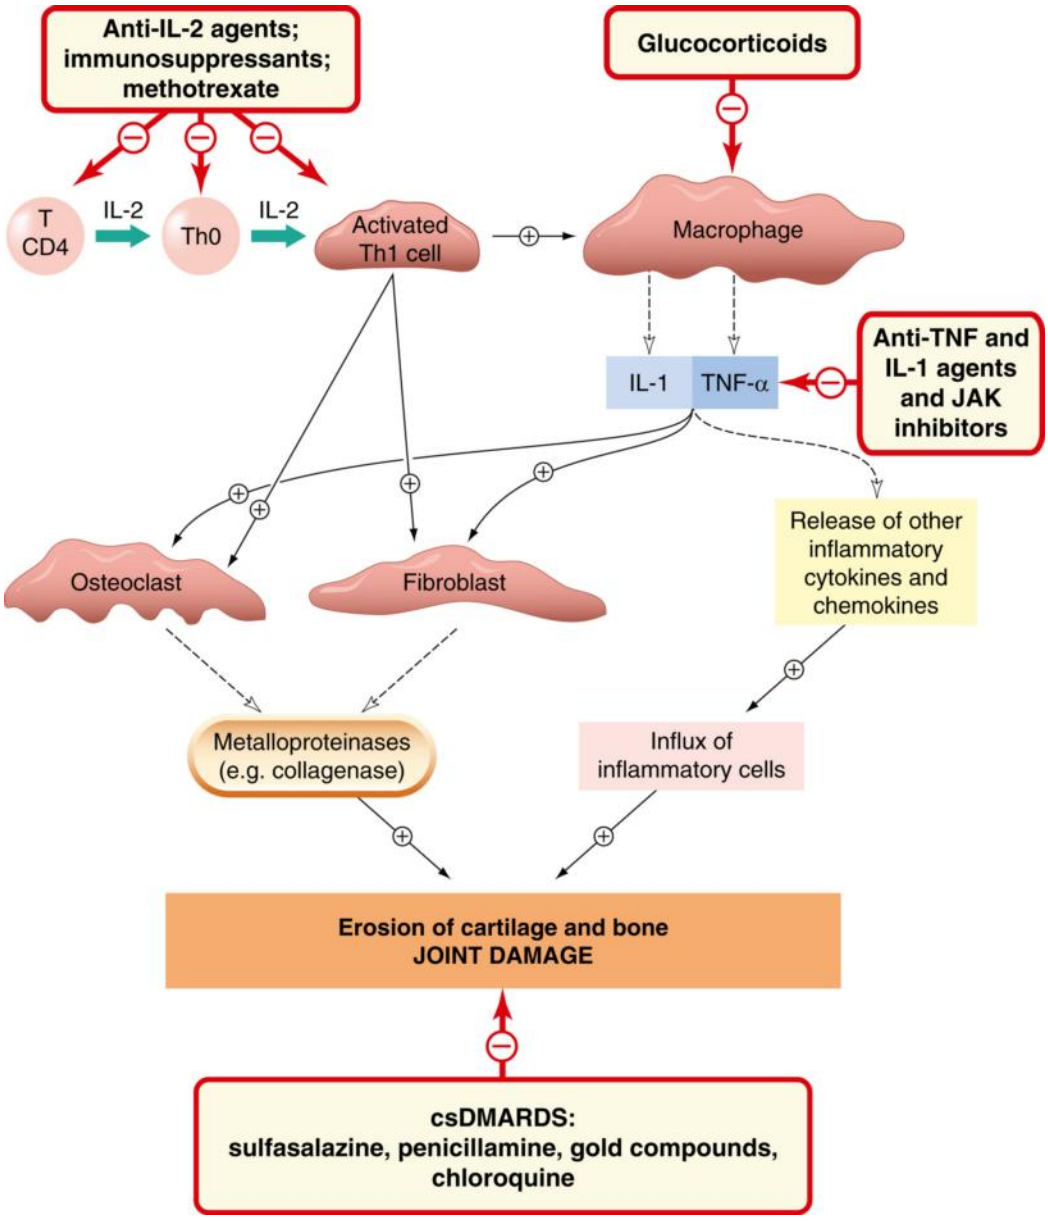

FIG. 25.3 A schematic diagram of the cells and mediators involved in the pathogenesis of rheumatoid joint damage, indicating the sites of action of disease-modifying antirheumatic drugs (conventional synthetic DMARDs, targeted synthetic DMARDs and biological DMARDs) and other drugs.For details of the anti–tumour necrosis factor (TNF), interleukin (IL)-1 and IL-2

receptor agents, see **Chapter 7** and **Table 25.4**. The details of the cytokine receptors and the Janus associated tyrosine kinase (JAK) signalling pathways have been omitted for clarity.

We will now look at some of the common csDMARDs in a little more detail.

Methotrexate

Methotrexate is a folic acid antagonist with cytotoxic and immunosuppressant activity (see **Ch. 57**). It has a useful and reliable antirheumatoid action and is a common first-choice drug. It has a more rapid onset of action than other DMARDs, but treatment must be closely monitored because of bone marrow depression, leading to a drop in white cell and platelet counts (potentially fatal) and liver cirrhosis. It is, however, superior to most other DMARDs in terms of efficacy and patient tolerance and is often given in conjunction with the anticytokine drugs.

Its mechanism of action is unrelated to its effect on folic acid (which is routinely co-administered to prevent blood disorders) but may well be connected with its ability to block adenosine uptake (see **Ch. 16** and **Chan and Cronstein, 2010**).

Sulfasalazine

Sulfasalazine, another common first-choice sDMARD in the United Kingdom, produces remission in active rheumatoid arthritis and is also used for chronic inflammatory bowel disease (see **Ch. 30**). It probably acts partly by inhibiting COX and lipoxygenase

pathways or by scavenging toxic free radicals, but it also reduces the release of IL-8 from colonic myofibroblasts, suggesting an additional immunosuppressive mechanism (**Lodowska et al., 2015**). The drug is a complex of a sulfonamide (**sulfapyridine**) and **salicylate** and is split into its component parts by bacteria in the colon. It is poorly absorbed after oral administration.

Table 25.2

AD, Atopic dermatitis; *IBS,* inflammatory bowel disease; *JRA,* juvenile rheumatoid arthritis; *NSAID,* non-steroidal anti-inflammatory drug; *PA,* psoriatic arthritis; *PS,* psoriasis; *RA,* rheumatoid arthritis; *SLE,* systemic lupus erythematosus.

Data from various sources, including the British National Formulary, 2021.

Sulfasalazine is generally well tolerated but common side effects include GI disturbances, malaise and headache. Skin reactions and leukopenia can occur but are reversible on stopping the drug. The absorption of folic acid is sometimes impaired; this can be countered by giving folic acid supplements. A reversible decrease in sperm count has also been reported. As with other sulfonamides, bone marrow depression and anaphylactic-type reactions may occur in a few patients. Haematological monitoring may be necessary.

Penicillamine

Penicillamine is *dimethylcysteine*; it is produced by hydrolysis of **penicillin** and appears in the urine after treatment with that drug.

The D-isomer is used in the therapy of rheumatoid disease. About 75% of patients with rheumatoid arthritis respond to **penicillamine**. Therapeutic effects are seen within weeks but do not reach a plateau for several months. **Penicillamine** is thought to modify rheumatoid disease partly by decreasing the immune response and IL-1 generation, and/or partly by preventing the maturation of newly synthesised collagen. However, the precise mechanism of action is still a matter of conjecture. The drug has a highly reactive thiol group and also has metal-chelating properties, which are put to good use in the treatment of *Wilson's disease* (pathological copper deposition causing neurodegeneration and liver disease) and heavy metal poisoning.

Penicillamine is given orally, but only about half the dose is absorbed. It reaches peak plasma concentrations in 1–2 h and is excreted in the urine. Treatment is initiated with low doses and increased only gradually to minimise the unwanted effects, which occur in about 40% of patients and which may necessitate cessation of therapy. Rashes and stomatitis are the most common unwanted effects but may resolve if the dosage is lowered. Anorexia, fever, nausea and vomiting and disturbances of taste (the last related to the chelation of zinc) are seen, but often disappear with continued treatment. Proteinuria occurs in 20% of patients and should be monitored. Haematological monitoring is also required when treatment is initiated. Thrombocytopenia may require reduction in the dose. Leukopenia and aplastic anaemia are absolute contraindications, as are autoimmune conditions (e.g. thyroiditis, myasthenia gravis).

Antimalarial drugs

Hydroxychloroquine and chloroquine are 4-amino-quinoline drugs used mainly in the prevention and treatment of malaria (see **Ch. 55**), but they are also used as DMARDs. **Chloroquine** is usually reserved for cases where other treatments have failed. They are also used to treat another autoimmune disease, lupus erythematosus, but are contraindicated in patients with psoriatic arthropathy because they exacerbate the skin lesions. The related antimalarial, **mepacrine**, is also sometimes used for discoid (cutaneous) lupus. The antirheumatic effects do not appear until a month or more after the drug is started, and only about half the patients treated respond. The administration, pharmacokinetic aspects and unwanted effects of **chloroquine** are dealt with in **Chapter 55**; screening for ocular toxicity is particularly important.

Immunosuppressant Drugs

Immunosuppressants are used in the therapy of autoimmune disease and also to prevent and/or treat transplant rejection. Because they impair the immune response, they also carry the hazard of a decreased response to infections and may facilitate the emergence of malignant cell lines. However, the relationship between these adverse effects and potency in preventing graft rejection varies with different drugs. The clinical use of immunosuppressants is summarised in the clinical box.

Immunosuppressants

- Clonal proliferation of T-helper cells can be decreased through inhibition of transcription of IL-2: **ciclosporin**,

tacrolimus, sirolimus and **pimecrolimus** and glucocorticoids act in this way.
  - **Ciclosporin**-like drugs bind to cytosolic proteins (immunophilins) which inhibit calcineurin triggering changes in gene transcription.
  - They are given orally or intravenously; a common adverse effect is nephrotoxicity.
- For glucocorticoid actions, see separate box.
- Lymphocyte proliferation is also blocked by inhibitors of DNA synthesis such as:
  - **azathioprine**, through its active metabolite **mercaptopurine**;
  - **mycophenolate mofetil**, through inhibition of de novo purine synthesis.

Most of these drugs act during the induction phase of the immunological response, reducing lymphocyte proliferation (see **Ch. 7**), although others also inhibit aspects of the effector phase. There are three main groups:

- drugs that inhibit IL-2 production or action (e.g. **ciclosporin**, **tacrolimus** and related drugs);
- drugs that inhibit cytokine gene expression (e.g. corticosteroids);
- drugs that inhibit purine or pyrimidine synthesis (e.g. **azathioprine**, **mycophenolate mofetil**).

Ciclosporin

Ciclosporin is a naturally occurring compound first identified in a fungus. It is a cyclic peptide of 11 amino acid residues (including some not found in animals) with potent immunosuppressive activity but no effect on the acute inflammatory reaction per se. Its unusual activity, which (unlike earlier immunosuppressants) does not entail cytotoxicity, was discovered in 1972 and was crucial for the development of transplant surgery (for a detailed review, see **Borel et al., 1996**). The drug has numerous actions but those of relevance to immunosuppression are:

- decreased clonal proliferation of T cells, primarily by inhibiting IL-2 synthesis and possibly also by decreasing expression of IL-2 receptors;
- reduced induction and clonal proliferation of cytotoxic T cells from $CD8^+$ precursor T cells;
- reduced function of the effector T cells responsible for cell-mediated responses (e.g. decreased delayed-type hypersensitivity);
- some reduction of T cell-dependent B-cell responses.

The main action is a relatively selective inhibitory effect on IL-2 gene transcription, although a similar effect on interferon (IFN)-γ and IL-3 has also been reported. Normally, interaction of antigen with a T-helper (Th) cell receptor results in increased intracellular Ca^{2+} (Chs **2** and 7), which in turn stimulates *calcineurin*, a phosphatase. This activates various transcription factors that initiate IL-2 expression. **Ciclosporin** binds to *cyclophilin*, a cytosolic protein member of the immunophilin family (a group of proteins that act as intracellular receptors for such drugs). The

drug–immunophilin complex binds to, and inhibits, calcineurin and thus acts in opposition to the many protein kinases involved in signal transduction (see **Ch. 3**), preventing activation of Th cells and production of IL-2 (see **Ch. 7**).

Ciclosporin itself is poorly absorbed by mouth but can be given orally in a more readily absorbed formulation, or by intravenous infusion. After oral administration, peak plasma concentrations are usually attained in about 3–4 h. The plasma half-life is approximately 24 h. Metabolism occurs in the liver, and most of the metabolites are excreted in the bile. **Ciclosporin** accumulates in most tissues at concentrations three to four times that seen in the plasma. Some of the drug remains in lymphomyeloid tissue and remains in fat depots for some time after administration has stopped.

The commonest and most serious unwanted effect of **ciclosporin** is nephrotoxicity, which is thought to be unconnected with calcineurin inhibition. It may be a limiting factor in the use of the drug in some patients (see also **Ch. 58**). Hepatotoxicity and hypertension can also occur. Less important unwanted effects include anorexia, lethargy, hirsutism, tremor, paraesthesia (tingling sensation), gum hypertrophy (especially when co-prescribed with calcium antagonists for hypertension; see **Ch. 21**) and GI disturbances. **Ciclosporin** has no depressant effects on the bone marrow.

Tacrolimus

Tacrolimus is a macrolide antibiotic of fungal origin with a very similar mechanism of action to **ciclosporin**, but higher potency.

The main difference is that the internal receptor for this drug is not cyclophilin but a different immunophilin termed FKBP (FK-binding protein, so called because **tacrolimus** was initially termed FK506). The **tacrolimus**–FKBP complex inhibits calcineurin with the effects described previously. It is not used for arthritis but mainly in organ transplantation and severe atopic eczema (see **Ch. 26**). **Pimecrolimus** (used topically to treat atopic eczema) acts in a similar way. **Sirolimus** (used to prevent organ rejection after transplantation, and also in coating on cardiac stents to prevent restenosis; see **Ch. 20**) also combines with an immunophilin but activates a protein kinase to produce its immunosuppressant effect.

Tacrolimus can be given orally, by intravenous injection or as an ointment for topical use in inflammatory disease of the skin. It is 99% metabolised by the liver and has a half-life of approximately 7 h. The unwanted effects of **tacrolimus** are similar to those of **ciclosporin** but are more severe. The incidence of nephrotoxicity and neurotoxicity is higher, but that of hirsutism is lower. GI disturbances and metabolic disturbances (hyperglycaemia) can occur. Thrombocytopenia and hyperlipidaemia have been reported but decrease when the dosage is reduced.

Azathioprine

Azathioprine interferes with purine synthesis and is cytotoxic. It is widely used for immunosuppression, particularly for control of autoimmune diseases such as rheumatoid arthritis and to prevent tissue rejection in transplant surgery. This drug is metabolised to **mercaptopurine**, an analogue that inhibits DNA synthesis (see **Ch. 57**). Because it inhibits clonal proliferation during the

induction phase of the immune response (see **Ch. 7**) through a cytotoxic action on dividing cells, both cell-mediated and antibody-mediated immune reactions are depressed by this drug. As is the case with **mercaptopurine** itself, the main unwanted effect is depression of the bone marrow. Other toxic effects are nausea and vomiting, skin eruptions and a mild hepatotoxicity.

Cyclophosphamide

Cyclophosphamide is a potent immunosuppressant that is mainly used to treat cancer. Its mechanism of action is explained in **Chapter 57**. It has substantial toxicity and is therefore generally reserved for serious cases of rheumatoid arthritis in which all other therapies have failed.

Mycophenolate mofetil

Mycophenolate mofetil is a semisynthetic derivative of a fungal antibiotic and is used for preventing organ rejection. In the body, it is converted to mycophenolic acid, which restrains proliferation of both T and B lymphocytes and reduces the production of cytotoxic T cells by inhibiting inosine monophosphate dehydrogenase. This enzyme is crucial for de novo purine biosynthesis in both T and B cells (other cells can generate purines through another pathway), so the drug has a fairly selective action.

Mycophenolate mofetil is given orally and is well absorbed. Magnesium and aluminium hydroxides impair absorption, and colestyramine reduces plasma concentrations. The metabolite mycophenolic acid undergoes enterohepatic cycling and is eliminated by the kidney as the inactive glucuronide. Unwanted GI effects are common.

Glucocorticoids

The therapeutic action of the glucocorticoids involves both their inhibitory effects on the immune response and their anti-inflammatory actions. These are described in **Chapters 3** and **33**, and their sites of action on cell-mediated immune reactions are indicated in **Fig. 25.3**.

Glucocorticoids are immunosuppressant chiefly because, like **ciclosporin**, they restrain the clonal proliferation of Th cells, through decreasing transcription of the gene for IL-2. However, they also decrease the transcription of many other cytokine genes (including those for TNF-α, IFN-γ, IL-1 and many other interleukins) in both the induction and effector phases of the immune response. The synthesis and release of anti-inflammatory proteins (e.g. IL-10, annexin 1, protease inhibitors) are also increased. These effects are mediated through inhibition of the action of transcription factors, such as activator protein-1 and NFκB as well as through the action of liganded glucocorticoid receptor in the cytosol of target cells (see **Ch. 3**).

Clinical uses of immunosuppressant drugs

Immunosuppressant drugs are used by specialists, often in combination with glucocorticoid and/or cytotoxic drugs:

- To slow the progress of rheumatoid and other arthritic diseases including psoriatic arthritis, ankylosing spondylitis, juvenile arthritis: *DMARDs*, e.g. **methotrexate**, **ciclosporin**; *cytokine modulators* (e.g. **adalimumab**,

etanercept, **infliximab**) are used when the response to methotrexate or other DMARDs has been inadequate.

- To suppress rejection of transplanted organs, e.g. **ciclosporin**, **tacrolimus**, **sirolimus.**
- To suppress graft-versus-host disease following bone marrow transplantation, e.g. **ciclosporin.**
- In autoimmune disorders including idiopathic thrombocytopenic purpura, some forms of haemolytic anaemias and of glomerulonephritis and myasthenia gravis.
- In severe inflammatory bowel disease (e.g. **ciclosporin** in ulcerative colitis, **infliximab** in Crohn's disease).
- In severe skin disease (e.g. **pimecrolimus**, **tacrolimus** topically for atopic eczema uncontrolled by maximal topical glucocorticoids; **etanercept**, **infliximab** for very severe plaque psoriasis which has failed to respond to **methotrexate** or **ciclosporin**).

Miscellaneous drugs

Sitting (admittedly rather uncomfortably) in the sDMARD group of drugs is **apremilast**, a phosphodiesterase (type 4) inhibitor. By elevating levels of cAMP in cells it can suppress the generation and release of proinflammatory mediators. It is generally used for the treatment of psoriatic arthritis and only used in patients who do not respond adequately to other treatment.

Targeted synthetic disease-modifying antirheumatic drugs

The biological activity of inflammatory cytokines is transduced by their receptors (several types) which in turn (with the important exception of TNF) activate members of the *JAK* or *TYK* (tyrosine kinase) family of molecules. There are four members of the JAK family, JAK 1–4 (see **Ch. 3**), and these in turn can interact with members of the *signal transducer and activation of transcription (STAT)* family of transcription factors (six in total) thus activating the JAK–STAT signalling pathway which modulates gene translation/transcription.

Gain of function and other mutations in JAK family members are associated with a variety of rheumatological and other inflammatory disorders strongly suggesting a functional link between the activation of the JAK–STAT pathway and inflammatory pathologies and based upon this idea, inhibitors of JAK kinases such as **tofacitinib, baricitinib** and **upadacitinib** were developed for use in inflammatory and other pathologies (see **Bertsias, 2020**, and **Table 25.3**).

Table 25.3

EPO, Erythropoietin; *GMCSF*, granulocyte-macrophage colony stimulating factor; *IFN*, interferon; *IL,* interleukin; *JAK*, Janus associated tyrosine kinase; *RA,* rheumatoid arthritis; *UC*, ulcerative colitis.

[a] Only the key proinflammatory cytokines/growth factors are included in this table.

Data from various sources, including Bertias, 2020, and the British National Formulary, 2021.)

Since any interference with the immune system is likely to adversely affect the host response to infection and cytokines activate different JAK kinases, the question of which of these proinflammatory mediators was inhibited by these drugs became rather significant and there were clearly some concerns about indiscriminate inhibition of these signalling pathways.

The first of these drugs to be introduced into clinical practice was **tofacitinib** in 2012. This is a non-selective compound which inhibited JAK1 and JAK3 which was effective in reducing the action of the 'γ-chain cytokines' such as IL-2, IL-6, IL-15 and IFNγ (JAK1) and IL-2, IL-4 and IL-15 (JAK3). Later, **baricitinib** which selectively targeted JAK1 and JAK2 was approved. This drug blocked, in addition, several growth factors such as granulocyte-macrophage colony-stimulating factor (GM-CSF) and erythropoietin (EPO). Concerns about the effect of these drugs on haematological function (through inhibition of JAK2) led to the subsequent introduction of **upadacitinib,** a selective JAK1 inhibitor.

The chief adverse effects of this family of drugs include, as might be anticipated, a reduction of host response to infectious diseases and possibly activation of latent infections such as TB. Various other side effects such as nausea, joint pains fever and dyslipidaemia are commonly reported (see **Table 25.3**).

BIOLOGIC DISEASE-MODIFYING ANTIRHEUMATIC DRUGS, ANTICYTOKINE DRUGS AND OTHER BIOPHARMACEUTICALS

The *biopharmaceuticals* in this section represent the greatest technological and conceptual breakthrough in the treatment of severe chronic inflammation for decades (see **Maini, 2005**). These drugs are engineered recombinant antibodies and other proteins (see **Ch. 5**). As such, they are difficult and expensive to produce, and this limits their use. In the United Kingdom (in the National Health Service), they are generally restricted to patients who do not respond adequately to other DMARD therapy, and they are administered only under specialist supervision. Some are usually administered in combination with **methotrexate**, which apparently provides a synergistic anti-inflammatory action.

The characteristics and indications of some current biopharmaceuticals are shown in **Table 25.4**. The effect of two of these agents on rheumatoid arthritis is shown in **Fig. 25.4**. Many neutralise soluble cytokines. **Adalimumab**, **certolizumab pegol**, **golimumab**, **etanercept** and **infliximab** target TNF-α; **anakinra** and **canakinumab** target IL-1; **sarilumab** and **tocilizumab**, IL-6 and **ustekinumab**, IL-12 and -23. **Abatacept**,

alemtuzumab, **basiliximab**, **belatacept**, **daclizumab** and **natalizumab** target T cells, disrupting either activation, proliferation or emigration. **Rituximab** and **belimumab** target B cells directly. While they are not used for treating arthritis, **basiliximab**, **belatacept** and **daclizumab** are included in the table as they act to prevent the rejection of transplanted organs in a similar way – by suppressing T-cell proliferation.

There is some debate over the precise nature of the target of the anti-TNF agents. Some target both soluble and membrane-bound forms of TNF whereas others are more selective. Antibodies that target membrane-bound TNF (e.g. **infliximab** and **adalimumab**) may kill the host cell by complement-induced lysis. This produces a different quality of effect than simple sequestration of the soluble mediator (by, for example, **etanercept**). This fact is probably the reason why some of these drugs exhibit a slightly different pharmacological profile despite ostensibly acting through the same mechanism (see **Arora et al., 2009**, for further details).

As proteins, none of these drugs can be given orally. Administration is usually by subcutaneous injection or intravenous infusion and their pharmacokinetic profiles vary enormously. Dosing regimes differ but, for example, **anakinra** is usually given daily; **efalizumab** and **etanercept** once or twice per week; **adalimumab**, **certolizumab pegol**, **infliximab** and **rituximab** every 2 weeks; and **abatacept**, **belimumab**, **golimumab**, **natalizumab** and **tocilizumab** every month. Sometimes a loading dose of these drugs is given as a preliminary to regular administration.

Usually, these biopharmaceuticals are only given to severely affected patients or to those in whom other therapies have failed. For reasons that are not entirely clear, a proportion of these patients (about 30%) do not respond and therapy is generally discontinued if no therapeutic benefit is evident within 2–4 weeks. Some studies suggest that if treatment is begun using drugs such as **infliximab** in combination with **methotrexate** this failure rate is reduced and a superior final therapeutic outcome achieved (**van der Kooij et al., 2009**).

Table 25.4

ab, Antibody; AS, ankylosing spondylitis; *CD,* Crohn's disease; *GA,* gouty arthritis; *IL,* interleukin; *mAb,* monoclonal antibody; *MS,* multiple sclerosis; *PA,* psoriatic arthritis; *PP,* plaque psoriasis (e.g. skin); *PS,* psoriasis; *RA,* rheumatoid arthritis; *SLE,* systemic lupus erythematosus; *TNF,* tumour necrosis factor; *UC,* ulcerative collitis.

[a] Used in conjunction with methotrexate.

Data from various sources, including the British National Formulary, 2021.

Cytokines are crucial to the regulation of host defence systems (see **Ch. 17**), and leukocytes are key players in its successful functioning. One might predict, therefore, that anticytokine or antileukocyte therapy – like any treatment that interferes with immune function – may precipitate latent infections (e.g. tuberculosis or hepatitis B) or encourage opportunistic infections. Reports suggest that this is a problem with some of these agents

(e.g. **adalimumab**, **etanercept**, **infliximab**, **natalizumab** and **rituximab**). The area has been reviewed by **Bongartz et al. (2006)**. Another unexpected, but fortunately rare, effect seen with these drugs is the onset of psoriasis-like syndrome (**Fiorino et al., 2009**). Hypersensitivity, injection site reactions or mild GI symptoms may be seen with any of these drugs.

Drugs Used in Gout

Gout (also known as *gouty arthritis*) is a metabolic disease in which urate crystals are deposited in tissues, usually because plasma urate concentration is raised. Sometimes this is linked to overindulgence in alcoholic beverages, especially beer, or purine-rich foods such as offal (urate is a product of purine metabolism). Increased cell turnover in haematological malignancies, particularly after treatment with cytotoxic drugs (see **Ch. 57**), and impaired excretion of uric acid by drugs such as ordinary therapeutic doses of **aspirin** (see earlier) are other causes. It is characterised by extremely painful intermittent attacks of acute arthritis produced by the deposition of the crystals in the synovial tissue of distal joints, such as the big toe, as well as the external ear – the common theme being that these tissues are generally relatively cool, favouring crystal deposition. An inflammatory response is evoked, involving activation of the kinin, complement and plasmin systems (see Chs **7** and **17**), generation of prostaglandins, lipoxygenase products such as leukotriene B_4 (see **Ch. 17**), and local accumulation of neutrophil granulocytes. These engulf the crystals by phagocytosis, releasing tissue-damaging toxic oxygen metabolites and subsequently causing

lysis of the cells with release of proteolytic enzymes. Urate crystals also induce the production of IL-1 and possibly other cytokines.

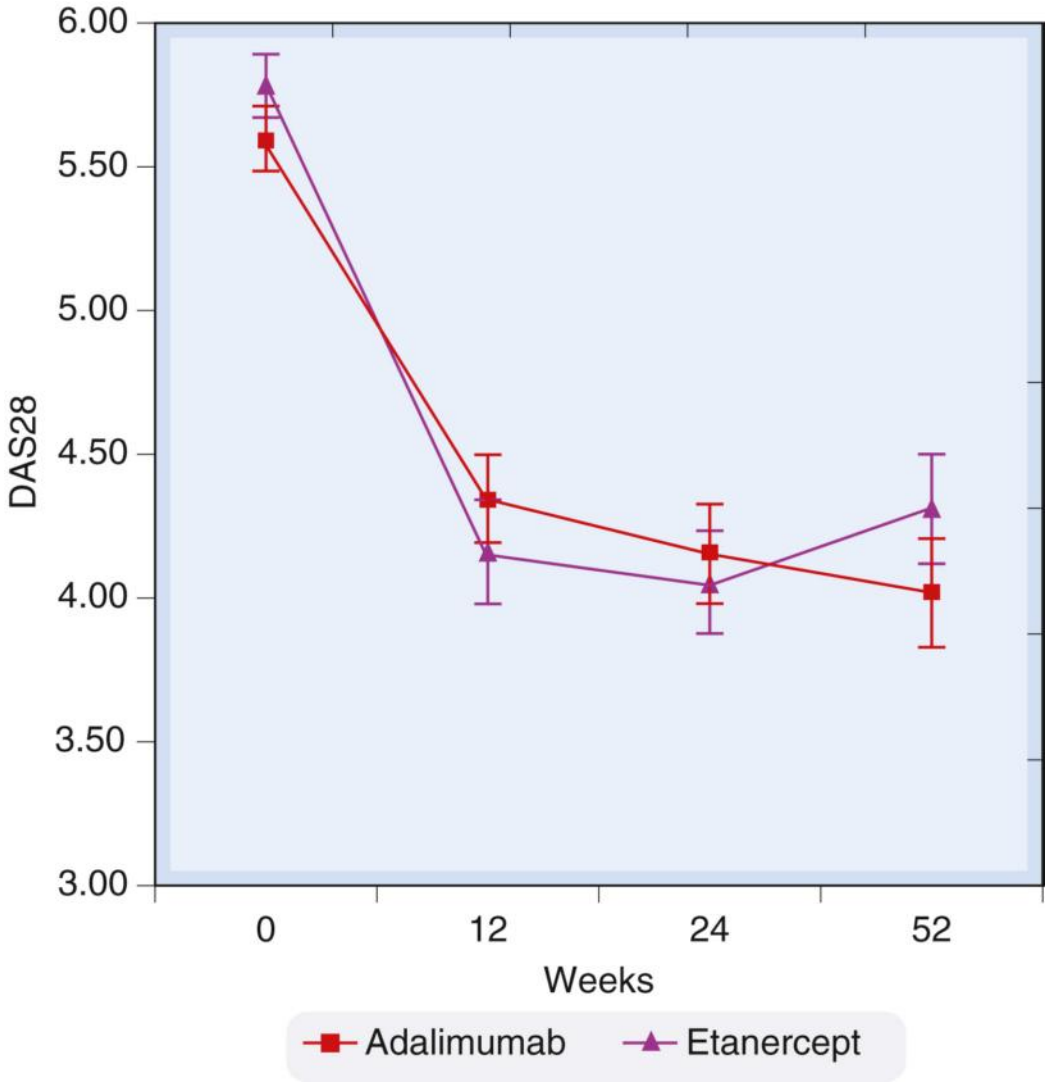

FIG. 25.4 The effect of anticytokine biopharmaceuticals on rheumatoid arthritis.In this figure, adalimumab (a humanised monoclonal antibody that neutralises tumour necrosis factor (TNF)) and etanercept (a fusion protein decoy receptor that binds to TNF) were used to treat patients with active rheumatoid arthritis. The Y-axis measures a composite disease activity scores obtained from clinical assessment of 28 joints (DAS28: the lower the

score, the less swollen and painful the joints). From Jobanputra et al., 2012.

Drugs used to treat gout act in the following ways:

- by decreasing uric acid synthesis **allopurinol** (the main prophylactic drug) or **febuxostat**;
- by increasing uric acid excretion (*uricosuric agents*: **probenecid**, **sulfinpyrazone**; see **Ch. 29**);
- by inhibiting leukocyte migration into the joint (**colchicine**);
- as an 'IL-1-dependent' disease, biopharmaceuticals such as **anakinra** may be useful;
- by exerting a general anti-inflammatory and analgesic effect (NSAIDs and occasionally glucocorticoids).

Their clinical uses are summarised in the clinical box.

Drugs used in gout and hyperuricaemia

To treat acute gout:

- An NSAID, e.g. **ibuprofen**, **naproxen.**
- **Colchicine** is useful if NSAIDs are contraindicated.
- A glucocorticoid, e.g. **hydrocortisone** (oral, intramuscular or intra-articular) is an alternative to an NSAID.

For prophylaxis

- **Allopurinol**; (must not be started until the patient is asymptomatic):

  - a uricosuric drug (e.g. **probenecid**, **sulfinpyrazone**), for patients allergic to **allopurinol**
- **Rasburicase** by intravenous infusion for prevention and treatment of acute hyperuricaemia in patients with haematological malignancy at risk of rapid lysis.

Allopurinol

Allopurinol is an analogue of *hypoxanthine* that reduces the synthesis of uric acid by competitive inhibition of xanthine oxidase (**Fig. 25.5**). The drug is first converted by xanthine oxidase to *alloxanthine*, which persists in the tissue for a considerable time, and is an effective non-competitive inhibitor of the enzyme. Some inhibition of de novo purine synthesis also occurs.

Allopurinol reduces the concentration of the relatively insoluble urates and uric acid in tissues, plasma and urine, while increasing the concentration of their more soluble precursors, the xanthines and hypoxanthines. The deposition of urate crystals in tissues (tophi) is reversed, and the formation of renal urate stones is inhibited. **Allopurinol** is the drug of choice in the long-term treatment of gout, but it actually exacerbates inflammation and pain in an acute attack (see later). **Febuxostat** has a similar mechanism of action and pharmacology.

Allopurinol is given orally and is well absorbed. Its half-life is 2–3 h: its active metabolite alloxanthine (see **Fig. 25.5**) has a half-life of 18–30 h. Renal excretion is a balance between glomerular filtration and **probenecid**-sensitive tubular reabsorption.

Acute attacks of gout occur commonly during the early stages of therapy (possibly as a result of physicochemical changes in the surfaces of urate crystals as these start to re-dissolve), so treatment with **allopurinol** is never initiated during an acute attack and is usually initially combined with an NSAID. Unwanted effects are otherwise few. GI disturbances, allergic reactions (mainly rashes) and some blood problems can occur but usually disappear if the drug is stopped. Potentially fatal skin diseases such as toxic epidermal necrolysis and Stevens–Johnson syndrome are rare – but devastating.

Allopurinol increases the effect of mercaptopurine, an antimetabolite used in cancer chemotherapy, which is inactivated by xanthine oxidase (see **Ch. 57**), and also that of **azathioprine** (see **Table 25.2**), which is metabolised to mercaptopurine. **Allopurinol** also enhances the effect of another anticancer drug, **cyclophosphamide** (see **Ch. 57**). The effect of warfarin is increased because its metabolism is inhibited.

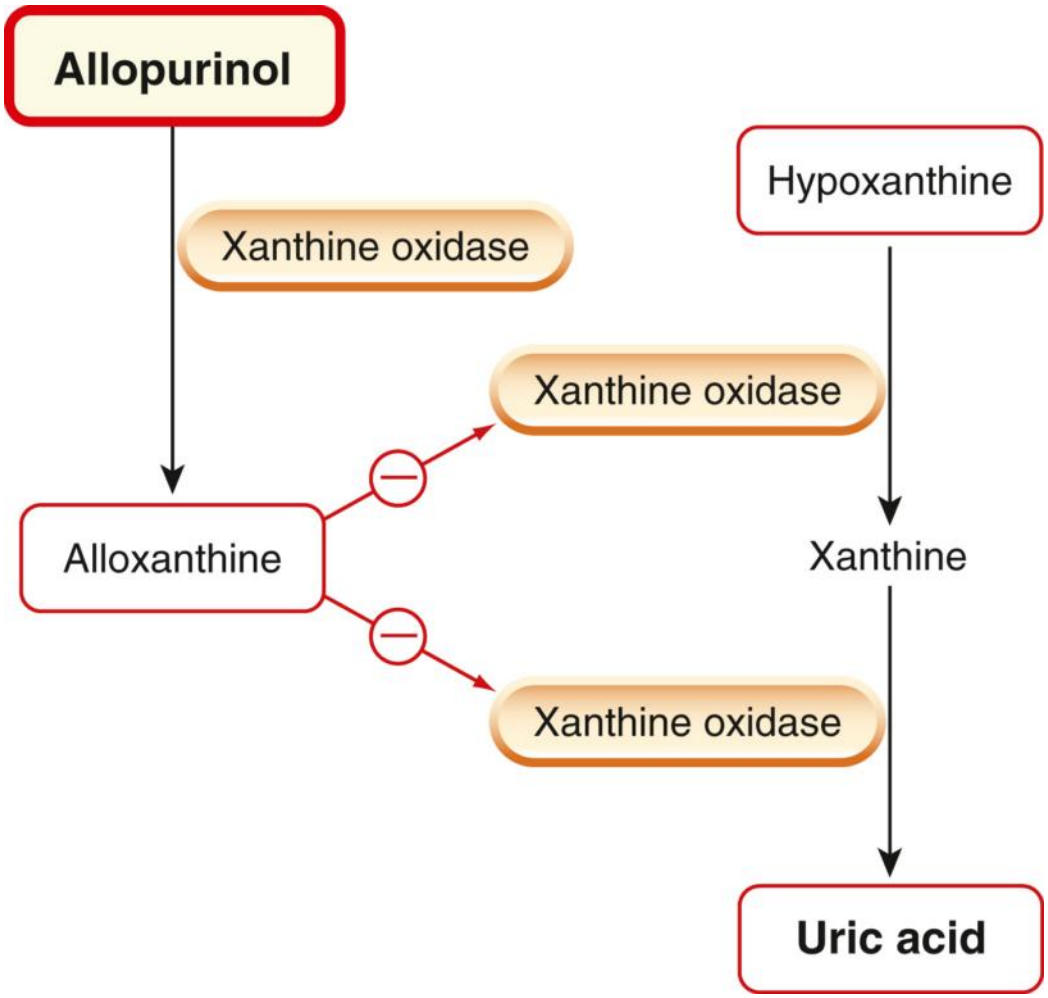

FIG. 25.5 Inhibition of uric acid synthesis by allopurinol.See text for details.

Uricosuric agents

Uricosuric drugs increase uric acid excretion by a direct action on the renal tubule (see **Ch. 29**). They remain useful as prophylaxis for patients with severe recurrent gout who may not tolerate **allopurinol**. Drugs in this class include **probenecid** and **sulfinpyrazone** (which also has NSAID activity). **Benzbromarone** has a role in the treatment of patients with renal impairment. Treatment with uricosuric drugs is initiated together

with an NSAID, as in the case of **allopurinol**. However, **aspirin** and salicylates antagonise the action of uricosuric drugs and should not be used concurrently.

Although not strictly speaking in this group, **rasburicase**, a preparation containing the enzyme uric acid oxidase, is sometimes used for aggressive treatment of gout. It oxidises uric acid in the blood to allantoin, which is more soluble and thus more readily excreted.

Colchicine

Colchicine is an alkaloid extracted from the autumn crocus. It has a beneficial effect in gouty arthritis and can be used both to prevent and to relieve acute attacks. It prevents migration of neutrophils into the joint apparently by binding to tubulin, resulting in the depolymerisation of the microtubules and reduced cell motility. **Colchicine**-treated neutrophils exhibit erratic locomotion often likened to a 'drunken walk'. **Colchicine** may also prevent the production, by neutrophils that have phagocytosed urate crystals, of a putative inflammatory glycoprotein. Other mechanisms may also be important in bringing about its effects. At higher doses than are used to treat gout, **colchicine** inhibits mitosis, carrying a risk of serious bone marrow depression. As such it has a narrow therapeutic index and is extremely dangerous in overdose.

Colchicine is given orally and is excreted partly in the GI tract and partly in the urine.

The acute unwanted effects of **colchicine** during therapy are largely GI and include nausea, vomiting and abdominal pain. Severe diarrhoea [9] may be a problem, and with large doses, or prolonged

treatment, its antimitotic action may cause serious side effects, including GI haemorrhage, kidney damage, bone marrow depression and peripheral neuropathy.

Antagonists of Histamine

As we explained in **Chapter 17**, histamine was first identified as a mediator of anaphylaxis by Dale and his colleagues in the early 20th century and later shown to be particularly released during other immune reactions. Mast cells are a prominent source of this mediator and release it into the local environment in response to a variety of immunological and other stimuli. Evidently therefore, there was a potential for developing drugs which inhibited histamine generation or action for the treatment of allergic inflammation.

Antihistamines were introduced by Bovet and his colleagues in the 1930s, before the discovery of the four histamine receptor subtypes described in **Chapter 17**. By convention, the generic term 'antihistamine' usually refers only to the H_1-receptor antagonists that are used for treating various inflammatory and allergic conditions, and it is these drugs that are discussed in this section

Details of some typical systemic H_1-receptor antagonists are shown in **Table 25.5**. There are several others that are primarily used topically (e.g. in nasal sprays or eye drops) in the treatment of hay fever and other allergic symptoms. These include **antazoline**, **azelastine**, **epinastine**, **olopatadine** and **emedastine**. In addition to their H_1 antagonist activities, some antihistamines (e.g. **ketotifen**) may also have 'mast cell stabilising' and other anti-

inflammatory properties unrelated to histamine antagonism (see **Assanasen and Naclerio, 2002**).

Pharmacological actions

Conventionally, the antihistamines are divided into 'first-generation' drugs, which cross the blood–brain barrier and, by acting at histamine receptors in the CNS, often have sedating actions, and 'second-generation' drugs, which, broadly speaking, do not. Some of the original second-generation agents (e.g. **terfenadine**) exhibited some cardiac toxicity (e.g. *torsade de pointes*, see **Ch. 20**). While the risk was extremely low, it was increased when the drug was taken with grapefruit juice or with agents that inhibit cytochrome P450 in the liver (see Chs **10** and **58**). These drugs were therefore withdrawn and replaced by 'third-generation cardio-safe' drugs (often active metabolites of the original drugs, e.g. **fexofenadine**).

Pharmacologically, most of the effects of the H_1-receptor antagonists follow from the actions of histamine outlined in **Chapter 17**. In vitro, for example, they decrease histamine-mediated contraction of the smooth muscle of the bronchi, the intestine and the uterus. They inhibit histamine-induced increases in vascular permeability and bronchospasm in the guinea pig in vivo but are unfortunately of little value in allergic bronchospasm in humans. The clinical uses of H_1-receptor antagonists are summarised in the clinical box.

Table 25.5

AE, Allergic emergency (e.g. anaphylactic shock); *H,* hay fever; *PAF,* platelet activating factor; *S,* sedation; *U,* urticaria and/or pruritus.

Data from various sources, including the British National Formulary, 2021.

Clinical uses of histamine H_1-receptor antagonists

- Allergic reactions (see **Ch. 7**):
  - non-sedating drugs (e.g. **fexofenadine**, **cetirizine**) are used for allergic rhinitis (hay fever) and urticaria
  - topical preparations may be used for insect bites
  - injectable formulations are useful as an adjunct to **adrenaline** (**epinephrine**) for severe drug hypersensitivity reactions and emergency treatment of anaphylaxis.
- As antiemetics (see **Ch. 30**):
  - prevention of motion sickness (e.g. **cyclizine**, **cinnarizine**)
  - other causes of nausea, especially labyrinthine disorders
  - for sedation (see **Ch. 45**, e.g. **promethazine**).

The CNS 'side effects' of some older H_1-receptor antagonists are sometimes more clinically useful than the peripheral H_1-antagonist

effects (e.g. **chlorphenamine**; see **Table 25.5**). When used to treat allergies, the sedative effects are generally unwanted, but there are other occasions (e.g. when taking an overnight flight) when they are more desirable. Even under these circumstances, other CNS effects, such as dizziness and fatigue, are unwelcome. Other centrally acting antihistamines are antiemetic and are used to prevent motion sickness (e.g. **promethazine**; see **Ch. 30**).

Several H_1-receptor antagonists show weak blockade of α1 adrenoceptors (e.g. **promethazine**). **Cyproheptadine** is a 5-HT antagonist as well as an H_1-receptor antagonist and **rupatadine** is also a platelet activating factor (PAF) antagonist.

Pharmacokinetic aspects

Most orally active H_1-receptor antagonists are well absorbed and remain effective for 3–6 h, although there are some prominent exceptions (e.g. **loratadine**, which is converted to a long-acting metabolite). Most appear to be widely distributed throughout the body, but some do not penetrate the blood–brain barrier, for example the non-sedating drugs mentioned previously (see **Table 25.5**). They are mainly metabolised in the liver and excreted in the urine.

Many antihistamines have peripheral antimuscarinic side effects. The commonest of these is dryness of the mouth, but blurred vision, constipation and retention of urine can also occur. Unwanted effects that are not mechanism based are also seen; GI disturbances are fairly common, while allergic dermatitis can follow topical application.

Possible Future Developments in Anti-Inflammatory Therapy

Undoubtedly the most exciting area of current development is in biopharmaceuticals (see **Ch. 5**). The success of the anti-TNF and other biological agents has been very gratifying and development of therapeutic antibodies that neutralise inflammogens or block key leukocyte receptors or adhesion molecules is likely to continue unabated and, as research progresses, may also include RNA or other drugs (**Ch. 5**). The main problem with this sector is the cost of these drugs and lack of oral availability. This places a strain on healthcare budgets and often prevents them from being used as a first-line therapy. The recent availability of 'biosimilars' to originator biologics offers some hope and hopefully, ways will be found to reduce the cost of production and development of these important medicines.

Clearly therefore, a low-cost alternative to a neutralising anti-TNF antibody would be a welcome development. *TNF-converting enzyme* (TACE; at least two forms) cleaves membrane-bound TNF thus releasing the soluble active form into the blood, and so might be an attractive target. A number of putative small-molecule inhibitors of this enzyme are effective in animal models but have not transferred well to the clinic so far although there remains general optimism about this general approach. The area has recently been reviewed by **Murumkar et al. (2020)**.

The disconcerting realisation that all NSAIDs (and coxibs) have cardiovascular side effects has raised further questions about our existing therapeutic arsenal. [10] In an attempt to circumvent this and other, unwanted effects of conventional NSAIDs (such as GI

toxicity) several attempts have been made to derivatise these drugs in some way so as to reduce their potential for adverse effects. Based upon impeccable research and very encouraging animal data this has been achieved by attaching NO-donating or other, 'protective' groups such as H_2S (another gaseous mediator with protective properties) to standard drugs such as **naproxen**. One of these drugs (**naproxcinod**, an NO-releasing derivative of **naproxen**) is undergoing further clinical trials at the request of the FDA (see **Wallace et al., 2015**; **Costa et al., 2020**). However, **Kirkby et al. (2016)** have proposed that simple arginate salts of NSAIDs may lack the unwanted cardiovascular side effects of their parent drugs. Thus the quest for a 'safe' NSAID continues.

Taking a totally different approach are attempts to use, as anti-inflammatory drugs, the endogenous mediators which normally terminate inflammation under physiological conditions (see **Ch. 17**). Conceptually, this would be expected to have many advantages as such agents would not be expected to subvert the normal functioning of the immune system in the same way as those drugs referred to in this chapter. There have been some encouraging preclinical findings, but as yet, no agent has actually reached the market. The area has been reviewed recently by **Park et al. (2020)**.

QUESTIONS

QUESTION 25.1

Non-steroidal anti-inflammatory drugs (NSAIDs) are effective analgesic, antipyretic and anti-inflammatory agents due to their inhibitory effects on inflammatory mediators.

Which of the following statements about NSAIDs is incorrect?

OPTIONS:

A. NSAIDs irreversibly acetylate cyclo-oxygenase (COX) enzymes.

B. NSAIDs decrease the transcription of inflammatory genes by inhibiting the transcription factor nuclear factor κB (NFκB).

C. NSAIDs increase acid production in the gastric mucosa.

D. NSAIDs are effective anti-inflammatory agents as they decrease chemokine release.

E. NSAIDs decrease the sensitisation of nociceptors to inflammatory mediators such as bradykinin.

QUESTION 25.2

Activation and clonal expansion of T lymphocytes by interleukin (IL)-2 is a central part of the inflammatory response.

Which agents exert their anti-inflammatory activity through a direct reduction in IL-2 production?

OPTIONS:

A. Tofacitinib

B. Ciclosporin

C. Adalimumab

D. Glucocorticoids

E. Tocilizumab

ANSWERS

ANSWER 25.1

RATIONALE:

A.

B. NFκB is a transcription factor involved in the transcription of several inflammatory genes.

C. NSAIDs block the production of prostaglandins which normally serve to inhibit acid production and protect the gastric mucosa.

D. NSAIDs are effective anti-inflammatory agents as they decrease chemokine release which enhance cell migration from the blood into the tissues.

E. Prostaglandins produced by the COX enzymes are involved in the sensitisation of nociceptors to inflammatory mediators such as bradykinin.

CORRECT ANSWER WITH EXPLANATION:

A. Most NSAIDs bind reversibly. Only aspirin irreversibly acetylates COX enzymes.

ANSWER 25.2

RATIONALE:

A. Tofacitinib inhibits JAK which inhibits IL-2 signalling but not production.

B.

C. Adalimumab 'mops' up excess tumour necrosis factor (TNF) and so reduces acute inflammatory mediators and cellular infiltration.

D. Celecoxib is an NSAID that works through inhibition of proinflammatory prostaglandins.

E. Tocilizumab binds and reduces levels of IL-6.

CORRECT ANSWER WITH EXPLANATION:

B. Ciclosporin inhibits calcineurin required for Il-2 gene transcription.

---

[1] Here, we use the term *NSAID* to include the coxibs but this convention is not always followed in the literature.

[2] With possible exception of paracetamol, which has been used clinically to lower body temperature during surgery.

[3] A horrible condition where skin peels away in sheets as if scalded.

[4] So called because the availability of NSAIDs (often in combination with other substances, such as caffeine) in over-the-counter proprietary medicines has tempted some people to consume them in prodigious quantities, for every conceivable malady. Swiss

workers manufacturing watches used to share analgesics in the same way as sweets or cigarettes!

[5] An odd side effect of the NSAID diclofenac came to light when a team of scientists investigated the curious decline in the vulture population of the Indian subcontinent. These birds feed on dead cattle some of which had been treated with diclofenac for veterinary reasons. Apparently, residual amounts of the drug in the carcasses proved uniquely toxic to this species.

[6] Indeed, many people do not seem to regard it as a 'drug' at all. Many studies of human platelet aggregation have been ruined by the failure of volunteers to declare their consumption of aspirin.

[7] The term *arthritis* simply refers to inflammatory joint disorders. Clinically, more than 50 distinguishable types are recognised. To the lay person though, arthritis usually denotes either *osteoarthritis* or *rheumatoid arthritis*. These are often confused although they are entirely separate entities.

[8] Historically classified as such because, unlike NSAIDs, they lowered the erythrocyte sedimentation rate (ESR) – a marker of acute inflammation linked to increased plasma fibrinogen. Today, other acute phase reactants such as C-reactive protein (CRP) are generally preferred by rheumatologists as biochemical markers of disease activity.

[9] Because the therapeutic margin is so small, it used to be said by rheumatologists that 'patients must run before they can walk'!

[10] This does not, of course, apply to low-dose aspirin.

26: Skin

OVERVIEW

With a surface area of about 1.6–1.8 m^2 and a weight of about 4.5 kg in the average adult, skin qualifies as the largest and heaviest organ in the body. It is also an important target for drug therapy as well as cosmetic and other agents. Here, we look at the structure of human skin and briefly review some common skin disorders. We then discuss some of the many types of drugs that act upon, or through, this organ.

Introduction

Skin is a complex organ with many roles. [1] Firstly, it acts as a barrier. Being impermeable to water, it prevents the loss of moisture from the body as well as the ingress of water and many other substances into the body. It also cushions underlying tissues against thermal and mechanical damage and shields them from ultraviolet radiation and infection. Even if microorganisms survive in the slightly acidic environment of the skin's surface, they cannot easily cross the outer barrier of the skin. In the event that they do, they encounter specialised immunological surveillance systems comprising *Langerhans cells*, a type of dendritic cell, as well as mast cells and other immunocompetent cell types. [2]

A second function is thermoregulation. Approximately 10% of the total blood volume is contained within the dense capillary networks of the skin. Skin arterioles, controlled by the sympathetic nervous system, regulate blood flow and heat loss. Also involved in thermoregulation, and under cholinergic control, are the sweat glands (*eccrine glands*). These secrete an aqueous fluid that increases heat loss upon evaporation.

In the presence of sunlight, vitamin D_3 (cholecalciferol) is synthesised in the *stratum basale* and *stratum spinosum* of skin. Absence of this vitamin caused by inadequate exposure to the ultraviolet (UV B) component of sunlight can lead to deficiency symptoms (see **Ch. 36**). The dark-coloured pigment *melanin*, which protects skin against excessive and potentially damaging solar radiation and which gives skin its characteristic colour, is produced by melanocytes in the basal dermal layer. Melanin granule formation is stimulated by sunlight to match the prevailing light intensity.

Skin is also a profoundly sensory organ. It is densely innervated with neurons, including specific nerve endings that signal pain, heat and cold, and specialised receptors that detect touch (*Meissner corpuscles*) and pressure (*Pacinian corpuscles*) as well as itch – a sensation unique to skin with an interesting pharmacology. The cell bodies of cutaneous sensory nerves reside in the dorsal root ganglia.

Being highly visible, skin and its specialised appendages, hair and nails, play an important part in social and sexual signalling. As such, it is an important target for cosmetic preparations, camouflaging agents, suntan lotions, ‘anti-ageing’ compounds and more. Because unsightly skin can cause problems of social adjustment or even

frank psychiatric illness, the distinction between a therapeutic agent and a cosmetic preparation can become blurred. This is exacerbated by controversies about the classification of 'cosmeceuticals', as they are called, which contain pharmacologically active ingredients and associated safety issues. Nevertheless, the market for such preparations is huge. According to some estimates, the global spend will rise from US $500 billion in 2018 and to over US $700 billion by 2025.

Here we look briefly at some common conditions affecting the skin and at some of the drugs used to treat them (Tables **26.1** and **26.2**). In most cases, these drugs also have other uses, and their mechanisms of action are described elsewhere in the book, so the appropriate cross-references are given. Inflammation is a common feature of skin diseases, and anti-inflammatory drugs, discussed in detail in **Chapter 25**, are often used. In some other instances, the drugs themselves, or their particular utility, are almost unique to skin pharmacology, so they will be explained in a little more detail. Drugs used to treat skin infections and cancers are discussed in **Chapters 52**, **54** and **57**. Of note, drugs may also precipitate dermatological problems with adverse reactions frequently manifesting in the skin. These may range from mild self-limiting rashes through to the life-threatening Stevens-Johnson syndrome and relate factors such as sun exposure (photosensitivity, for instance with tetracycline antibiotics). These are expanded upon in **Chapter 58**.

Topical application of drugs onto the skin can be used as a route for systemic administration (transdermal drug delivery, see **Ch. 9**), but also as a means of targeting therapy to treat local underlying

tissues. For example, non-steroidal anti-inflammatory drugs (NSAIDs) applied topically can reduce the inflammation of underlying joints and connective tissue with less unwanted effects than those seen after systemic administration (**Klinge and Sawyer, 2013**). However, we will not deal in depth with this topic here.

Structure of Skin

Skin comprises three main layers: the outermost layer, the *epidermis*; a middle layer, the *dermis*; and the innermost layer, the *subdermis*, sometimes called the *hypodermis* or *subcutis* (**Fig. 26.1**).

Table 26.1

DMARDs, Disease-modifying antirheumatic drugs.

Sources: BNF (2021) and others.

Table 26.2

See **Chapter 5** for more information on these types of drug.

Sources: BNF (2021) and others.

The epidermis consists largely of keratinocytes. There are four histologically distinct zones: the *stratum basale* is the innermost layer and lies adjacent to the *dermoepidermal junction*. It comprises mainly dividing keratinocytes interspersed with

melanocytes. The latter cells produce granules of melanin in *melanosomes*, which are transferred to the dividing keratinocytes. As the keratinocytes divide and mature, they progress towards the skin surface. In the next layer, they form the *stratum spinosum* ('spiny' layer), so-called because *desmosomes* (intercellular protein links) begin to appear on the cells. Gradually, these cells begin to flatten, adopting a *squamous* (scaly) morphology. They lose their nuclei, and the cytoplasm acquires a granular appearance. Lying immediately above this is a thin translucent layer of tissue called the *stratum lucidum*. The outermost layer of skin is the *stratum corneum*. By now, individual keratinocytes are no longer viable because they have fused together (cornified). Most tissues have 10–30 layers of these hardened sheets of tissue. The *corneocytes*, as they are now called, are surrounded with a hydrated proteinaceous envelope. Lipid bilayers occupy the extracellular space providing a hydrophilic waterproof layer. The water and lipid content of skin is critical to its function. If the moisture content of the hydrated layer falls, the skin loses its supple properties and cracks. The keratinocytes are normally replenished about every 45 days (**Bergstresser and Taylor, 1977**) and so healthy skin constantly sheds the outer layer of cornified cells. If this does not occur, patches of dry skin begin to appear.

Below the epidermis lies the dermis. This layer varies in thickness. In some tissues, it is very thick (e.g. the palms and the soles of the feet) and in others, very thin (e.g. the eyelids). Histologically, the dermis comprises a *papillary layer* and a deeper *reticular layer*. The main cell types are fibroblasts. These produce and secrete important structural elements of the skin such as

glycoproteins, which contribute to the hydration of the tissue, and collagen and elastin that provide strength and elasticity. Other types of cells associated with the immune system are also present (see **Ch. 7**). The dermis is richly endowed with blood vessels and lymphatics and densely innervated.

Hair follicles, *sebaceous glands* and *sweat glands* are embedded in the dermis. Hair follicles are lined with specialised cells that produce keratin and associated melanocytes that produce pigment for the growing hair shaft. Associated with each hair follicle is an *erector pili* muscle that causes the hair shaft to become erect. Cold, fear and other strong emotional stimuli trigger this response giving the sensation of 'goose bumps'. Sebaceous glands associated with hair follicles coat the hair with waxy substances. The growth of hair and the activity of these glands are controlled by androgens. While *eccrine* sweat glands are distributed over much of the skin surface, *apocrine* sweat glands are also associated with hair, especially in the armpits and perineum. They empty their proteinaceous secretion into the hair follicle.

The innermost layer of skin is the hypodermis or cutis. This comprises connective tissue and adipose tissue, which may be particularly thick at some anatomical locations (e.g. the abdomen).

Skin

Skin is the largest and heaviest organ in the body. It is composed of three main components:

- *The epidermis*. This is the outermost layer and is composed of four layers of keratinocytes with interspersed melanocytes.

Keratinocytes divide in the basal layer and migrate upwards to the skin surface where they form cornified layers. Lipids in the extracellular spaces confer water-repellent properties.

- *The dermis*. The middle layer is of variable thickness. It consists of fibroblasts that produce structural components such as collagen and elastin as well as immunocompetent cells. Hair follicles and sweat glands are also embedded in this layer and it is densely innervated with nerves, blood vessels and lymphatics.
- *The subdermis* (*hypodermis* or *hypocutis*). This comprises connective tissue and varying amounts of adipose tissue.

Skin has four main functions:

- *A barrier*. Skin prevents the egress or ingress of water, other chemicals and microorganisms. It also acts as a mechanical and thermal barrier and a shock absorber.
- *Thermoregulation*. Vasodilatation of the rich capillary network of the skin, in combination with sweating, increases the loss of heat whilst vasoconstriction has the reverse effect.
- *Vitamin D synthesis*. In the presence of sunlight, vitamin D_3 is synthesised by cells in the epidermal layer.
- *A sensory organ*. Skin contains abundant sensory receptors for touch, heat, cold, pain and itch. Information arising from these dermal receptors is one of the chief ways in which we interact with the outside world.

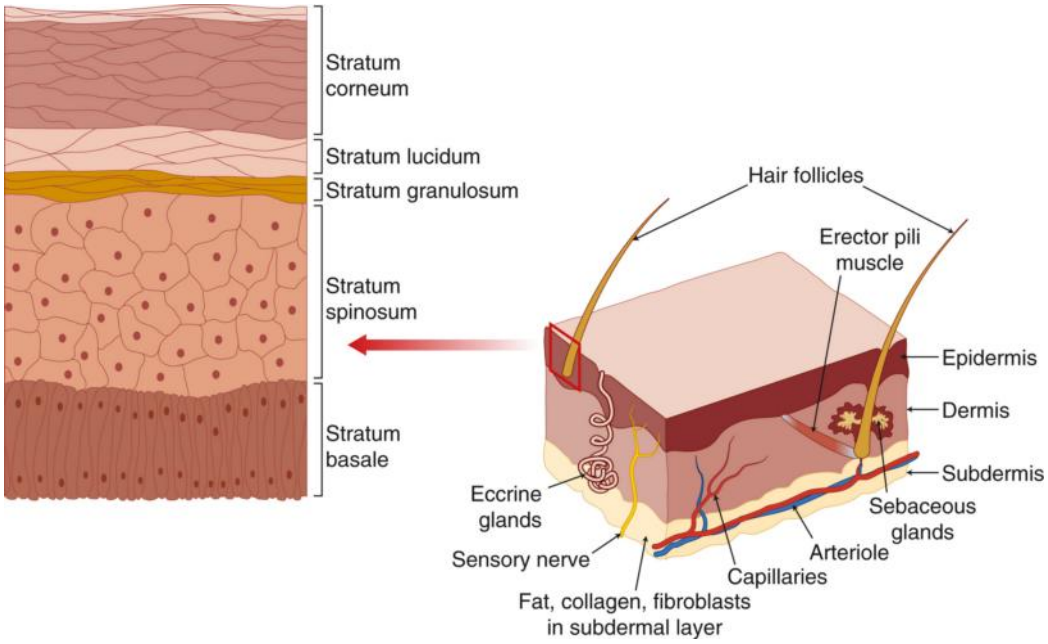

FIG. 26.1 A simplified diagram showing the structure of the skin.The skin comprises three main layers coloured differently in the right-hand drawing: epidermis *(dark red/brown)*; dermis *(pink)*; and subdermis *(yellow)*. On the left is an enlarged diagram of the complex outer, epidermal, layer. Not shown are the apocrine glands within the hair follicles.

Common Diseases of the Skin

Here we briefly review some common skin disorders (see **Fig. 26.2**).

Acne

The most common form of the disease occurs during puberty, especially in boys but also in girls. Changes in circulating androgens

stimulate the sebaceous glands associated with hair follicles, which become enlarged and blocked with sebum and debris. The confined material may become infected, causing an inflammatory reaction that compounds the problem. Normally acne disappears after *puberty*, but some forms may persist or manifest in later life and require long-term treatment. If severe, acne can cause irreversible scarring and considerable psychological misery.

Rosacea

The diagnostic feature of rosacea is the presence of a chronic hyperaemia of the facial skin which often adopts a characteristic pattern, spreading across the cheeks, forehead and the nose. It can sometimes cause *rhinophyma*, a condition in which the nose becomes red, the pores enlarge, and the skin becomes bumpy. Eventually the nose may actually change shape, possibly because of the formation of scar tissue. The erythema is caused by vasodilatation, and dilated blood vessels close to the surface of the skin are usually visible. The affected skin may become dry and flaky; there may be a stinging or burning sensation, and a tendency to flush in response to various stimuli, including exertion, emotional stress, heat, sunlight and spicy foods.

Rosacea affects about 10% of the population and there is a genetic basis for this disorder. It is more prevalent in women than men and may be exacerbated during the menopause. The condition cannot be cured, and the symptoms can be very long lasting and difficult to control, with both drug and other therapies such as *phototherapy* playing a role.

G, Courtesy of the Dr. Leonard Swinyer Collection, © 2020 University of Utah and Oregon Health & Science University.

There is debate about the cause of rosacea. Although predominately inflammatory in nature, infection may be a trigger, and rosacea could be a disorder of the innate immune system in which antimicrobial peptides in the skin are indirectly responsible for the symptoms. Antibiotics or anti-inflammatory agent treatments are usually the first choices where clinical management

demands drugs, but α2-agonists also play a part in controlling the erythema. **Sharma et al. (2022)** have recently reviewed this area.

Baldness and Hirsutism

There are two main types of baldness, *male-pattern baldness (androgenic alopecia)* and *alopecia areata*. Androgenic alopecia is caused by rising androgen levels and so particularly affects men after puberty; it starts with bi-temporal recession and progresses. Androgens inhibit the growth of hair on the scalp but stimulate it elsewhere (e.g. the face, chest, back, etc.). Alopecia areata is a condition where hair falls out in patches. These generally come and go but may eventually coalesce, leading to total baldness. The disease seems to be of autoimmune origin.

Hirsutism is common in men (who seldom complain) but is less socially acceptable in women. Once again, rising androgen levels are the cause, stimulating the growth of hair on areas of the body where it does not normally occur in women (e.g. the face); this is commoner in some ethnic groups and seldom pathological, although it can be a symptom of androgenising endocrine tumours (such as *Sertoli–Leydig cell tumours*, which are a rare type of ovarian tumour).

Eczema

This is a generic term and refers to a common condition where the skin becomes dry, itchy, flaky and inflamed. The distribution is distinctive, namely on flexor surfaces such as the wrists, elbows and behind the knees (in contrast to psoriasis). There are several potential causes. *Atopic eczema* (also called *atopic dermatitis*) is the

most common inflammatory skin disease, affecting about a quarter of all children and about 5% of adults. It is often seen in patients who also suffer from asthma or seasonal rhinitis (hay fever), although the long-held notion that this type of eczema is *primarily* an immunological disorder has rather little support. It tends to run in families, indicating a genetic susceptibility. *Contact dermatitis* arises when the skin becomes 'sensitised' to a particular antigen. Nickel sensitivity is a classic example: contact with the metal either provokes the production of antibodies or modifies structural elements of the epidermis so that autoantibodies are produced. This is more often seen in women because it is a common component of (less-expensive) jewellery. [3] The pathophysiology is now believed to stem from disordered barrier function leading to epidermal water loss, and a vicious cycle of itching and scratching with release of inflammatory mediators. Penetration of allergens and interaction with immunoglobulin E (IgE)-bearing Langerhans cells can add a Th2-mediated immunological component. *Xerotic eczema* refers to eczema that is produced when the skin dries out. This is more common in the winter months, especially among older people.

Pruritus

Pruritus – itch – is a common symptom of skin diseases, but can also occur with systemic disorders, such as obstructive jaundice, or neurological disorders such as shingles (herpes zoster). Some drugs (e.g. opioids) also can cause itching. There is a complex relationship between the neural systems that detect and transduce pain and itch (see **Greaves and Khalifa, 2004**; **Ikoma et al., 2006**). Confirming the long-held notion that there may be a dedicated

population of nociceptors that function as ‘itch transducers’, two G protein–coupled receptors (MRGPX2 and 4) that are sensitive to peptide allergens, and which are also thought to play a part in neurogenic inflammation and other disorders, have recently been identified and cloned (**Cao et al., 2021**; **Yang et al., 2021**).

Skin diseases commonly causing itch include eczema, urticaria and psoriasis. These conditions are generally accompanied by the release of inflammatory mediators in the skin from mast cells (e.g. histamine, leukotrienes, proteases and cytokines).

Urticaria

This term refers to a range of inflammatory changes in the skin characterised by the presence of raised wheals or bumps (‘nettle rash’). They are normally surrounded by a red margin and are intensely itchy. There are many known causes, including exposure to the sun (*solar urticaria* [4]), heat or cold, insect bites or stings, foodstuffs or infection, as well as some drugs. Many cases are allergic in nature while others have no known cause. A bizarre manifestation of urticaria seen in some people is *dermographia* – literally ‘skin writing’. This is an exaggerated form of the ‘triple response’ (localised erythema, flare and wheal) seen after injecting histamine into the skin (see **Ch. 17**) and in this case provoked by scratching or in some cases simply rubbing or stroking the skin.

Urticaria is associated with inflammatory changes in the dermis, including mast cell degranulation and the accompanying release of mediators. It may co-exist with a related condition, *angio-oedema*, which primarily affects the blood vessels of the subdermal layer. This again relates to histamine or bradykinin release or metabolism

and may be precipitated by drugs (commonly the angiotensin-converting enzyme inhibitors) as well as rare disease states such as hereditary angio-oedema (including C1 esterase inhibitor deficiency) and lymphoproliferative disorders. Urticaria can resolve relatively rapidly or can persist for weeks (*chronic urticaria*). The disorder can be difficult to manage and even glucocorticoids, which suppress most inflammatory responses, are usually ineffective. Hereditary angio-oedema management is dependent on subtype and may include recombinant C1 esterase inhibitor therapy (**conestat alfa**), bradykinin receptor antagonists (**icatibant**) and plasma kallikrein inhibitors (**ecallantide**, **lanadelumab** and **berotralstat**).

Psoriasis

Aside from atopic dermatitis, psoriasis is the most common inflammatory skin disease, affecting about 2%–3% of Europeans. It is an autoimmune condition and there is a genetic component. Several susceptibility loci have been identified, most of which are connected with the operation of the immune system.

Histologically, psoriasis manifests as inflammation accompanied by hyperproliferation of keratinocytes. This leads to an accumulation of scaly dead skin at the sites of the disease. The most common form is *plaque psoriasis*. This presents as areas of scaly silvery-white skin surrounded by red margins. The distribution is usually quite characteristic, with plaques first appearing on the knees and elbows. The lesions may be painful and are sometimes itchy (in fact the word ‘psoriasis’ originates from Greek and literally means ‘itchy skin’, although in contrast to eczema, itch is by no

means a predominant symptom). Psoriasis can also affect the fingernails, giving a 'pitted' appearance, and/or the joints (typically but not exclusively the distal inter-phalangeal joints) or other connective tissue (*psoriatic arthritis*).

Psoriatic lesions exhibit major histological changes, including hyperproliferation of keratinocytes, vasodilatation and abnormalities in other dermal structures. The lesions are heavily infiltrated with inflammatory cells such as neutrophils but also T cells. By 2015 it had become clear that a hitherto unknown subset of T cells, Th17 cells, were present in abundance in psoriatic lesions. Th17 cells are activated by interleukin 23 (IL-23) derived from dendritic cells or monocyte/macrophages or by other cytokines to produce IL-17 (several subtypes of which IL-17A is the principal member: see **Ch. 7**). This cytokine is also generated by T cells, neutrophils, mast and other cell types. It stimulates keratinocytes (and other cells) to produce a panoply of other pro-inflammatory molecules. In animal models, IL-17 reproduces many of the characteristics of psoriasis and it was subsequently recognised as a major driver of the pathogenesis of this condition in humans (**Kirkham et al., 2014**; **Martin et al., 2013**) and thus a potential target for drugs that blocked either its action, generation or signalling mechanisms.

Psoriasis is generally a lifelong condition but one that can appear and disappear for no apparent reason. Stress is said to be a precipitating factor, as is dry skin. Several drugs (e.g. β-adrenoceptor antagonists, NSAIDs and **lithium**) are purported to precipitate bouts of the disease (**Basavaraj et al., 2010**).

Treatment is usually with anti-inflammatory or immunosuppressive drugs (see **Table 26.2**) but anti-cytokine biopharmaceuticals (which obviously have to be administered systemically rather than topically) can be used to treat severe manifestations of this and related diseases.

Warts

Warts are caused by infection with one of the many types of human papilloma virus (HPV; see also **Ch. 53**). They are characterised by small, raised lesions with an irregular shape. As infection of the epidermis by the virus causes *hyperkeratinisation*, they also have a 'rough' feel.

The many varieties of HPV are generally tissue specific, so different strains give rise to warts at diverse anatomical locations. The most common type is usually found on hands and feet (e.g. as *verrucas*). Rather less acceptably, other types of HPV specifically infect the anogenital region, giving *anogenital warts*.

Most warts are benign in nature and disappear spontaneously after a period of time (usually weeks–months). However, some types of HPV are linked to cancers such as cervical cancer. The recent introduction of an anti-HPV vaccine has proved highly successful, reducing the incidence of this disease by 90% in young women who received the vaccine when young.

Other Infections

In addition to acne and rosacea, there are a number of other important bacterial skin infections that can be treated with appropriate antibiotics, either topical or systemic. These include

superficial skin infections such as *erysipelas impetigo*, and *cellulitis*, which is a more deep-seated infection mainly involving the dermis and subdermis usually of the lower limbs.

Fungal infections of the skin are also a common problem. *Tinea*, *candida* and other infections (see **Ch. 54**) affect skin at several sites (e.g. *tinea pedis* – 'athlete's foot'). These infections are easy to catch and can be difficult to eradicate completely.

The most common viral infections affecting the skin are *herpes simplex* (cold sores) and *herpes zoster* (shingles), both of which can be treated with antiviral drugs (see **Ch. 53**). The most common parasite infections of the skin are head lice (*Pediculus humanus capitis*), crab lice (*Pthirus pubis*) and scabies (*Sarcoptes scabiei*).

Melanoma

Melanoma (from a classical Greek term meaning 'black') is a malignant cancer caused by mutations in the pigment producing melanocytes, usually as a result of overexposure to UV light. A melanoma may therefore arise in the *stratum basale* layer of skin but also at other locations where these cells are found, including the inner ear and the eye. Melanoma may also develop from a *mole*, a pigmented lesion of the skin more correctly described as a type of *nevus* (birthmark). Melanoma is the most common type of skin cancer and, because of the rapidity with which it can metastasise, it is also the most dangerous, with a poor survival rate if not diagnosed and treated early. Global rates are increasing, and those with pale skins are at most risk.

Initial treatment is usually by surgical resection of the lesion, or metastatic tissue, but various other therapeutic modalities may also

be useful, including dynamic phototherapy, radiotherapy, chemotherapy and immunotherapy. In the latter cases, expert supervision is essential because melanoma is notoriously adept at evading drug therapy. The pharmacology of most of the chemotherapeutic agents used (e.g. **cisplatin**, **5-fuorouracil**, **taxanes** and vinca alkaloids, protein kinase inhibitors, tissue metalloproteinase inhibitors) are dealt with in **Chapter 57**, but biopharmaceuticals have recently revolutionised treatment of some cases (see later). The area has been recently reviewed by **Dhanyamraju and Patel (2022)**.

Drugs Acting on Skin

Formulation

Targeting drugs to the skin is both easy and difficult. Unlike most therapeutic situations, drugs can be applied directly to the diseased tissue in the form of ointments, solutions, creams, pastes or dusting powders, etc. There is an important caveat, however: since skin is a highly effective barrier, it can prevent the entry of many medicinal agents, and this can pose a therapeutic problem. To reach its site of action (often the lower layer of the epidermis or the dermis), a drug has to pass through the epidermal layer with its highly enriched lipid and aqueous environment. The transdermal delivery of drugs is therefore a highly specialised topic (see **Ch. 9**). Generally speaking, absorption is facilitated if the molecule is predominately hydrophobic in nature: thus, for example, glucocorticoids are often derivatised with fatty acid esters to render them more easily absorbed. The use of a waterproof *occlusion dressing* to cover the

skin after applying the drug improves absorption by keeping the epidermis fully hydrated.

The vehicle in which the drug is dissolved is also important. Creams and ointments – essentially stable oil/water emulsions – can be tailored to individual drugs. For example, **tacrolimus** formulated as an ointment can be used topically on the skin, whilst an oil-in-water formulation is better for a water-soluble drug such as an NSAID. The appearance and odour of the formulated drug are also important. Most patients would rather take a tablet than apply creams that may be greasy, smelly or unsightly to large areas of their skin (see **Tan et al., 2012**).

The physical condition of the skin is important in maintaining its barrier function and various agents can be used to protect the skin and promote repair. These include *emollients*, which re-hydrate the skin, and *barrier creams* that help to prevent damage from irritants. Use of such agents is often indicated alongside treatment with drugs.

Assessing the pharmacokinetics (PK) of drugs absorbed from the skin is therefore quite complex and it is consequently more difficult to estimate doses of drugs given topically compared to (say) oral administration. This can be particularly problematic in the case of drugs which may cause unwanted systemic side effects if they are extensively absorbed (e.g. glucocorticoids). Many new ideas for formulating drugs for passage into and through the skin are under investigation, both for treating skin disorders and also for general systemic treatment (see for example **Baveloni et al., 2021**).

Formulation. Because the skin comprises a unique combination of hydrophobic/hydrophilic structures, many drugs are not absorbed, and special formulations may be necessary to promote penetration.

Many drugs used for skin conditions are also used to treat disorders in other organs. The main groups are:

- *Glucocorticoids*. Widely used to treat psoriasis, eczema and pruritus because of their anti-inflammatory properties. They are usually specially formulated to enhance topical penetration.
- *Antimicrobial agents*. Used topically or systemically to treat skin infections (e.g. acne, impetigo, cellulitis and rosacea).
- *Hormone antagonists*. Androgen antagonists are used topically or systemically to treat male-pattern baldness or hirsutism in women.
- *Vitamin D derivatives*. Drugs such as **calcitriol**, **calcipotriol** and **tacalcitol** are used to treat psoriasis.
- *Anticancer drugs and biopharmaceuticals* are used to treat melanoma.

Some drugs are used almost exclusively for skin disorders. These include:

- *Retinoids*. These are derivatives of vitamin A and include **tretinoin**, **isotretinoin**, **alitretinoin**, **tazarotene** and **adapalene.** They are used to treat acne, eczema and psoriasis. They are usually given topically but can be given systemically.

Principal Drugs Used in Skin Disorders

Many drugs in the dermatological arsenal are also used to treat other diseases and their mechanism of action is the same. The use of agents described later to treat specific skin disorders is shown in Tables **26.1** and **26.2**. We refer the reader to other chapters in the book where information about these agents may be found. Other drugs, such as analogues of vitamins A and D, are rather specific to skin pharmacology.

Of note, it is relatively common practice to use mixtures of drugs in dermatological treatments. Thus anti-inflammatory glucocorticoids may be mixed with antibiotics, antiviral or keratogenic agents; coal tar derivatives mixed with emollients and so on.

Antimicrobial Agents

Chapters 51–56 deal in depth with the mechanism of action of this group of drugs. Antibiotics can be applied topically in diseases such as impetigo and acne or given systemically in the case of cellulitis or rosacea. Fungal infections of the skin are generally treated with topical fungicidal drugs, but oral preparations of (e.g.) **ketoconazole** may be used under some circumstances. Herpes simplex infections may be treated with topical or systemic **acyclovir** or **penciclovir**.

Biopharmaceuticals

The recognition that cytokines such as tumour necrosis factor α (TNF-α) was elevated in skin inflammation in conditions such as psoriasis led to the testing of anti-cytokine drugs such as **etanercept, adalimumab** and **infliximab** with encouraging successes. The more recent recognition of the importance of the IL-23/IL-17 axis in psoriasis has led to the introduction of a number of new biopharmaceutical agents which specifically block, immunoneutralise or otherwise affect this pathway. These agents include **brodalumab**, **ixekizumab**, **guselkumab**, **risankizumab**, **tildrakizumab** and **dupilumab** which act at different points in the pathway (see **Table 26.2**). These have met with great success outperforming previous biopharmaceuticals for the treatment of psoriasis when used for a year (**Yasmeen et al., 2022**). **Fig. 26.3** shows the beneficial effect of treatment of **brodalumab** on the response of patients with moderate to severe psoriasis for periods up to 12 weeks.

IL-4, which is associated with autoimmune conditions, shares a receptor with the structurally related IL-13 and this cytokine itself has been strongly implicated in allergic conditions of various sorts. **Dupilumab**, a mAb which blocks the IL-4 receptor, has found utility in several allergic conditions, including eczema.

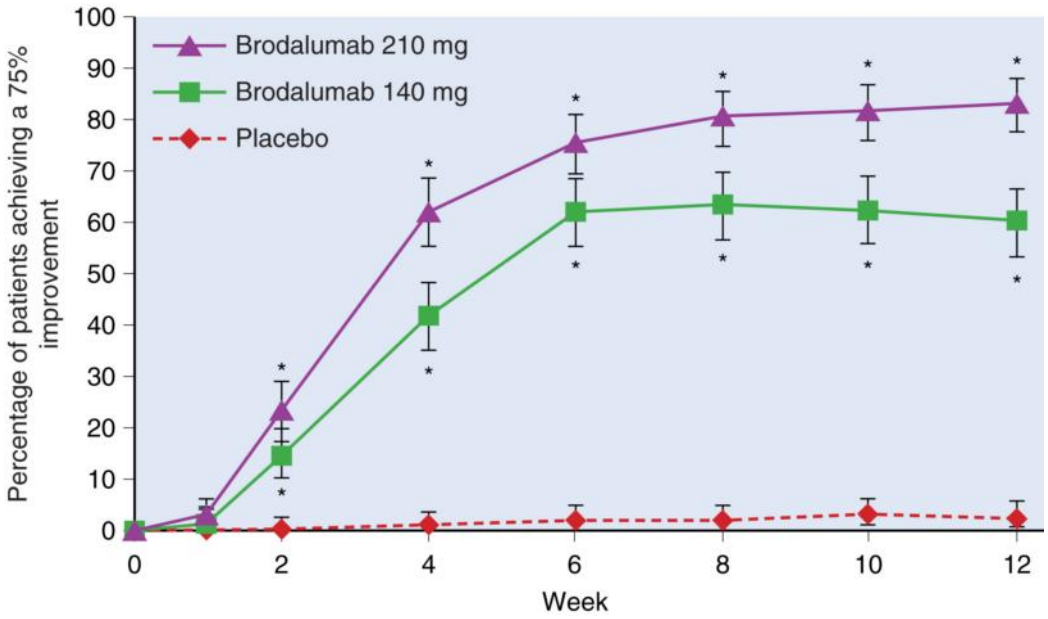

FIG. 26.3 The beneficial effect of the biopharmaceutical anti IL-17 drug **brodalumab** on the severity of moderate-severe psoriasis.The extent and severity of the psoriatic lesions in patients were assessed using a combined scale (PASI index) which takes into account both the extent and severity of the disease. The study was a random double-blind placebo-controlled study in which two doses of **brodalumab** (140 mg and 210 mg) were tested against a placebo for periods up to 12 weeks. In the graph, the percentage of patients responding with a 75% decrease in PASI score was plotted against time. Adapted and modified from Papp, K.A., Reich, K., Paul, C., et al., 2016. A prospective phase III, randomized, double-blind, placebo-controlled study of brodalumab in patients with

moderate-to-severe plaque psoriasis. Br. J. Dermatol. 175, 273–286..

Biopharmaceuticals are also used in the treatment of melanoma where their overall aim is to eliminate the mutated cells. **Ipilimumab** is a human mAb which acts on T cells removing an inhibitory circuit such that they are activated and consequently more able to remove the cancerous tissue. **Nivolumab** and **pembrolizumab** are human or humanised mAbs which kill melanoma cells by acting on the 'programmed death receptor', PD-1. These biopharmaceutical drugs are commonly used in combination with other anticancer agents.

Unwanted effects.

Because cytokines are intimately involved with the operation of the immune system, one might anticipate adverse effects on the host response to infection. This is a common finding with all these agents and care must be taken to resolve any current infections prior to therapy. Other common side effects seen with some of these drugs include arthralgia, myalgia, fatigue, headache and gastrointestinal symptoms such as diarrhoea.

Glucocorticoids and Other Anti-Inflammatory Agents

Antihistamines (see **Ch. 17**) are useful when controlling mild pruritus, at least in some circumstances, e.g. eczema, insect bites and mild inflammation. Another topical drug which is useful in treating pruritus is **crotamiton**. This acts rapidly and has long-lasting effects. The mechanism of action is not known.

However, the main agents used to treat inflammation of the skin are the glucocorticoids, which are widely used to treat psoriasis and eczema and to suppress pruritus. Their general mechanism of action is described in **Chapters 3**, 25 and 33. Preparations used in dermatological practice are often formulated as fatty acid esters of the active drugs. This promotes their absorption through the highly hydrophobic layers of the skin but also alters their efficacy: for example, the potency of topical **hydrocortisone** on the skin is greatly enhanced by formulating it as a butyrate ester.

Although schemes around the world vary, the convention is to classify these drugs by potency. For example:

- *Mild,* e.g. **hydrocortisone**;
- *Moderate,* e.g. **alclometasone dipropionate**, **clobetasone butyrate**, **fludroxycortide** and **fluocortolone**;
- *Potent,* e.g. **beclomethasone dipropionate**, **betamethasone** (various esters), **fluocinolone acetonide**, **fluocinonide**, **fluticasone propionate**, **mometasone furoate** and **triamcinolone acetonide**;
- *Very potent,* e.g. **clobetasol propionate** and **diflucortolone valerate.**

The choice of glucocorticoid depends upon the severity of the disease and, because the thickness of skin varies from one location to the other, its anatomical site. They are sometimes combined with antibacterial or fungicidal drugs if they are to be used at the site of an infection.

The action of glucocorticoids on the skin is similar in mechanism to their effect elsewhere in the body. They are potent inhibitors of the release of inflammatory mediators from mast cells, of neutrophil activation and emigration, and immune cell activation (see Chs 7 and **25**). Interestingly, and contrary to dogma, it seems that skin cells can themselves generate cortisol and there is some evidence that this ability is deficient in patients who suffer from psoriasis (**Hannen et al., 2017**). The topical application of glucocorticoids produces vasoconstriction in the skin causing a characteristic 'blanching' reaction. [5] The exact mechanism is unknown.

Unwanted effects. Generally speaking, short-term treatment with low-potency steroid preparations is safe; in fact, some **hydrocortisone** formulations are available from pharmacies without prescription. There are potentially serious side effects associated with prolonged usage or with the more potent members of the class, however. These include:

- *Steroid 'rebound'*. If topical steroid therapy is suddenly discontinued, the underlying disease often returns in a more aggressive form. This is probably because the glucocorticoid receptor is down-regulated during topical treatment and can no longer respond to circulating glucocorticoids, which maintain an anti-inflammatory 'tone', when treatment is withdrawn. Gradually tapering the drug can avoid this problem.
- *Skin atrophy*. Catabolic effects of glucocorticoids (see **Ch. 33**) can lead to atrophy of the skin, including stretch marks

(*striae*) and small visible vessels (*telangiectases*), that is only partially reversible upon stopping treatment.

- *Systemic effects*. Systemic absorption can theoretically cause depression of the hypothalamic–pituitary–adrenal axis, as described in **Chapter 33**, but this does not seem to constitute a significant risk in normal clinical practice (**Castela et al., 2012**).
- *Spread of infection*. Because glucocorticoids suppress the immune system, there is a danger that they may encourage or reactivate infection. For this reason, they are contraindicated in acne, where there is a co-existent infection.
- *'Steroid rosacea' (skin reddening with pimples)* is a recognised problem when treating facial skin with potent glucocorticoids.

For more serious cases of eczema or psoriasis or where glucocorticoids are ineffective, topical or systemic application of immunosuppressants such as **ciclosporin, pimecrolimus** or **tacrolimus** may be successful (see **Ch. 25**). As described earlier, biopharmaceuticals also play an increasingly important role in the treatment of refractory cases (see **Table 26.2**).

Drugs Used to Control Hair Growth

Hair growth in both sexes is driven by androgens, but so is male-pattern baldness. Because of this, androgen antagonists, or compounds that modulate androgen metabolism, can be used to treat both hirsutism in women and androgenic alopecia in men.

Co-cyprindiol is a mixture of an anti-androgen, **cyproterone acetate**, and a female sex hormone, **ethinylestradiol**. Antagonising androgenic actions reduces sebum production by sebaceous glands and also hair growth (which is androgen-dependent), so it can be used for treating acne as well as hirsutism in women. Unwanted effects include venous thromboembolism, and it is contraindicated in women with a family history of cardiovascular disease.

Finasteride inhibits the enzyme (5α-reductase) that converts testosterone to the more potent androgen, dihydrotestosterone (see **Ch. 35**). It is used topically (usually in combination with **minoxidil**) for the treatment of androgenic alopecia, as well as orally for prostatic hypertrophy. The treatment takes months to produce real changes. Unwanted effects resulting from its action on androgen metabolism include a reduction in libido, possibly impotence and tenderness of the breasts.

Eflornithine was originally developed as an antiprotozoal drug (see **Ch. 55**). It can be used topically to treat hirsutism because it irreversibly inhibits *ornithine decarboxylase* in hair follicles. This interrupts cell replication and the growth of new hair. Unwanted effects include skin reactions and acne.

Minoxidil is a vasodilator drug that was originally developed for treating hypertension (see **Ch. 21**). Applied topically, it is converted in hair follicles to a more potent metabolite, **minoxidil sulfate** (some preparations contain this salt). Perhaps because of its ability to increase blood supply to hair follicles, it stimulates growth of new hair and the progression of the new follicle through successive phases of the cell cycle (see **Ch. 6**). Existing follicles, usually stalled

in their resting (telogen) phase, must first be 'shed' to make way for new, rapidly growing follicles, so hair loss following initial treatment is a frequent – and presumably rather alarming – action of the drug. Other unwanted effects are few, but some local irritation may occur. Hair loss recurs when topical application is discontinued.

Retinoids

Disturbances in vitamin A metabolism are known to result in skin pathology. The vitamin is normally acquired in ester form from dietary sources. It is converted to *retinol* in the gut and this seems to be a storage form of the vitamin.

Vitamin A has many biological roles. As *retinal*, it is an essential component of rhodopsin and hence crucial for normal vision. However, it can also undergo an irreversible oxidation to *retinoic acid*, which has potent effects on skin homeostasis.

The retinoid drugs are derivatives of retinoic acid. The principal examples are **acitretin, adapalene, alitretinoin, isotretinoin, tretinoin**, and **tazarotene**. They are widely used (sometimes in combination with other drugs) for the treatment of acne, eczema and psoriasis. Topical application is the usual route of administration, but oral therapy is sometimes used for severe cases.

Retinoids probably act by binding to retinoid X receptor (RXR) and retinoid acid receptor (RAR) nuclear receptors (see **Ch. 3** and **Fig. 26.4**) in their target cells, which include keratinocytes and the cells of sebaceous glands, although some have questioned this mechanism (**Arechalde and Saurat, 2000**). Retinoid binding proteins (RBPs) on the surface of, and within, the cell aid in

transport of the molecule to its receptor and facilitate its eventual catabolism (**Napoli, 2017**). The main dermatological actions of retinoids include modulation of epidermal cell growth and reduction in sebaceous gland activity and sebum production. They also have pleiotropic actions on the adaptive and innate immune system, including inhibition of IL-6-induced activation of Th17 cells and Toll receptors that contribute to an anti-inflammatory effect .The area has been reviewed by **Khalil et al. (2017)**.

Unwanted effects. After oral administration, retinoids may cause dry or flaky skin, stinging or burning sensations and joint pains, possibly because they can also activate the TRPV1 receptor (**Yin et al., 2013**). Retinoids are teratogenic (this is linked to the effects of retinoids on epidermal differentiation that underlie their efficacy) and can be used in women only in the presence of suitable contraception (see Chs **35** and **58**). Because of their chemical relationship to retinal, retinoid drugs may cause disturbances in the visual system as well as impairment of hearing. They may also incur a plethora of unwanted gastrointestinal and other effects.

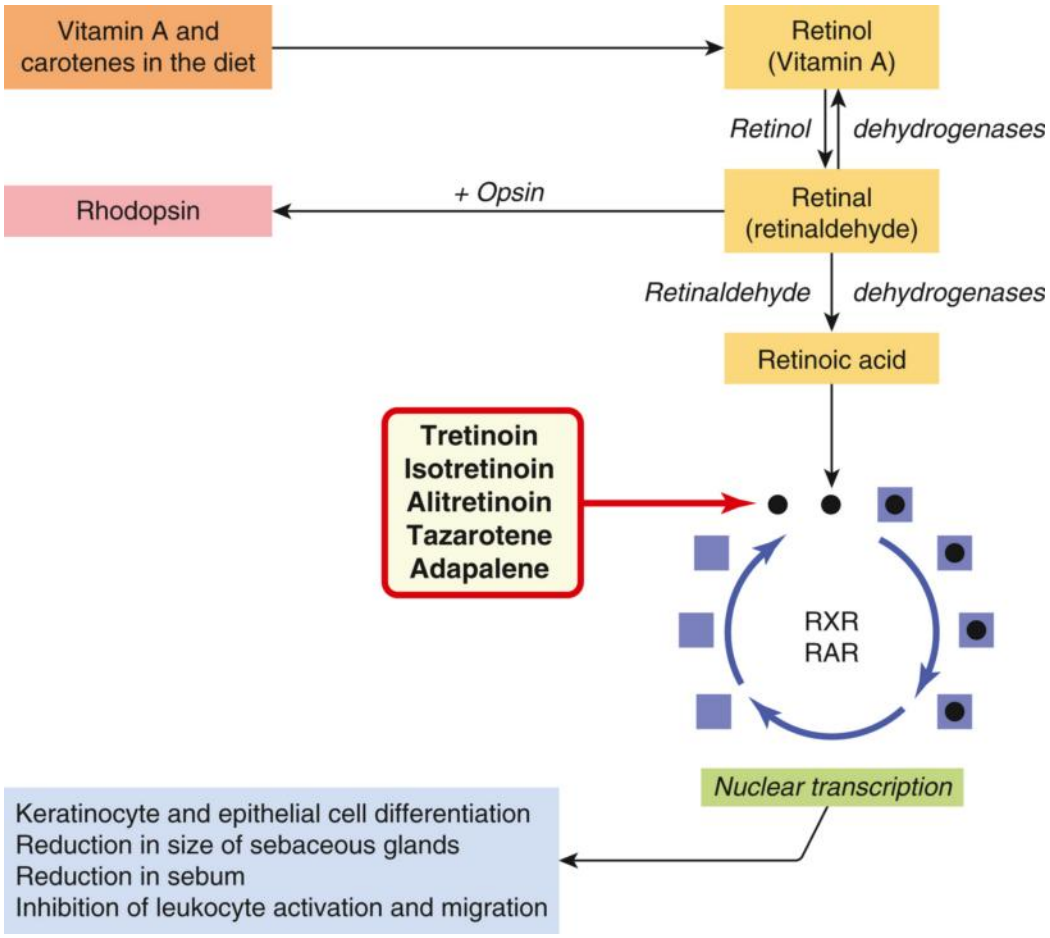

FIG. 26.4 The retinoid pathway.Vitamin A (retinol) is acquired largely through dietary sources and is reversibly converted to retinal (retinaldehyde).This may be combined with opsin to produce the visual pigment rhodopsin or irreversibly oxidised to retinoic acid. The latter species can interact with nuclear receptors (RXR and RAR; see **Ch. 3**) to produce changes in genes that modulate keratinocyte differentiation, reduce the size and output of sebaceous glands and exert a general anti-inflammatory action. The synthetic congeners **acitretin**, **adapalene**,

alitretinoin, **isotretinoin**, **tazarotene** and **tretinoin** can also act at the RXR and RAR, also producing potent actions in skin disorders such as acne and psoriasis.

Vitamin D Analogues

Vitamin D is actually a mixture of several related substances. Although classed as a 'vitamin' and therefore by implication an essential dietary factor, vitamin D_3 (cholecalciferol) is synthesised by the skin in the presence of sufficient sunlight (in fact, *phototherapy* is an important therapeutic modality in some skin disorders for this and other reasons). Other forms of the vitamin (e.g. D_2) can be obtained from the diet. The vitamin plays a crucial role in calcium and phosphate metabolism and bone formation (see **Ch. 36**). It also has complex pleiotropic regulatory actions on the innate and adaptive immune systems, reducing the activity of the adaptive system but increasing the activity of the innate immune system producing a net anti-inflammatory action (**Charoenngam and Holick, 2020**).

The biologically active metabolite *calcitriol* (see **Ch. 36**) is synthesised in the body by a multi-step process that requires transformations in the liver and kidney. At the molecular level, vitamin D and its analogues act though the vitamin D receptor (VDR) group of nuclear receptors (see **Ch. 3**) in keratinocytes, fibroblasts, Langerhans cells and sebaceous gland cells, to modulate gene transcription. Amongst the effects seen after treatment are antiproliferative and pro-differentiation actions on keratinocytes, increased apoptosis of plaque keratinocytes (**Tiberio et al., 2009**)

and the inhibition of T-cell activation (**Tremezaygues and Reichrath, 2011**).

The main analogues used are **calcitriol** itself, **calcipotriol** and **tacalcitol**. Their principal clinical use is treating psoriasis. Oral administration is possible, but they are generally administered topically, sometimes in combination with a glucocorticoid.

Unwanted effects.There is always a concern about the possible effects of the drugs on bone and they should be avoided in patients who have problems related to calcium or bone metabolism. Topical application can lead to skin irritation.

Agents Acting by Other Mechanisms

Many ancillary agents are used in dermatology, including topical antiseptics, emollients, soothing lotions and other substances. Amongst this group are '**coal tars**' or their derivatives such as **dithranol**. The former, which are poorly defined mixtures containing thousands of phenolic compounds and polycyclic aromatic hydrocarbons, are generated during the conversion of coal to coke or gas. They contain chemicals that formed the basis for many early medicines. Topical coal tar preparations have been used in dermatological practice for decades. Having anti-inflammatory, anti-pruritic and anti-infective properties, they can bring about a useful therapeutic benefit in eczema, psoriasis and some other skin conditions, and are often the first agents to be tried even though their mechanism of action was far from clear. However, recent research points to the activation of the *aryl hydrocarbon receptor* (AHR) in the skin as one possible mechanism since this leads to down-regulation of proinflammatory cytokines, including IL-17, and

influences skin barrier function. Consequently, AHR is an exciting potential target for novel therapeutic drugs, and the FDA is currently evaluating one agent (**tapinarof**) that binds and activates this receptor as a topical therapy for plaque psoriasis (see **Bissonnette et al., 2021**). As one might expect, given their origin, coal tars contain carcinogenic substances, but in clinical use, the risk appears to be slight (**Roelofzen et al., 2010**).

Among other drugs unique to skin pharmacology are **salicylic acid** and **podophyllotoxin**. Topical **salicylic acid** has a *keratolytic* effect in situations when excess skin is being produced (e.g. warts), causing epidermal layers to be shed. It is a common ingredient of numerous proprietary wart removers. **Podophyllotoxin** is a toxin extracted from plants of the podophyllum family. It is usually reserved for treating anogenital warts. It is applied topically and prevents the excess growth of skin, probably because it inhibits tubulin polymerisation and hence arrests the normal cell cycle.

Another agent used for anogenital warts is **imiquimod**. This drug is an immune modifier, exerting antiproliferative effects through stimulation of pro-inflammatory cytokine release by activating innate immune cells via the Toll-like receptor 7 as well as up-regulating growth factor receptor expression. It is also used for the topical treatment of some types of pre-cancerous (e.g. actinic keratosis) and cancerous (e.g. basal cell carcinoma) skin lesions. Unwanted effects include local skin reactions.

Concluding Remarks

Despite the plethora of preparations available to treat skin disorders, there is clearly still an unfilled therapeutic need in several areas (e.g. rosacea) and, as always, reducing the unwanted effects of existing drugs is a further worthwhile objective that would greatly enhance their clinical utility. Some of the most interesting ideas have arisen from reconsidering the design of the glucocorticoids, vitamin D analogues and especially the retinoids. All these drugs act predominantly through nuclear receptors and recent thinking suggests that differentiating the mechanisms of transrepression and transactivation of genes by these drugs may be an achievable goal. Progress towards separating the useful from the unwanted effects of glucocorticoids is slowly yielding fruit (see **Ch. 33** for a discussion of this), and clearly, the prospects of separating the calcaemic from the anti-inflammatory effects of vitamin D analogues (**Tremezaygues and Reichrath, 2011**) and improving the selectivity of retinoids (**Orfanos et al., 1997**) are also very attractive therapeutic goals.

It is perhaps surprising that 'itch' is still such a problem. Hopefully the recent identification of 'itch'-sensitive GPCRs mentioned earlier will impact on this area.

Biopharmaceuticals are one of the big success stories in dermatology and one can reasonably expect their numbers to increase as the search for new therapies for psoriasis, atopic dermatitis and other inflammatory conditions proceeds.
