QUESTIONS

QUESTION 26.1

The skin is an abundant and complex organ. Knowledge of its structure and function is important in understanding a number of pathological disease states and its therapeutic potential as a site of drug action and absorption.

Which of the following statements about the physiological function of the skin is correct?

OPTIONS:

A. Melanin formation is stimulated by sunlight.

B. Epithelial lymphocytes are the key immune cells in protection against invading microorganisms.

C. Cholecalciferol is synthesised in the stratum corneum by the action of ultraviolet B (UVB) irradiation.

D. Meissner's corpuscles detect pressure on the skin.

E. Parasympathetic innervation regulates arteriolar vasodilatation and heat loss.

QUESTION 26.2

Vitamins A and D have also been shown to be important in the maintenance of skin physiology and function. Disturbances to the levels of these vitamins can therefore result in pathological disorders.

Which of the following statements about vitamins A and D relating to skin function is incorrect?

OPTIONS:

A. Vitamin D_3 is synthesised in the skin from sunlight.

B. Vitamin A from the diet is converted to retinoic acid.

C. Vitamin A and its analogues promote keratinocyte proliferation and leukocyte activation.

D. Vitamin A decreases sebaceous gland secretion and sebum production.

E. Vitamin D increases the activity of the innate immune system.

QUESTION 26.3

Topical glucocorticoid preparations are frequently used to treat inflammatory skin conditions.

Which of the following statements about the clinical use of glucocorticoids is correct?

OPTIONS:

A. Glucocorticoids can promote skin healing through keratinocyte proliferation.

B. Rapid withdrawal of topical steroid therapy can cause a hypersensitivity to endogenous glucocorticoids.

C. Topical application of glucocorticoids produces vasodilation in the skin causing a characteristic 'reddening' reaction.

D. Preparations are often formulated in aqueous solutions to enhance hydration of the skin.

E. The immunosuppressant effects of glucocorticoids are useful in the treatment of acne.

ANSWERS

ANSWER 26.1

RATIONALE:

A.

B. Types of dendritic cells, called Langerhans' cells, are the key cellular mediators of immunological surveillance.

C. Cholecalciferol is synthesised in the stratum basale and spinosum by the action of UVB.

D. Pressure is detected by Pacinian corpuscles.

E. The sympathetic nervous system controls the thermoregulation of the skin.

CORRECT ANSWER WITH EXPLANATION:

A. Melanin formation is stimulated by sunlight.

Melanin, which protects skin against excessive and potentially damaging solar radiation and which gives skin its characteristic colour, is produced by melanocytes in the basal dermal layer. Melanin granule formation is stimulated by sunlight to match the prevailing light intensity.

ANSWER 26.2

RATIONALE:

A. Cholecalciferol (vitamin D_3) is made in the skin in the presence of sunlight.

B. Vitamin A from the diet is converted to retinol in the gut and can then undergo irreversible oxidation to retinoic acid.

C.

D. Vitamin A, probably by binding the intracellular receptors, acts as a transcription factor to regulate gene transcription. Expressed proteins act to reduce gland secretion.

E. Vitamin D has complex pleiotropic regulatory actions on the innate and adaptive immune systems, reducing the activity of the adaptive system but increasing the activity of the innate immune system producing a net anti-inflammatory action.

CORRECT ANSWER WITH EXPLANATION:

C. Vitamin A and its analogues promote keratinocyte proliferation and leukocyte activation.

Isotretinoin, a vitamin A retinoid analogue, promotes keratinocyte differentiation so reducing cell growth and division and a reduction in leukocyte activation to reduce inflammation.

ANSWER 26.3

RATIONALE:

A. Catabolic effects of glucocorticoids can lead to atrophy of the skin.

B.

C. The topical application of glucocorticoids produces vasoconstriction in the skin causing a characteristic 'blanching' reaction. The exact mechanism is unknown.

D. Drug absorption through the skin is more effective if hydrophobic in nature, so glucocorticoids are often derivatised with fatty acid esters to aid absorption.

E. As they are immunosuppressant in nature, they are contraindicated in acne where there is a co-existent infection.

CORRECT ANSWER WITH EXPLANATION:

B. Rapid withdrawal of topical steroid therapy can cause a hypersensitivity to endogenous glucocorticoids.

If topical steroid therapy is suddenly discontinued, the underlying disease often returns in a more aggressive form. This is probably because the glucocorticoid receptor is down-regulated during topical treatment and can no longer respond to circulating glucocorticoids.

[1] As the American humourist and songwriter Alan Sherman so succinctly put it, ‘Skin's the thing that if you’ve got it outside/It keeps your insides in’.

[2] Dendritic cells were named as such by Paul Langerhans, who discovered them in 1868 while still a medical student in Berlin. Because of their shape, he mistook them for nerve cells, but they are actually phagocytic antigen-presenting immune cells of the monocyte/macrophage lineage.

[3] However, the number of men suffering from the condition is rising because of the popularity of skin piercing. If body art is your thing, always insist on high-quality nickel-free jewellery.

[4] Not to be confused with *miliaria* (prickly heat), which is caused by blocked sweat glands.

[5] This interesting observation was used by Cornell and Stoughton in 1985 as the basis for the first quantitative assay of glucocorticoid potency in man.

27: The eye

OVERVIEW

Several unique aspects to the eye make its pharmacology both challenging and interesting. The autonomic nervous system control of the pupil and the lens is one key area that is targeted by drugs that act on the parasympathetic and the sympathetic nervous systems. Maintenance of intraocular pressure within the globe is also another area where specific pharmacological therapy such as the prostaglandin analogues has been developed. A wide range of eye drops are now available for treatment of open-angle glaucoma which is one of the most common causes of visual impairment worldwide. Targeted drug delivery is a key consideration because drops act on the external eye, cornea and anterior chambers but do not penetrate behind the lens. Systemic or intravitreal administration is required for the retina. Several pathological processes can lead to new vessel formation with subsequent complications of haemorrhage and oedema causing visual loss. Vascular endothelial growth factor (VEGF) inhibitors are given by intravitreal injection to manage conditions where new vessel formation has pathological consequences.

Introduction

The eye (**Fig. 27.1**), functionally analogous to a high-tech photographic camera, is a tough fluid-filled globe with an outer

transparent layer (the cornea) at the front, a light receptive layer (the retina) at the back and variable-aperture and variable-focus lens at the interface between anterior and posterior chambers. The wall of the posterior chamber incorporates a dark layer of melanin-rich epithelium, so stray light is absorbed rather than being reflected within the chamber. The retina, on which light passing through the pupil is focused by refraction at the cornea and by the lens, contains the light sensitive cells (rods and cones) and the transparent nerve fibres and ganglion cells that connect the rods and cones to the optic nerve and hence to the brain where the image is interpreted.

Within this globe the anterior components are bathed in clear fluid ('aqueous humour') that helps maintain the smooth functioning of the iris and lens (**Fig. 27.2**). Behind the lens a clear jelly like substance ('vitreous humour') supports retinal function. The integrity and transparency of these liquid and gel-like compartments in an enclosed space are important for the pharmacology and the pathology of the eye.

The retina has high metabolic demands, and disordered blood supply is a common feature of retinal pathology. The ophthalmic artery supplies the eye via two distinct vascular networks: the choroidal network, which supplies the choroid, optic nerve head and the outer retina plus the inner layer of the macula, with the central retinal artery, which supplies almost all of the retina's inner layers of transparent nerve fibres and ganglion cells. The macula, the central area of the retina containing cones and responsible for high acuity central vision, lacks superficial retinal vessels but obtains part of its supply by diffusion from both supplies. The retinal

endothelial junctions are tight, as is Bruch's membrane, the basement membrane deep to retinal pigmented epithelium. The retinal blood vessels are uniquely accessible to direct visualisation through ophthalmoscopic examination, enabling the early diagnosis of conditions that are common causes of blindness if untreated but for which effective preventive therapies are available – notably proliferative diabetic retinopathy and wet age-related macular degeneration (see later).

Eye disorders are common and range in severity from transient redness and discomfort to permanent loss of vision. Common pathological processes such as infection, inflammation and malignancy affect the eye as they do other parts of the body, but several unique aspects of ocular structure and function make its pharmacology both challenging and interesting. The close relationship between rhodopsin and its associated retinal G protein–coupled receptors is mentioned in **Chapter 3**; in the present chapter we emphasise aspects of therapeutic relevance.

Readers requiring a detailed account of the structure, function and pathology of the human eye are referred to *The Eye: Basic Sciences in Practice* (**Forrester et al., 2020**).

Special Pharmacokinetic Considerations in the Eye

Delivering treatment to the eye presents unique challenges. There is a scleral and conjunctival barrier at the front which limits the absorption of topical therapies and subsequent drug diffusion to the retina through the fluid-filled chambers of the eye. Systemic therapies administered by mouth or intravenously may not

penetrate the tight junctions at the blood–retinal barrier. There are two parts to this barrier, with the inner retinal portion comprising of tight junctions between capillary endothelial cells, and the outer aspect involving tight junctions between retinal pigment epithelial cells. The impermeability of these barriers to certain drug formulations has led to the development of intravitreal injection (see **Ch. 9**), together with depot delivery systems that allow the slow dispersion of drugs introduced directly into the vitreous humour (**Fig. 27.1**).

Disease at the front of the eye is treated with topical agents, where possible. Formulations of eye drops are typically weak acids or bases with pH close to 7.4 and must not be irritant in nature. The blinking mechanism and release of tears means that topically delivered therapies such as eye drops remain only for a short time on the surface of the eye. A proportion of the drug will pass down the nasolacrimal duct and may be systemically absorbed to cause adverse effects such as wheezing in asthmatic patients treated with **timolol** eye drops (see further in the chapter and **Ch. 15**). Adherence to eye drops may be problematic particularly for formulations that have to be regularly delivered every 6–8 h, or for older patients with impaired manual dexterity. Some drops for the cornea have to be given as frequently as every hour, a problem especially overnight, for which ointments are thought to be more suitable as a depot delivery approach.

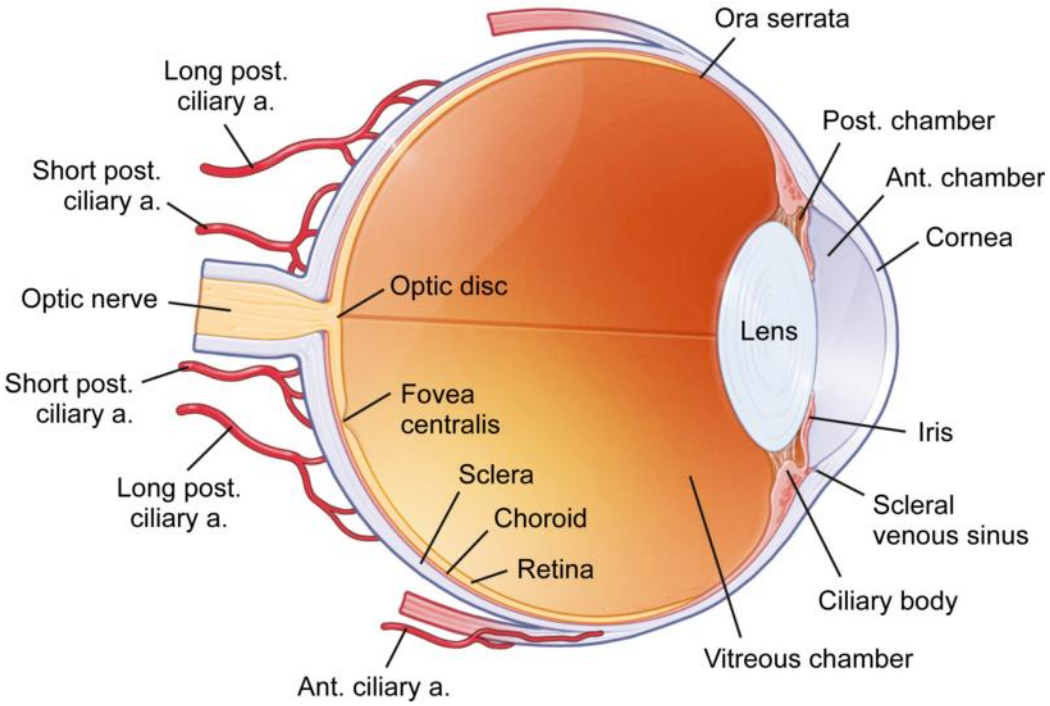

FIG. 27.1 Anatomy of the eye.Cross-section showing the three layers of the globe and key structures. Reproduced from Drake, R., Vogl, A.W., Mitchell, A.W.. 2016. Gray's Basic Anatomy. Elsevier, London.

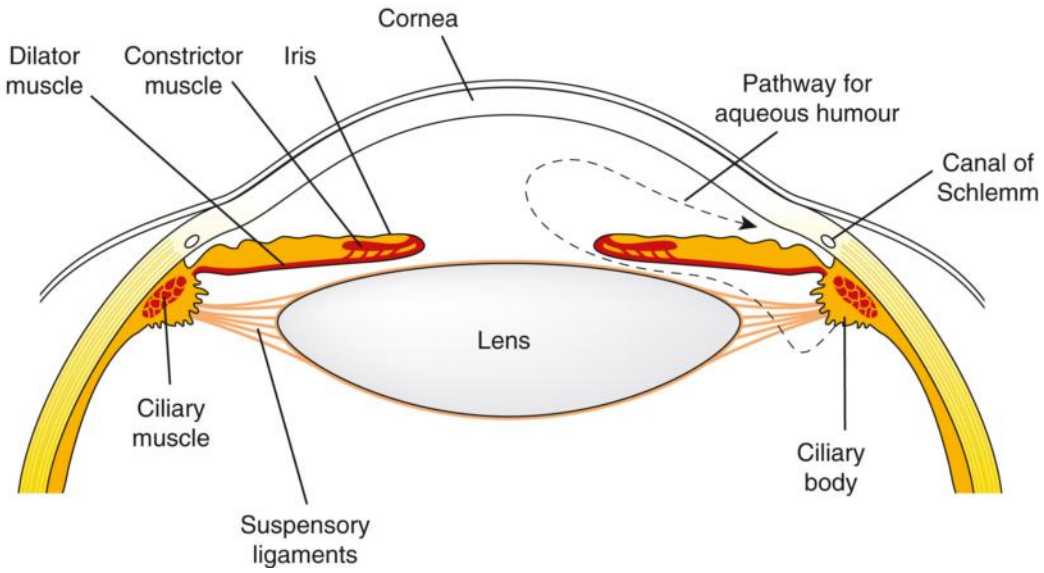

FIG. 27.2 The anterior chamber of the eye, showing the pathway for secretion and drainage of the aqueous humour.

The outer part of the eye is lined by a fascial sheath known as Tenon's capsule and it is possible to inject drugs into the cavity bounded by this sheath and the sclera. This sub-Tenon or parabulbar technique can be used for local anaesthesia, e.g. cataract surgery, or corticosteroid delivery in posterior uveitis/macular oedema.

Autonomic Control of the Lens and Pupil, and Related Therapeutic Drugs

Autonomic regulation of the **lens** is analogous to an autofocusing camera. The shape of the human lens is constantly being adjusted by the ciliary body and muscles through suspensory ligaments that bind it to the lens capsule (**Fig. 27.2**). This enables accommodation of the eye to distant or nearby objects, so that sharply focused images can be rendered onto the retina. Parasympathetic

innervation of the **ciliary body** and the constrictor pupillae muscle is mimicked or antagonised by, respectively, muscarinic agonists and antagonists. Parasympathetic stimulation contracts the ciliary muscles, pulls the ciliary body forward and inward, thus relaxing the tension on the suspensory ligament of the **lens**. This allows the lens to bulge more, with reduction in focal length to facilitate near vision. In contrast, anticholinergic drugs that block parasympathetic stimulus relax the ciliary muscle and impair near vision due to paralysis of accommodation.

Another key component at the front of the eye is the **iris** which regulates pupillary diameter (akin to the aperture of a camera). Here, autonomic nervous system pathways regulate the amount of light entering the eye so visual perception can remain optimal within both bright and dark environments.

The diameter of the **iris** is regulated by the balance between constrictor sphincter pupillae (parasympathetic system) and the dilator pupillae (sympathetic system). Parasympathetic tone narrows the diameter of the iris (i.e. constricts the pupil) whereas the sympathetic nervous system dilates the pupil. Antimuscarinic drugs cause dilated pupils (*mydriasis*) and loss of accommodation (*cycloplegia*), and hence difficulty seeing in bright conditions and difficulty reading small print.

Dilation of the pupil enables detailed fundoscopic examination (visualising the back of the eye) and is also used in certain types of eye surgery to prevent synechiae (adhesions of the iris to the capsule of the lens) for which the long action of **atropine** is an advantage, and as an adjunct to anti-inflammatory drugs in treating inflammation of the uvea (‘uveitis’) which can accompany several

systemic inflammatory diseases. This is usually achieved with tertiary amine muscarinic antagonists such as **tropicamide** (favoured for its rapid onset but relatively short duration of action) or **cyclopentolate** which is longer acting; atropine is longer acting still (several days). However, pupillary dilation with muscarinic antagonists can block drainage of aqueous humour into the canal of Schlemm, thus potentially triggering angle-closure glaucoma in susceptible patients (see later). **Phenylephrine** (a_1-agonist), given as eye drops, is an alternative way to dilate the pupil but can cause local irritation and systemic effects including transient hypertension. It is often used to supplement tropicamide for full dilatation.

The autonomic nervous system is also involved in regulating ocular blood flow, as well as in maintaining intraocular pressure, through its effects on aqueous humour production and outflow (**Fig. 27.3**). Sympathetic signalling to the blood vessels of the **ciliary body** and epithelium is a key regulator of aqueous humour production. The autonomic nervous system has an impact on the trabecular meshwork and episcleral blood vessels that drain aqueous fluid. These effects may contribute to the therapeutic effect of drugs that act on adrenoceptors in treating some forms of glaucoma (see later).

Treatment of Inflammation and Infection in the Eye

Drugs for treating infection and inflammation in the eye are similar to those used elsewhere in the body, but are usually specially formulated in terms of concentration and mode of delivery.

Several antibiotics and antivirals are licensed for use in the eye, typically for treatment of conjunctivitis or corneal ulcers (often due to herpes simplex virus). Topical formulations include chloramphenicol, macrolides, aminoglycosides and quinolones (see also **Ch. 52**). Antivirals (see also **Ch. 53**) are also available – aciclovir, for instance, is used in herpes infections. Treatment of viral infections at the back of the eye is more complicated because of challenges in drug delivery (see earlier). In addition to standard oral or intravenous dosing, modified release formulations of ganciclovir or cidofovir may be delivered by intravitreal injection to achieve higher or more prolonged concentrations for treatment of cytomegalovirus retinitis – a particular issue in patients with HIV infection and AIDS.

Corticosteroids (see also **Ch. 33**) are used for a wide range of non-infection-related inflammatory conditions in the eye such as uveitis (see earlier) and macular oedema. Topical preparations, for example **betamethasone** drops or ointment, can be used at the surface of the eye, and there are now modified release formulations and implants that can be introduced intravitreally so that the corticosteroid is gradually released into the posterior compartment. Examples include **dexamethasone** and **fluocinolone** vitreal implants that are used for treating conditions such as posterior uveitis, retinal vein occlusion and diabetic macular oedema. These formulations can have durations of action lasting weeks to months. However, corticosteroids can harm the eyes and are normally administered and monitored under expert supervision. In particular, they worsen the effects of herpes (especially of the cornea) and

other infections, can cause acute glaucoma in susceptible individuals and can cause cataracts during prolonged use.

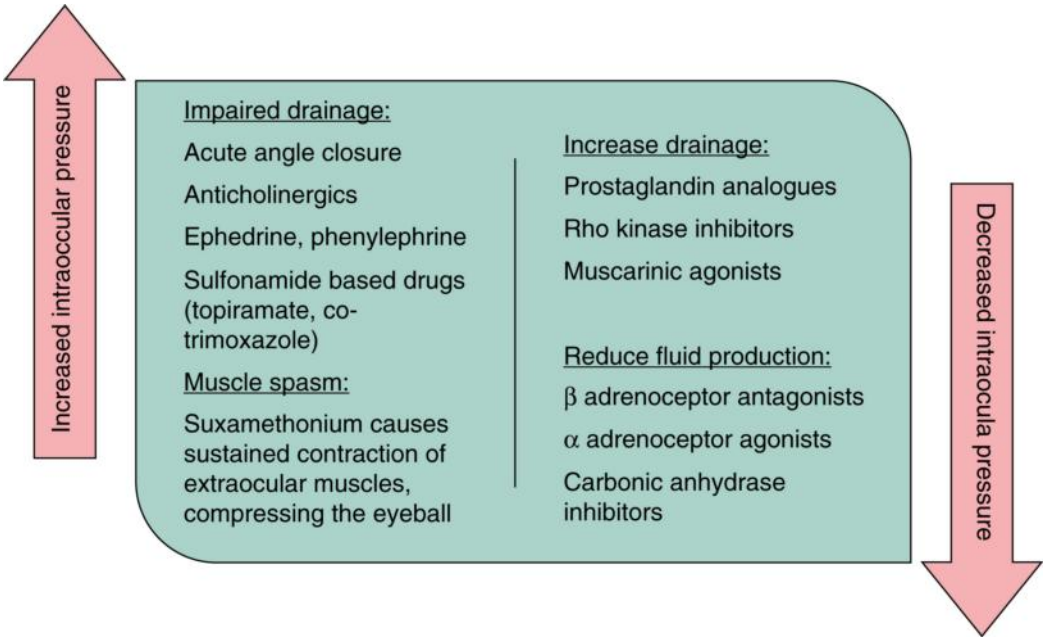

FIG. 27.3 Variation in intraocular pressure depends on balance between production of aqueous humour and outflow.

Topical formulations of non-steroidal anti-inflammatory drugs (e.g. **diclofenac**, **ketorolac**, see **Ch. 25**) are available, as are antihistamines (e.g. **azelastine**) and **cromoglicate** or **nedocromil** (see **Ch. 28**) for eye allergies. They are less effective than corticosteroids and may themselves cause local irritation but are sometimes used by non-experts while awaiting definitive diagnosis of a sore red eye.

Control of Intraocular Pressure and Treatment of Glaucoma

The intraocular pressure is normally about 15 mm Hg above atmospheric, which keeps the eye slightly distended. There is considerable variation in intraocular pressure, with a gradual increase during the night, as well as frequent upward spikes during the day related to mechanical stress and blood pressure. An important determinant is the production of aqueous humour, which is secreted slowly and continuously by the cells of the epithelium covering the ciliary body. Outflow drainage of the aqueous humour takes place mainly through the trabecular meshwork into the canal of Schlemm that runs around the outer margin of the iris (see **Fig. 27.2**). The ciliary muscle is a circular band of smooth muscle within the ciliary body and controls the flow of aqueous humour into the canal of Schlemm. A small proportion of aqueous drainage takes place through the uveoscleral outflow pathway. Here, the fluid seeps through or around ciliary muscles to reach the suprachoroidal space and sclera where it is drained through orbital veins. It is thought that prostaglandin analogues exert their effects on the uveoscleral outflow pathway to reduce intraocular pressure (see later).

Increased secretion and/or reduction in drainage causes a rise in intraocular pressure, a risk factor for primary open-angle glaucoma, the commonest form of glaucoma where drainage of aqueous humour through the trabecular meshwork is restricted.

The term *glaucoma* encompasses a group of disorders caused by damage to the retinal ganglion cells and optic nerve. This causes a distinctive appearance of the optic nerve head (the ‘optic disc’) called cupping of the disc and results in a loss of mid-peripheral vision. If untreated, open-angle glaucoma progresses gradually and

painlessly to blindness (a 'chronic' course). This can sometimes occur when the intraocular pressure is within the normal range ('normal-tension glaucoma'), at least when measured at one or a few points in time. Drug treatment is nonetheless directed toward lowering the intraocular pressure.

Acute angle-closure glaucoma is much less common and can present as a medical/surgical emergency. The 'angle' referred to is that between the anterior outer part of the iris and the inner surface of the cornea (see the dashed arrow in **Fig. 27.2** which shows the direction of flow and pathway of the aqueous humour when unimpeded). Drainage can become acutely blocked in people with a narrow angle, for example by drugs that dilate the pupil (e.g. mydriatics such as tropicamide combined with phenylephrine, see earlier); *note that tropicamide alone is rarely responsible*. In the absence of such provocation the first symptoms may arise at night when the pupils are dilated – for instance the appearance of haloes around streetlights accompanied by pain in the eyes. Treatment of both conditions is directed at lowering of intraocular pressure, and we describe the main pharmacological approaches here. Where surgery (e.g. iridectomy) is required, ongoing drug treatment is often still needed to supplement it.

Prostaglandin FP Receptor Agonists (See Ch. 17)

FP receptors are targeted by several prostaglandin analogues, **latanoprost, travoprost, tafluprost** and prostamide **bimatoprost,** which are used in treatment of glaucoma. Prostaglandin analogues are pro-drugs that are converted by esterases at the cornea to active forms acting on the FP receptor.

The mechanism whereby this lowers intraocular pressure has not been fully elucidated but these drugs are thought to increase aqueous drainage through the uveoscleral pathway. The prostaglandin analogues are first-line eye drops for open-angle glaucoma because they offer 24-h control of intraocular pressure with once-a-day dosing, coupled with being relatively free of systemic adverse effects. However, the drugs can cause local effects through stimulation of melanocytes, e.g. eyelid pigmentation, and change in colour of the iris.

β_1 Adrenoceptor Antagonists

Beta adrenoceptor antagonist eye drops (**timolol, betaxolol, levobunolol**) are widely used to reduce the production of aqueous humour. Systemic absorption that may cause bradycardia and, in asthmatic patients, bronchoconstriction is described.

α_2 Adrenoceptor Agonists

Alpha-2-adrenoceptor agonist eye drops (e.g. **brimonidine**) decrease aqueous humour production and increase uveoscleral outflow. They are used for chronic glaucoma when β_1 adrenoceptor antagonists are inappropriate or, in combination, when treatment with a single agent was inadequate. Local symptoms such as burning sensation are common and systemic adverse effects (e.g. dry mouth) have been reported. Brimonidine eye drops are given twice a day.

Carbonic Anhydrase Inhibitors

Oral carbonic anhydrase inhibitors (e.g. **acetazolamide**, see **Ch. 29**) were an early treatment to lower intraocular pressure by reducing aqueous humour production and are still sometimes used for a short period to lower pressure urgently (e.g. preoperatively); however, systemic effects during chronic use led to the development of topical agents. Prostaglandin analogues and b_1 adrenoceptor antagonists subsequently became first-line glaucoma therapies, but topical carbonic anhydrase inhibitors continue to be prescribed in combination with β_1-antagonists and α-agonists (**Stoner et al., 2022**). The mechanism of aqueous humour secretion is not fully understood but carbonic anhydrase is implicated and it is believed that inhibitors of this enzyme reduce secretion of aqueous humour by a direct effect on ciliary epithelial carbonic anhydrase leading to reduced bicarbonate ion movement with a consequent reduction in the transport of sodium ions and fluids. Local adverse effects of the available eye drops (**brinzolamide, dorzolamide**) such as corneal erosion, conjunctival inflammation and blurred vision are common, but systemic adverse effects are not.

Inhibitors of Rho Kinase

The rho/rho kinase system is described in **Chapter 3**. Inhibitors of rho kinase lower intraocular pressure and two such drugs, **netarsudil** and **ripasudil,** have recently become available, formulated as eye drops, for the pharmacological management of glaucoma. Rho kinase influences the structure and function of the actin cytoskeleton and extracellular matrix, thus influencing the drainage channels in the trabecular meshwork of the eye. The Rho kinase inhibitors exert a beneficial effect through greater drainage

of aqueous humour, thus reducing intraocular pressure. These compounds are relatively new, and their long-term tolerability and place in treatment remain to be established.

Muscarinic Agonists

Pilocarpine facilitates drainage of aqueous humour by contracting the constrictor pupillae muscles to constrict the pupil (miosis), pulling the iris away from the trabecular mesh in angle-closure glaucoma. However, pilocarpine is now seldom used in long-term treatment because of adverse local effects (excessive lacrimation, conjunctival hyperaemia, blurred vision and headache from contraction of the ciliary muscle) as well as the potential for cholinergic action systemically. Such systemic parasympathomimetic effects are rare but dose related.

Treatment of glaucoma

Prostaglandin analogues are the first-line drug treatment of primary open-angle glaucoma; they are often used in combined formulations with other agents. In order to help patient adherence, a wide (and sometimes bewildering) range of different permutations of compounds can be prescribed. Laser therapy is recommended for patients where eye drops have not been effective. Surgery is another option in such instances.

Tropicamide or cyclopentolate eye drops are used when mydriasis or cycloplegia is required during ophthalmic examinations or surgery.

Ocular Vasculature and Vascular Endothelial Growth Factor Inhibitors

Angiogenesis in the eye involves a complex balance of processes regulated by many cytokines, growth factors and components of the extracellular matrix. Proangiogenic factors include, most importantly, vascular endothelium–derived growth factor (VEGF), platelet-derived growth factors and fibroblast growth factor among a host of other mediators. Conversely, endostatin, thrombospondin and pigment epithelium–derived factor are considered to play an antiangiogenic role (reviewed by **Selvam et al., 2018**). Derangement of angiogenesis can result in serious harm. The pathological process can arise in the eye in isolation, for example with wet age-related macular degeneration (secondary to new vessels growing through Bruch's membrane) or through ischaemia secondary to retinal vessel occlusion, especially venous. Secondary processes from disease arising elsewhere in the body, such as diabetes mellitus (complicated by proliferative retinopathy, macular oedema and haemorrhage) and hypertension, are important causes of vascular damage to the eye. The new vessel proliferation and haemorrhages within the eye can cause significant impairment of vision, which may be permanent and extensive. Inhibitors of VEGF are the mainstay in the pharmacological management of pathological angiogenesis within the eye.

VEGF acts through activation of two tyrosine kinase receptors (VEGF-1 and VEGF-2) that are involved in physiological angiogenesis in the eye. Stimulation of the receptors leads to greater endothelial proliferation and migration, with new vessel formation and an increase in microvascular permeability. Pathological new

vessel formation, with associated vascular fragility, leads to an increased risk of haemorrhage, with loss of vision due to blood in the chambers and retina of the eye. New vessels that form on the iris can provoke episodes of glaucoma. Enhanced microvascular permeability causes visual disturbance due to fluid leakage, oedema and swelling of the retina. Fibrovascular proliferation increases traction on the retina leading to sight threatening detachment of the retina from the posterior wall of the eye.

VEGF inhibitors are used to inhibit new vessel formation arising from these pathologies, and they are administered through intravitreal injection. Adverse effects stem from the trauma and infection risk of the procedure (endophthalmitis is a particular concern), as well as uncommon systemic problems such as hypertension and gastrointestinal disturbance as the drug is absorbed from the vitreous.

Available agents include:

Bevacizumab is a full-length humanised IgG1 monoclonal antibody that binds with high affinity to VEGF, thus blocking its activity at VEGF receptors. This drug was first made available for use in colorectal cancer but has also been found to be effective for neovascular conditions in the eye.

Ranibizumab is a monoclonal antibody fragment directed at all isoforms of VEGF-A. In contrast to bevacizumab, the formulation of ranibizumab is specifically aimed for use in the eye.

Aflibercept is a hybrid molecule consisting of the Fc segment of IgG1 structurally joined to extracellular domains from VEGF-1 and -2 receptors. Intriguingly, aflibercept was designed

to have high affinity for VEGF and placental growth factor. It therefore acts as a 'decoy' molecule to soak up VEGF-A, thus reducing activation of VEGF-1 and -2 receptors at target sites in the eye (as well as in treatment of metastatic colon cancer).

Vascular endothelial growth factor (VEGF) inhibitors

VEGF inhibitors are used in a variety of conditions where new vessel formation and proliferation, or oedema without neovascularisation, are a significant threat to vision.

- Wet age-related macular degeneration secondary to choroidal neovascularisation
- Proliferative diabetic retinopathy (as a short-term adjunct to laser photocoagulation)
- Retinal vessel occlusion
- Choroidal neovascularisation
- Retinopathy of prematurity
- Diabetic macular oedema

QUESTIONS

QUESTION 27.1

The eye is functionally analogous to a high-tech photographic camera. It is a tough fluid-filled globe with an outer transparent layer at the front, a light receptive layer at the back and variable-aperture and variable-focus lens at the interface between anterior and posterior chambers.

Which of the following statements about the structure of the eye are correct?

OPTIONS:

A. The wall of the anterior chamber incorporates a dark layer of melanin-rich epithelium.

B. The retina is bathed in a clear liquid called aqueous humour.

C. The macula receives its blood supply directly from the ophthalmic artery.

D. The macula comprises both rod and cone cells, the former responsible for high acuity central vision.

E. The retinal membranes consist of tight epithelial junctions.

QUESTION 27.2

The tertiary amine muscarinic antagonist **cyclopentolate is used as** an adjunct to anti-inflammatory drugs in treating inflammation of the uvea ('uveitis') which can accompany several systemic inflammatory diseases.

Which of the following would NOT be a side effect of **cyclopentolate** administered to the eye?

OPTIONS:

A. Risk of inducing angle closure glaucoma

B. Transient hypertension

C. Difficulty seeing in bright conditions

D. Loss of near vision

E. Pupillary dilation

ANSWERS

ANSWER 27.1

RATIONALE:

A. The wall of the posterior chamber incorporates a dark layer of melanin-rich epithelium, so stray light is absorbed rather than being reflected.

B. The aqueous humour helps maintain the smooth functioning of the iris and lens, whilst the vitreous humour supports retinal function.

C. The ophthalmic artery supplies the eye indirectly via two distinct vascular networks: the macula lacks superficial retinal vessels but obtains part of its supply by diffusion from both supplies.

D. The macula is the central area of the retina containing cones which are responsible for high acuity central vision.

E.

CORRECT ANSWER WITH EXPLANATION:

E. The retinal membranes consist of tight epithelial junctions. This protects the eye but can also restrict drug penetration. Systemic or intravitreal administration is required for the retina.

ANSWER 27.2

RATIONALE:

A. Pupillary dilation with muscarinic antagonists can block drainage of aqueous humour into the canal of Schlemm, thus potentially triggering angle closure glaucoma in susceptible patients.

B.

C. Antimuscarinic drugs cause loss of accommodation (*cycloplegia*), and hence difficulty seeing in bright conditions, and difficulty reading small print.

D. Anticholinergic drugs relax the ciliary muscle and impair near vision due to paralysis of accommodation.

E. Antimuscarinic drugs cause dilated pupils (*mydriasis*).

CORRECT ANSWER WITH EXPLANATION:

B. Transient hypertension

Transient hypertension is a systemic side effect of Phenylephrine (a_1-agonist), if given as eye drops as an alternative way to dilate the pupil due to its effects on the vasculature.

28: Respiratory system

OVERVIEW

Basic aspects of respiratory physiology (regulation of airway smooth muscle, pulmonary vasculature and glands) are considered as a basis for a discussion of pulmonary disease and its treatment. We devote most of the chapter to asthma, dealing first with pathogenesis and then the main drugs used in its treatment and prevention – inhaled bronchodilators and anti-inflammatory agents. We also discuss chronic obstructive pulmonary disease (COPD), bronchiectasis as well as idiopathic pulmonary fibrosis. There are short sections on allergic emergencies, surfactants and the treatment of cough.

The Physiology of Respiration

Control of Breathing

Respiration is controlled by spontaneous rhythmic discharges from the respiratory centre in the medulla, modulated by input from pontine and higher central nervous system (CNS) centres and vagal afferents from the lungs. Various chemical factors affect the respiratory centre, including the partial pressure of carbon dioxide in arterial blood ($P_A CO_2$) by an action on medullary chemoreceptors, and of oxygen ($P_A O_2$) by an action on the chemoreceptors in the carotid bodies.

Some voluntary control can be superimposed on the automatic regulation of breathing, implying connections between the cortex and the motor neurons innervating the muscles of respiration. Bulbar poliomyelitis and certain lesions in the brain stem result in loss of the automatic regulation of respiration without loss of voluntary regulation. [1]

Regulation of Musculature, Blood Vessels and Glands of the Airways

Irritant receptors and non-myelinated afferent nerve fibres respond to chemical irritants and cold air, and also to inflammatory mediators. Efferent pathways controlling the airways include cholinergic parasympathetic nerves and non-noradrenergic non-cholinergic (NANC) inhibitory nerves (see **Ch. 13**). Bronchial hyper-responsiveness can be triggered by changes in the afferent sensory and efferent pathways, as well as the neural control networks in the brainstem (see **Pincus et al., 2021**, for a comprehensive review). Inflammatory mediators (see **Ch. 17**) and other bronchoconstrictor mediators also have a role in diseased airways.

The tone of bronchial muscle influences airway resistance, which is also affected by the state of the mucosa and activity of the submucosal mucus-secreting glands in patients with asthma and bronchitis. Airway resistance can be measured indirectly by instruments that record the volume or flow of forced expiration. FEV_1 is the forced expiratory volume in 1 second. The peak expiratory flow rate (PEFR) is the maximal flow (expressed as

L/min) after a full inhalation; this is simpler to measure at the bedside than FEV_1, which it follows closely.

Efferent Pathways

Autonomic innervation

The autonomic innervation of human airways is reviewed by **van der Velden and Hulsmann (1999)**.

Parasympathetic innervation

Parasympathetic innervation of bronchial smooth muscle predominates. Parasympathetic ganglia are embedded in the walls of the bronchi and bronchioles, and the postganglionic fibres innervate airway smooth muscle, vascular smooth muscle and glands. Five types of muscarinic (M) receptors are present (see **Ch. 14**, **Table 14.2**). M_3 receptors are pharmacologically the most important in airways disease. They are found on bronchial smooth muscle and gland cells, and mediate bronchoconstriction and mucus secretion. M_1 receptors are localised in ganglia and on postsynaptic cells, and facilitate nicotinic neurotransmission, whereas M_2 receptors are inhibitory autoreceptors mediating negative feedback on acetylcholine release by postganglionic cholinergic nerves. Stimulation of the vagus causes bronchoconstriction – mainly in the larger airways. The possible clinical relevance of the heterogeneity of muscarinic receptors in the airways is discussed later.

A distinct population of NANC nerves (see **Ch. 13**) also regulates the airways. Bronchodilators released by these nerves include

vasoactive intestinal polypeptide (**Table 13.2**) and *nitric oxide* (NO; see **Ch. 19**).

Sympathetic innervation

Sympathetic nerves innervate tracheobronchial blood vessels and glands, but not human airway smooth muscle. However, β adrenoceptors are abundantly expressed on human airway smooth muscle (as well as mast cells, epithelium, glands and alveoli) and β agonists relax bronchial smooth muscle, inhibit mediator release from mast cells and increase mucociliary clearance. In humans, β adrenoceptors in the airways are of the β_2 variety.

In addition to the efferent autonomic innervation, non-myelinated sensory fibres, linked to irritant receptors in the lungs, release tachykinins such as *substance P*, *neurokinin A* and *neurokinin B* (see **Ch. 17**), producing *neurogenic inflammation*.

Sensory Receptors and Afferent Pathways

Slowly adapting *stretch receptors* control respiration via the respiratory centre. Unmyelinated sensory *C fibres* and rapidly adapting *irritant receptors* associated with myelinated vagal fibres are also important.

Physical or chemical stimuli, acting on irritant receptors on myelinated nerve fibres in the upper airways and/or C-fibre receptors in the lower airways, cause coughing, bronchoconstriction and mucus secretion. Such stimuli include cold air and irritants such as ammonia, sulfur dioxide, cigarette smoke and the experimental tool *capsaicin* (see **Ch. 43**), as well as endogenous inflammatory mediators.

Regulation of airway muscle, blood vessels and glands

Afferent pathways

- Irritant receptors and C fibres respond to exogenous chemicals, inflammatory mediators and physical stimuli (e.g. cold air).

Efferent pathways

- Parasympathetic nerves cause bronchoconstriction and mucus secretion through M_3 receptors.
- Sympathetic nerves innervate blood vessels and glands, but not airway smooth muscle.
- β_2-Adrenoceptor agonists relax airway smooth muscle. This is pharmacologically important.
- Inhibitory NANC nerves relax airway smooth muscle by releasing NO and vasoactive intestinal peptide.
- Excitation of sensory nerves causes neuroinflammation by releasing tachykinins: substance P and neurokinin A.

Pulmonary Disease and its Treatment

Common symptoms of pulmonary disease include shortness of breath, wheeze, chest pain and cough with or without sputum production or haemoptysis (blood in the sputum). Ideally, treatment is of the underlying disease, but sometimes symptomatic

treatment, for example of cough, is all that is possible. The lung is an important target organ of many diseases addressed elsewhere in this book, including infections (Chs **52**–**56**), malignancy (see **Ch. 57**) and occupational and rheumatological diseases; drugs (e.g. **amiodarone**, **methotrexate**) can damage lung tissue and cause pulmonary fibrosis. Heart failure leads to pulmonary oedema (see **Ch. 21**). Thromboembolic disease (see **Ch. 23**) and pulmonary hypertension (see **Ch. 21**) affect the pulmonary circulation. In this present chapter, we concentrate on two important diseases of the airways: asthma and chronic obstructive pulmonary disease (COPD).

Bronchial Asthma

Asthma affects about 8% of the population; it is the commonest chronic disease in children in economically developed countries and is also common in adults. It is an inflammatory condition in which there is recurrent reversible airways obstruction in response to irritant stimuli that are too weak to affect non-asthmatic subjects. The obstruction usually causes wheeze and merits drug treatment, [2] although the natural history of asthma includes spontaneous remissions. Reversibility of airways obstruction in asthma contrasts with COPD, where the obstruction is either not reversible or at best incompletely reversible by bronchodilators.

Characteristics of Asthma

Asthmatic patients experience intermittent attacks of wheezing, shortness of breath – with difficulty especially in breathing out, chest tightness and, sometimes, cough. As explained earlier, acute attacks are reversible, but the underlying pathological disorder can

progress in older patients to a chronic state superficially resembling COPD.

Acute severe asthma (also known as *status asthmaticus*) is not easily reversed and causes hypoxaemia. Hospitalisation is necessary, as the condition, which can be fatal, requires prompt and energetic treatment.

Asthma is a heterogeneous disease, typically characterised by:

- chronic inflammation of the airways
- bronchial hyper-reactivity
- variable and reversible airflow limitation

Bronchial hyper-reactivity (or hyper-responsiveness) is abnormal sensitivity to a wide range of stimuli, such as irritant chemicals, cold air and bronchoconstrictor drugs. In allergic asthma, these features may be initiated by sensitisation to allergen(s), but, once established, asthma attacks can be triggered by various stimuli such as viral infection, exercise (in which the stimulus may be cold air and/or drying of the airways) and atmospheric pollutants such as sulfur dioxide. Immunological desensitisation to allergens such as pollen or dust mites is popular in some countries but is not superior to conventional inhaled drug treatment.

Pathogenesis of Asthma

The pathogenesis of asthma involves both genetic and environmental factors, and the asthmatic attack itself consists, in many subjects, of two main phases: an immediate and a late (or delayed) phase (**Fig. 28.1**).

Numerous cells and mediators play a part, and the full details of the complex events involved are still a matter of debate. Disease processes in asthma are thought to involve both innate and adaptive immunity (see **Boonpiyathad et al., 2019**, for a comprehensive overview). The following simplified account is intended to provide a basis for understanding the rational use of drugs in the treatment of asthma.

Asthmatics have activated T cells, with a T-helper (Th)2 profile of cytokine production (see **Ch. 17**) in their bronchial mucosa. How these cells are activated is not fully understood, but allergens (**Fig. 28.2**) are one mechanism. The Th2 cytokines that are released do the following:

- Attract other inflammatory granulocytes, especially eosinophils, to the mucosal surface. Interleukin (IL)-5 and granulocyte–macrophage colony-stimulating factor prime eosinophils to produce cysteinyl leukotrienes (see **Ch. 17**), and to release granule proteins that damage the epithelium. This damage is one cause of bronchial hyper-responsiveness.
- Promote immunoglobulin (Ig)E synthesis and responsiveness in some asthmatics (IL-4 and IL-13 'switch' B cells to IgE synthesis and cause expression of IgE receptors on mast cells and eosinophils; they also enhance adhesion of eosinophils to endothelium).

Some asthmatics, in addition to these mechanisms, are also *atopic* – that is, they make allergen-specific IgE that binds to mast cells in the airways. Inhaled allergen cross-links IgE molecules on

mast cells, triggering degranulation with release of histamine and leukotriene B_4, both of which are powerful bronchoconstrictors to which asthmatics are especially sensitive because of their airway hyper-responsiveness. This provides a mechanism for acute exacerbation of asthma in atopic individuals exposed to allergen. The effectiveness of **omalizumab** (an anti-IgE antibody; see later) serves to emphasise the importance of IgE in the pathogenesis of asthma as well as in other allergic diseases. Noxious gases (e.g. sulfur dioxide, ozone) and airway dehydration can also cause mast cell degranulation. Non-steroidal anti-inflammatory drugs (NSAIDs), especially aspirin, can also precipitate asthma in sensitive individuals. Such aspirin-sensitive asthma is relatively uncommon (<10% of asthmatic subjects), and is often associated with nasal polyps

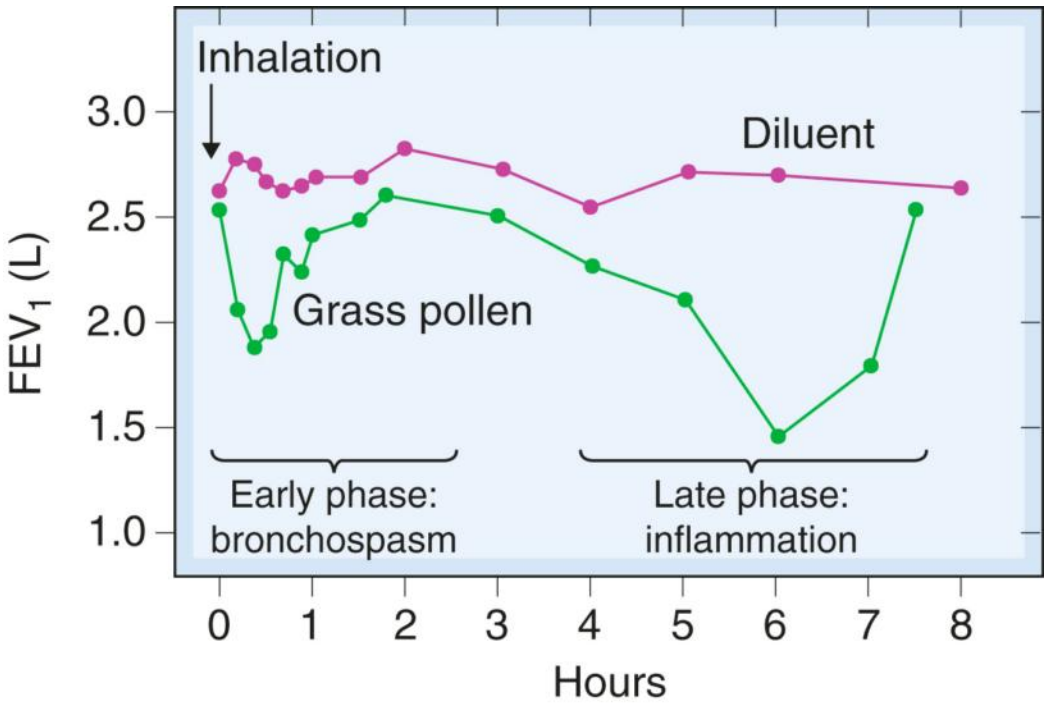

FIG. 28.1 Two phases of asthma demonstrated by the changes in forced expiratory volume in 1 second (FEV_1) after inhalation of grass pollen in an allergic subject. From Cockcroft, D.W., 1983. Lancet ii, 253.

Asthma is a complex heterogeneous condition with considerable variation in underlying aetiology and biological causes. Although multiple different phenotypic clusters can be considered based on clinical features, patient characteristics and physiological processes, there is no clear consensus on these classifications. In this text, we will mainly refer to the allergic and non-allergic forms.

Asthma

- Asthma is defined as recurrent reversible airway obstruction, with intermittent attacks of wheeze, shortness of breath, chest tightness and cough. Severe attacks cause hypoxaemia and are life-threatening.
- Typical features include:
  - airway inflammation, which causes
  - bronchial hyper-responsiveness, which in turn results in
    - recurrent reversible airway obstruction
- Pathogenesis involves exposure of genetically disposed individuals to allergens; activation of Th2 lymphocytes and cytokine generation promote:
  - differentiation and activation of eosinophils
  - IgE production and release
  - expression of IgE receptors on mast cells and eosinophils
- Important mediators include leukotriene B_4 and cysteinyl leukotrienes (C_4 and D_4); interleukins (IL)-4, IL-5, IL-13; and tissue-damaging eosinophil proteins.
- Antiasthmatic drugs include:
  - bronchodilators
  - anti-inflammatory agents
- Treatment is monitored by measuring forced expiratory volume in 1 second (FEV_1) or PEFR and, in acute severe disease, oxygen saturation and arterial blood gases.

The immediate phase of an asthma attack

In allergic asthma the immediate phase (i.e. the initial response to allergen provocation) occurs abruptly and is mainly caused by spasm of the bronchial smooth muscle. Allergen interaction with mast cell-fixed IgE causes release of histamine, leukotriene B_4 and prostaglandin (PG)D_2 (see **Ch. 17**).

Other mediators released include IL-4, IL-5, IL-13, macrophage inflammatory protein-1α and tumour necrosis factor (TNF)-α.

Various chemotaxins and chemokines (see **Ch. 17**) attract leukocytes – particularly eosinophils and mononuclear cells – setting the stage for the late phase (**Fig. 28.3**).

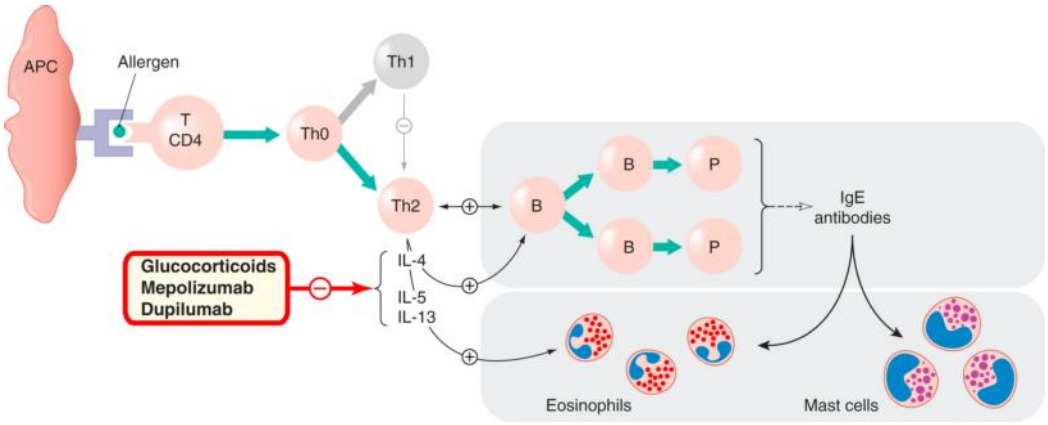

FIG. 28.2 The part played by T lymphocytes in allergic asthma.In genetically susceptible individuals, allergen *(green circle)* interacts with dendritic cells and $CD4^+$ T cells, leading to the development of Th0 lymphocytes, which give rise to a clone of Th2 lymphocytes. These then (1) generate a cytokine environment that switches B cells/plasma cells to the production and release of immunoglobulin (Ig) E; (2) generate cytokines, such as interleukin (IL)-5, which promote differentiation and activation of eosinophils; and (3) generate cytokines (e.g. IL-4 and IL-13) that induce expression of IgE receptors. Glucocorticoids inhibit the action of the cytokines specified. *APC,* Antigen-presenting dendritic cell; *B,* B cell; *P,* plasma cell; *Th,* T-helper cell.

The late phase

The late phase or delayed response (see Figs **28.1** and **28.3**) may be nocturnal. It is, in essence, a progressing inflammatory reaction, initiation of which occurred during the first phase, the influx of Th2 lymphocytes being of particular importance. The inflammatory cells include activated eosinophils. These release cysteinyl leukotrienes, interleukins IL-3, IL-5 and IL-8 and the toxic proteins *eosinophil cationic protein*, *major basic protein* and *eosinophil-derived neurotoxin*. These play an important part in the events of the late phase, the toxic proteins causing damage and loss of epithelium. Other putative mediators of the inflammatory process in the delayed phase are adenosine (acting on the A_1 receptor; see **Ch. 16**), induced NO (see **Ch. 19**) and neuropeptides (see **Ch. 17**).

Growth factors released from inflammatory cells act on smooth muscle cells, causing hypertrophy and hyperplasia, and the smooth muscle can itself release proinflammatory mediators and growth factors (Chs **6** and **17**). **Fig. 28.4** shows schematically the changes that take place in the bronchioles. Epithelial cell loss means that irritant receptors and C fibres are more accessible to irritant stimuli – an important mechanism of bronchial hyper-reactivity.

Drugs Used to Treat and Prevent Asthma

There are two categories of antiasthma drugs: *bronchodilators* and *anti-inflammatory agents*. Bronchodilators reverse the bronchospasm of the immediate phase; anti-inflammatory agents inhibit or prevent the inflammatory components of both phases (see **Fig. 28.3**). These two categories are not mutually exclusive: some drugs classified as bronchodilators also have some anti-inflammatory effect. In clinical practice, bronchodilator drugs are

considered for use as relievers (when or if breakthrough symptoms occur), whereas anti-inflammatory agents are taken regularly as preventers or controllers of the underlying pathology.

A guideline on the management of asthma (**BTS/SIGN, 2019**) specifies a stepwise approach for adults and children with chronic asthma. Very mild or infrequent disease may be treated with short-acting bronchodilator (usually an inhaled short-acting β_2 agonist such as **salbutamol** or **terbutaline**, used as required), but if patients need this more than three times a week, a regular inhaled corticosteroid should be added. If the asthma remains uncontrolled, the next step is to add a long-acting bronchodilator (**salmeterol** or **formoterol**), and/or consider increased doses of inhaled corticosteroid as well as a leukotriene antagonist (such as **montelukast**). **Theophylline or tiotropium** (a long-acting muscarinic antagonist) are subsequent treatment options in patients who remain symptomatic. Addition of a regular oral corticosteroid (e.g. **prednisolone**) is recommended only in the small group of patients who do not achieve adequate control despite high-dose therapies with the other agents. Corticosteroids are the mainstay of therapy because they are the only asthma drugs that potently inhibit T-cell activation, and thus the inflammatory response, in the asthmatic airways. Omalizumab and other monoclonal antibodies (see later) are options in those with poorly controlled asthma despite optimal treatment with other agents. **Cromoglicate** (see later) has only a weak effect and is now seldom used.

Bronchodilators

The main drugs used as bronchodilators are β_2-adrenoceptor agonists; others include **theophylline**, cysteinyl leukotriene receptor antagonists and muscarinic receptor antagonists.

β-Adrenoceptor agonists

The β_2-adrenoceptor agonists are dealt with in **Chapter 15**. Their primary effect in asthma is to dilate the bronchi by a direct action on the β_2 adrenoceptors of smooth muscle. Being physiological antagonists of bronchoconstrictors, they relax bronchial muscle whatever spasmogen is involved. They also inhibit mediator release from mast cells and TNF-α release from monocytes, and increase mucus clearance by an action on cilia.

β_2-Adrenoceptor agonists are usually given by inhalation of aerosol, powder or nebulised solution (i.e. solution that has been converted into a cloud or mist of fine droplets), but some products may be given orally or by injection. A metered-dose inhaler is used for aerosol preparations.

Two categories of β_2-adrenoceptor agonists are used in asthma:

- Short-acting agents: **salbutamol** and **terbutaline.** These are given by inhalation; they act immediately, peaking within 30 min and the duration of action is 3–5 h; they are usually used on an 'as needed' basis to control symptoms.
- Longer-acting agents: e.g. **salmeterol** and **formoterol.** These are given by inhalation, and the duration of action is 8–12 h. They are usually given regularly, twice daily, as adjunctive therapy in patients whose asthma is inadequately controlled by glucocorticoids.

Antiasthma drugs: bronchodilators

- β_2-Adrenoceptor agonists (e.g. **salbutamol**) are first-line drugs (for details, see **Ch. 15**):
  - They act as physiological antagonists of the spasmogenic mediators but have little or no effect on the bronchial hyper-reactivity.
  - Salbutamol is given by inhalation; its effects start immediately and last 3–5 h, and it can also be given by intravenous infusion in status asthmaticus.
  - **Salmeterol** or **formoterol** is given regularly by inhalation; their duration of action is 8–12 h.
- **Theophylline** (often formulated as **aminophylline**):
  - is a methylxanthine;
  - inhibits phosphodiesterase (PDE) and blocks adenosine receptors;
  - has a narrow therapeutic window: unwanted effects include cardiac dysrhythmia, seizures and gastrointestinal (GI) disturbances;
  - is a fall-back option when other safer and more established drugs have not worked. It can be given intravenously (by slow infusion) for acute severe asthma, or orally (as a sustained-release preparation) for inadequately controlled chronic asthma;
  - is metabolised in the liver by P450; liver dysfunction and viral infections increase its plasma concentration and half-life (normally approximately 12 h);

– interacts importantly with other drugs; some (e.g. specific antibiotics) increase the half-life of **theophylline**, others (e.g. anticonvulsants) decrease it.

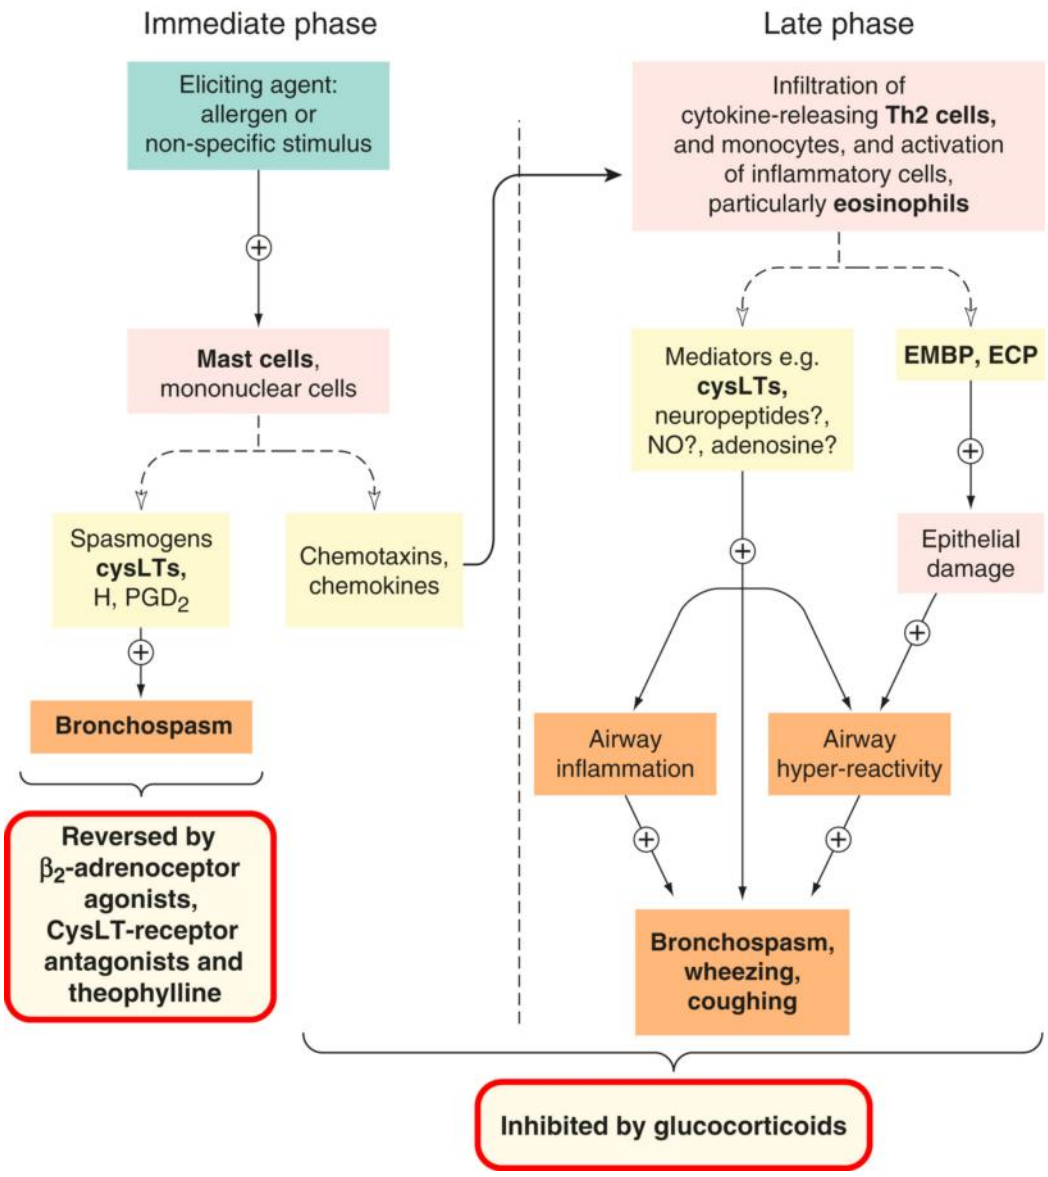

FIG. 28.3 Immediate and late phases of asthma, with the actions of the main drugs. *CysLTs*, Cysteinyl leukotrienes (leukotrienes C_4 and D_4); *ECP,* eosinophil cationic protein; *EMBP,* eosinophil major basic protein; *H,* histamine; *iNO,* induced nitric oxide. (For more detail of the Th2-derived cytokines and chemokines, see **Ch. 17** and **Ch. 6**.)

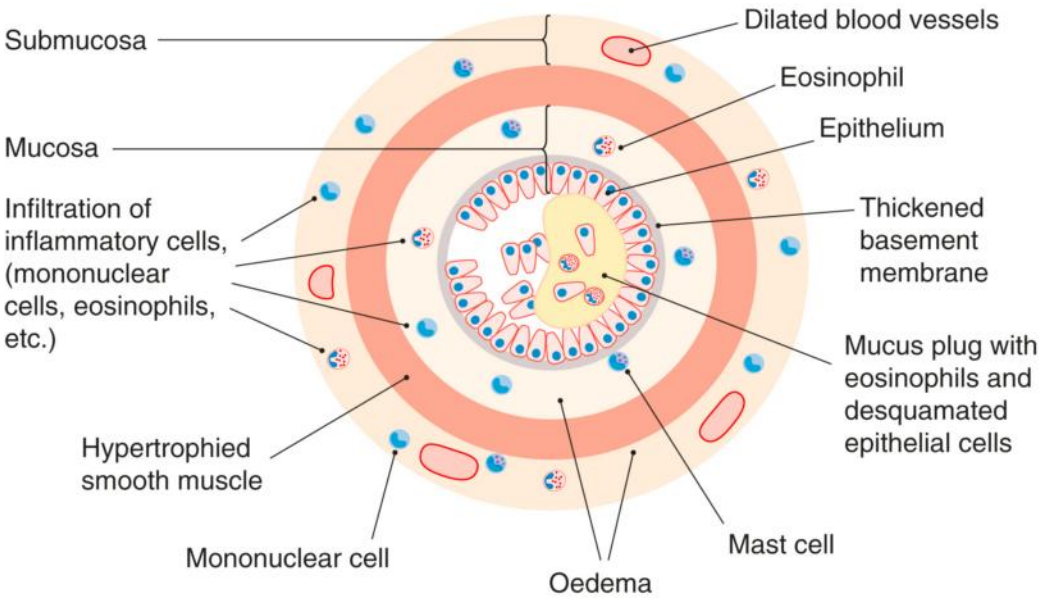

FIG. 28.4 Schematic diagram of a cross-section of a bronchiole, showing changes that occur with severe chronic asthma.The individual elements depicted are not, of course, drawn to scale.

Unwanted effects

The unwanted effects of β_2-adrenoceptor agonists result from systemic absorption and are given in **Chapter 15**. In the context of their use in asthma, the commonest adverse effect is *tremor*; other unwanted effects include *tachycardia* and *cardiac dysrhythmia*.

Clinical use of β_2-adrenoceptor agonists as bronchodilators

- Short-acting drugs (**salbutamol** or **terbutaline**, usually by inhalation) to prevent or treat acute symptoms in patients

with reversible obstructive airways disease.

- Long-acting drugs (**salmeterol**, **formoterol**) to prevent bronchospasm (e.g. at night or with exercise) in patients requiring long-term bronchodilator therapy. Formoterol is faster acting and can also be used as an acute reliever in combination inhalers that deliver inhaled corticosteroid at the same time. This single maintenance and reliever therapy inhaler as-needed option can be used instead of the more traditional model of separate short-acting reliever (e.g. salbutamol intermittently) with regular inhaled corticosteroid.

Methylxanthines (see Chs 16 and 49)

Theophylline (1,3-dimethylxanthine), which is also used as theophylline ethylenediamine (known as **aminophylline**), is the main therapeutic drug of this class, and has long been used as a bronchodilator. [3] Here we consider it in the context of respiratory disease, its only current therapeutic use.

Mechanism of action

The mechanism of theophylline is still unclear. The relaxant effect on smooth muscle has been attributed to inhibition of PDE isoenzymes, with resultant increase in cAMP and/or cGMP (see **Ch. 4**, **Fig. 4.10**). However, the concentrations necessary to inhibit the isolated enzymes exceed the therapeutic range of plasma concentrations.

Competitive antagonism of adenosine at adenosine A_1 and A_2 receptors (see **Ch. 16**) may contribute, but there are other

xanthines which have potent bronchodilatory effects, without any adenosine antagonist activity.

Type IV PDE is implicated in inflammatory cells, and methylxanthines may have some anti-inflammatory effect. (**Roflumilast**, a type IV PDE inhibitor, is mentioned later in the context of COPD.)

Theophylline activates *histone deacetylase* (HDAC), which controls gene expression and may thereby reverse resistance to the anti-inflammatory effects of corticosteroids (**Liao et al., 2020**).

Methylxanthines stimulate the CNS (see **Ch. 49**) and respiratory stimulation may be beneficial in patients with COPD who suffer from reduced respiration and retention of CO_2. **Caffeine** has a special niche in treating hypoventilation of prematurity (see **Ch. 49**).

Unwanted effects

When theophylline is used in asthma, its other actions (CNS, cardiovascular, GI and diuretic) result in unwanted effects (e.g. insomnia, nervousness). The therapeutic plasma concentration range is 30–100 μmol/L, and adverse effects are common with concentrations greater than 110 μmol/L; thus there is a relatively narrow therapeutic window. Serious cardiovascular and CNS effects can occur when the plasma concentration exceeds 200 μmol/L. The most serious cardiovascular effect is *dysrhythmia* (especially during intravenous administration of aminophylline), which can be fatal. *Seizures* can occur with theophylline concentrations at or slightly above the upper limit of the therapeutic range, and can be fatal in patients with impaired respiration due to severe asthma.

Monitoring the concentration of theophylline in plasma is useful for optimising the dose.

Pharmacokinetic aspects

Theophylline is given orally as a sustained-release preparation. Aminophylline can be given by slow intravenous injection of a loading dose followed by intravenous infusion.

Theophylline is well absorbed from the GI tract. It is metabolised by P450 enzymes in the liver; the mean elimination half-life is approximately 8 h in adults but there is wide inter-individual variation. The half-life is increased in liver disease, cardiac failure and viral infections, and is decreased in heavy cigarette smokers (as a result of enzyme induction leading to increased clearance). Unwanted drug interactions are clinically important: its plasma concentration is decreased by drugs that induce P450 enzymes (including **rifampicin**, **phenytoin** and **carbamazepine**). The concentration is increased by drugs that inhibit P450 enzymes, such as **erythromycin**, **clarithromycin**, **ciprofloxacin**, **diltiazem** and **fluconazole**. This is important in view of the narrow therapeutic window; antibiotics such as clarithromycin are often started when asthmatics are hospitalised because of a severe attack precipitated by a chest infection, and if the dose of theophylline is unaltered, severe toxicity can result.

Muscarinic receptor antagonists

Muscarinic receptor antagonists are dealt with in **Chapter 14**. **Ipratropium**, given by aerosol inhalation or nebuliser, is a short-acting muscarinic antagonist that is used as a bronchodilator in acute exacerbations. Inhaled long-acting muscarinic antagonists,

such as **tiotropium**, **aclidinium**, **umeclidinium** and **glycopyrrolate**, are now widely available for once-daily inhalation in COPD (see clinical box).

Ipratropium is a quaternary nitrogen compound that is derived from atropine. It does not discriminate between muscarinic receptor subtypes (see **Ch. 14**), and it is possible that its blockade of M_2 autoreceptors on the cholinergic nerves increases acetylcholine release and reduces the effectiveness of its antagonism at the M_3 receptors on smooth muscle. As the maximum effect occurs approximately 30 min after inhalation and persists only for 3–5 h, ipratropium has to be administered up to four times a day, thus limiting its clinical acceptability.

Long-acting muscarinic antagonists are also quaternary ammonium compounds, designed to have greater selectivity towards the M_3 receptor, and to dissociate from the receptor very slowly, producing a sustained effect with regular daily dosing. They are often used together with long-acting β_2-adrenoceptor agonists and/or inhaled corticosteroids in a combined inhaler for patients with COPD.

Clinical use of inhaled muscarinic receptor antagonists

- Ipratropium is used as an adjunct to β_2-adrenoceptor agonists in nebulised form for acute exacerbations of asthma or COPD.
- Long-acting drugs (e.g. tiotropium) are mainly indicated for regular daily use in patients with COPD; the long-term role in

asthma is less certain.

Cysteinyl leukotriene receptor antagonists

Cysteinyl leukotrienes (LTC_4, LTD_4 and LTE_4) act on *CysLT* $_1$ and *CysLT* $_2$ receptors (see **Ch. 17**), both of which are expressed in respiratory mucosa and infiltrating inflammatory cells, but the functional significance of each is unclear. The 'lukast' drugs (**montelukast** and **zafirlukast**) antagonise only $CysLT_1$.

Lukasts inhibit exercise-induced asthma and decrease both early and late responses to inhaled allergen. They dilate the airways in mild asthma but are less effective than salbutamol, with which their action is additive. They reduce sputum eosinophilia, but there is no clear evidence that they modify the underlying inflammatory process in chronic asthma.

The lukasts are taken by mouth and used mainly as add-on therapy to inhaled corticosteroids and long-acting β_2 agonists. They are generally well tolerated, adverse effects consisting mainly of headache and GI disturbances.

Histamine H_1-receptor antagonists

Although mast cell mediators, including histamine, play a part in the immediate phase of allergic asthma (see **Fig. 28.3**) and in some types of exercise-induced asthma, histamine H_1-receptor antagonists have no routine place in therapy, although they may be modestly effective in mild atopic asthma, especially when this is precipitated by acute histamine release in patients with concomitant allergy such as severe hay fever.

Anti-Inflammatory Agents

Glucocorticoids

Glucocorticoids (see **Ch. 33**) are the main drugs used for their anti-inflammatory action in asthma. They are not bronchodilators, but prevent the progression of chronic asthma and are effective in acute severe asthma (see 'Clinical use of glucocorticoids in asthma' clinical box, later). [4]

Actions and mechanism

The basis of the anti-inflammatory action of glucocorticoids is discussed in **Chapter 33**. An important action, of relevance for asthma, is that they restrain clonal proliferation of Th cells by reducing the transcription of the gene for IL-2 and decrease the formation of cytokines, in particular the Th2 cytokines that recruit and activate eosinophils and are responsible for promoting the production of IgE and the expression of IgE receptors. Glucocorticoids also inhibit the generation of the vasodilators PGE_2 and PGI_2, by inhibiting induction of COX-2 (see **Ch. 17**). By inducing *annexin 1* (see **Fig. 17.3**), they could inhibit the production of leukotrienes and platelet-activating factor, although there is currently no direct evidence that annexin 1 is involved in the therapeutic action of glucocorticoids in human asthma.

Corticosteroids inhibit the allergen-induced influx of eosinophils into the lung. Glucocorticoids up-regulate β_2 adrenoceptors, decrease microvascular permeability and indirectly reduce mediator release from eosinophils by inhibiting the production of cytokines (e.g. IL-5 and granulocyte–macrophage colony-stimulating factor) that activate eosinophils. Reduced synthesis of IL-3 (the cytokine

that regulates mast cell production) may explain why long-term steroid treatment eventually reduces the number of mast cells in the respiratory mucosa, and hence suppresses the early-phase response to allergens and exercise.

Glucocorticoids are sometimes ineffective, even in high doses, for reasons that are incompletely understood. Many individual mechanisms could contribute to glucocorticoid resistance. The phenomenon has been linked to the number of glucocorticoid receptors, but in some situations other mechanisms are clearly in play – for example, reduced activity of HDAC may be important in cigarette smokers.

The main compounds used are **beclometasone**, **budesonide**, **fluticasone**, **mometasone** and **ciclesonide**. These are given by inhalation with a metered-dose or dry-powder inhaler, the full effect on bronchial hyper-responsiveness being attained only after weeks or months of therapy. There are now several inhaler formulations where inhaled corticosteroids are combined together with long-acting β_2-adrenoceptor agonists and/or long-acting muscarinic antagonists (triple therapy in COPD) (**Cohen et al., 2016**). Oral glucocorticoids (see **Ch. 33**) are reserved for patients with the severest disease.

Unwanted effects

Serious unwanted effects are uncommon with inhaled steroids. Oropharyngeal candidiasis (thrush; see **Ch. 54**) can occur (T lymphocytes are important in protection against fungal infection), as can sore throat and croaky voice, but 'spacer' devices (plastic tubes that connect onto the mouthpiece of the inhaler on one end

while the patient uses a mouthpiece or mask at the other end) decrease oropharyngeal deposition of the drug and increase airway deposition, reducing these problems. Regular high doses of inhaled glucocorticoids can produce some adrenal suppression, particularly in children, and necessitate carrying a 'steroid card' (see **Ch. 33**). The unwanted effects of oral glucocorticoids are given in **Fig. 33.7**.

Clinical use of glucocorticoids in asthma

- Patients who require regular bronchodilators should also be prescribed glucocorticoid treatment (e.g. with low-dose inhaled **beclometasone**).
- More severely affected patients are treated with higher doses of inhaled corticosteroids in combination with long-acting beta-adrenoceptor agonists.
- Patients with acute exacerbations of asthma may require intravenous **hydrocortisone** followed by a course of oral **prednisolone.**
- A 'rescue course' of oral prednisolone may be needed at any stage of severity if the clinical condition is deteriorating rapidly.
- Prolonged treatment with oral prednisolone, in addition to inhaled bronchodilators and steroids, is needed by a few severely asthmatic patients.

Cromoglicate and nedocromil

These two drugs, of similar chemical structure and properties, are now hardly used for the treatment of asthma. Although very safe, they have only weak anti-inflammatory effects and a short duration of action. They are given by inhalation as aerosols or dry powders, and can also be used topically for allergic conjunctivitis or rhinitis. They are not bronchodilators, having no direct effects on smooth muscle, nor do they inhibit the actions of any of the known smooth muscle stimulants. Given prophylactically, they reduce both the immediate- and late-phase asthmatic responses and reduce bronchial hyper-reactivity.

Their mechanism of action is not fully understood. Cromoglicate is a 'mast cell stabiliser', preventing histamine release from mast cells. However, this is not the basis of its action in asthma, because compounds that are more potent than cromoglicate at inhibiting mast cell histamine release are ineffective against asthma.

Biopharmaceuticals

Anti-IgE treatment

Omalizumab is a humanised monoclonal anti-IgE antibody that is effective in patients with allergic asthma, as well as in chronic rhinosinusitis with nasal polyps, and in chronic spontaneous urticaria. However, omalizumab is expensive and has to be given by subcutaneous injection every 2 weeks. Its clinical role is principally for those patients with severe persistent confirmed allergic IgE-mediated asthma who have required continuous or frequent treatment with oral corticosteroids in addition to other standard therapies.

IL-5 antagonists

Eosinophilic asthma is a recognised variant for which specific therapies (such as **mepolizumab** or **reslizumab**) targeted at human IL-5 are now available. IL-5 is the key cytokine involved in growth, differentiation and activation of eosinophils (see **Ch. 19**). Antibodies that inhibit IL-5 signalling result in reduced production and survival of eosinophils that mediate the allergic inflammatory process in patients with asthma.

IL-4/IL-13 antagonist

Similarly, a combined inhibitor of IL-4 and IL-13 signalling (**dupilumab**) is prescribed for patients with moderate to severe eosinophilic asthma. Dupilimumab binds to the alpha subunit of the IL-4 receptor which is shared by the IL-4 and IL-13 receptor complexes. Clinical trials in asthma have found that dupilumab suppresses type 2 inflammatory biomarkers, with reductions in eotaxin-3, thymus and activation-regulated cytokine, and IgE. Intriguingly, strategies that target IL-4 or IL-13 cytokines individually have failed to yield demonstrable clinical benefits.

Thymic stromal lymphoprotein antagonist

In contrast, patients with non-allergic or non-eosinophilic asthma appear to benefit from treatment with another monoclonal antibody (**tezepelumab**) directed at thymic stromal lymphopoietin (TSLP) signalling. TSLP is a cytokine derived from epithelial cells that acts as mediator between the immune system and structural cells of the airway. This cytokine initiates several inflammatory cascades, and concentrations of TSLP are correlated with airflow limitation,

asthma severity and poor response to glucocorticoids. Tezepelumab blocks its binding to its receptor. Randomised trial data demonstrate significant benefit for patients with severe asthma (irrespective of baseline eosinophilic count) with regards to pulmonary function, symptoms and reduction in exacerbations and hospital admissions.

Drugs in development

There are several novel agents targeted at mediators of eosinophilic airway inflammation (**Bel and Ten Brinke, 2017**), and inhibitors of prostaglandin D2 (see **Fig. 28.3**) are currently in clinical trials (e.g. **timapiprant**) but **fevipiprant** has failed to demonstrate significant benefit in a randomised trial of patients with poorly controlled asthma.

Antiasthma drugs: glucocorticoids

Glucocorticoids (for details, see Ch. 33)

- These reduce the inflammatory component in chronic asthma and are life-saving in status asthmaticus (acute severe asthma).
- They do not prevent the immediate response to allergen or other challenges.
- The mechanism of action involves decreased formation of cytokines, particularly those generated by Th2 lymphocytes, decreased activation of eosinophils and other inflammatory cells.

- They are given by inhalation (e.g. **beclometasone**); systemic unwanted effects are uncommon at moderate doses, but oral thrush and voice problems can occur. In deteriorating asthma, an oral glucocorticoid (e.g. **prednisolone**) and/or intravenous **hydrocortisone** are also given.

Severe Acute Asthma (Status Asthmaticus)

Severe acute asthma is a medical emergency requiring hospitalisation. Treatment includes oxygen (to correct any hypoxia), inhalation of nebulised salbutamol with ipratropium and intravenous hydrocortisone followed by a course of oral prednisolone. Additional measures occasionally used include intravenous magnesium sulphate (considered to have bronchodilator effects) and, in some countries, intravenous salbutamol or aminophylline. Antibiotics are not routinely given unless there is clinical evidence of bacterial infection. Monitoring is by PEFR or FEV_1, and by measurement of arterial blood gases and oxygen saturation.

Allergic Emergencies

Anaphylaxis (see **Ch. 7**) and *angio-oedema* are emergencies involving acute airways obstruction; **adrenaline** (epinephrine) is potentially life-saving. It is administered intramuscularly (or occasionally intravenously, in specialist, intensively monitored settings). Patients at risk of acute anaphylaxis, for example, from food or insect sting allergy, may self-administer intramuscular adrenaline using a spring-loaded syringe. An antihistamine such as

chlorphenamine may also be used if there is angio-oedema or skin rash.

Angio-oedema is the intermittent occurrence of focal swelling of the skin or intra-abdominal organs caused by plasma leakage from capillaries. Most often, it is mild and 'idiopathic', but it can occur as part of acute allergic reactions, when it is generally accompanied by urticaria – 'hives' – caused by histamine release from mast cells. If the larynx is involved, it is life-threatening; swelling in the peritoneal cavity can be very painful and mimic a surgical emergency. It can be caused by drugs, especially *angiotensin-converting enzyme inhibitors* – perhaps because they block the inactivation of peptides such as bradykinin (see **Ch. 17**) – and by aspirin and related drugs in patients who are aspirin sensitive (see **Ch. 23**). Hereditary angio-oedema is associated with lack of C1 esterase inhibitor – C1 esterase is an enzyme that degrades the complement component C1 (see **Ch. 7**). **Tranexamic acid** (see **Ch. 23**) or **danazol** (see **Ch. 35**) may be used to prevent attacks in patients with hereditary angioneurotic oedema, and administration of partially purified C1 esterase inhibitor or fresh plasma, with antihistamines and glucocorticoids, can terminate acute attacks. **Icatibant**, a peptide bradykinin B_2 receptor antagonist (see **Ch. 17**), is effective for acute attacks of hereditary angio-oedema. It is administered subcutaneously but can cause nausea, abdominal pain and nasal stuffiness.

Chronic Obstructive Pulmonary Disease

COPD is a major global health problem – the World Health Organization estimates that there were 3.2 million deaths from

COPD in 2019, thus making it the third commonest cause of death worldwide by 2020. Cigarette smoking is the main cause, and is increasing in the developing world. Air pollution, also aetiologically important, is also increasing, and there is a huge unmet need for effective drugs. A resurgence of interest in new therapeutic approaches has yet to bear fruit but there are a number of promising avenues, in particular in defining subgroups of this rather heterogeneous disease that are responsive to particular therapeutic measures (**McDonald, 2017**).

Clinical features

The clinical picture starts with attacks of morning cough during the winter, and progresses to chronic cough with intermittent exacerbations, often initiated by an upper respiratory infection, when the sputum becomes purulent (i.e. yellow or green due to the presence of many pus cells – neutrophils or eosinophils). There is progressive breathlessness. Some patients have a reversible component of airflow obstruction identifiable by an improved FEV_1 following a dose of bronchodilator. Pulmonary hypertension (see **Ch. 21**) is a late complication, causing symptoms of heart failure (*cor pulmonale*). Exacerbations may be complicated by respiratory failure (i.e. reduced $P_A O_2$) requiring hospitalisation and intensive care. Tracheostomy and artificial ventilation, while prolonging survival, may serve only to return the patient to a miserable life.

Pathogenesis

There is fibrosis of small airways, resulting in obstruction, and/or destruction of alveoli and of elastin fibres in the lung parenchyma. The latter features are hallmarks of emphysema, [5] thought to be

caused by proteases, including elastase, released during the inflammatory response. Emphysema causes respiratory failure, because it destroys the alveoli, impairing gas transfer. There is chronic inflammation (bronchitis), predominantly in small airways and lung parenchyma, characterised by increased numbers of macrophages, neutrophils and T lymphocytes. The inflammatory mediators are thought to involve T helper cell type 1 and type 17, with neutrophil and CD8 lymphocyte infiltrates in the lungs (**Barnes, 2016**). Mediators include a diverse range of interleukins, tumour necrosis factor and reactive oxygen species.

Principles of treatment

Stopping smoking (see **Ch. 50**) slows the progress of COPD. Patients should be immunised against influenza and *Pneumococcus*, because superimposed infections with these organisms are potentially lethal. Glucocorticoids are less effective than in asthma. This contrast with asthma is puzzling, because in both diseases multiple inflammatory genes are activated, which might be expected to be turned off by glucocorticoids. Inflammatory gene activation results from acetylation of nuclear histones which opens up the chromatin structure, allowing gene transcription and synthesis of inflammatory proteins to proceed. HDAC de-acetylates histones, and suppresses the production of proinflammatory cytokines. Corticosteroids recruit HDAC to activated genes, switching off inflammatory gene transcription. Patients with COPD who do not respond to corticosteroid therapy are thought to be deficient in HDAC and nuclear factor erythroid 2-related factor (**Liao et al., 2020**). Inhaled steroids do not influence the

progressive decline in lung function in patients with COPD, but do improve the quality of life, probably as a result of a modest reduction in hospital admissions. This is counter-balanced by the increased risk of pneumonia associated with use of inhaled corticosteroids in patients with COPD.

Long-acting bronchodilators give modest symptomatic benefit, but do not deal with the underlying inflammation. No currently licensed treatments reduce the progression of COPD or suppress the inflammation in small airways and lung parenchyma. Several new treatments that target the inflammatory process are in clinical development (**Barnes, 2013**). Some, such as chemokine antagonists, are directed against the influx of inflammatory cells into the airways and lung parenchyma, whereas others target inflammatory cytokines such as TNF-α. The PDE IV inhibitor **roflumilast** is licensed as an adjunct to bronchodilators for patients with severe COPD and frequent exacerbations. Other drugs that inhibit cell signalling (see Chs **3** and **6**) include inhibitors of p38 mitogen-activated protein kinase, nuclear factor κβ and phosphoinositide-3 kinase-γ. More specific approaches include antioxidants, inhibitors of inducible NO synthase, and leukotriene B_4 antagonists. Other treatments have the potential to combat mucus hypersecretion, and there is a search for serine protease and matrix metalloprotease inhibitors to prevent lung destruction and the development of emphysema.

Specific aspects of treatment

Short- and long-acting inhaled bronchodilators can provide useful palliation in patients with a reversible component. The main short-

acting drugs are ipratropium and salbutamol; long-acting drugs include muscarinic antagonists (e.g. **tiotropium**) which are often given together with β_2 agonists (such as **salmeterol** or **formoterol)** and/or inhaled corticosteroids (Chs **14** and **15**; **Cohen et al., 2016**). A combination of inhaled corticosteroid with a long-acting b_2 agonist and a long-acting muscarinic antagonist is more effective than is dual therapy with a single long-acting bronchodilator. Theophylline (see **Ch. 16**) can be given by mouth but is of uncertain benefit. Other respiratory stimulants (e.g. **doxapram**) are sometimes used briefly in acute respiratory failure (e.g. postoperatively) but have largely been replaced by non-invasive ventilation as well as mechanical ventilatory support (intermittent positive-pressure ventilation).

Long-term oxygen therapy administered at home prolongs life in patients with severe disease and hypoxaemia (at least if they refrain from smoking – an oxygen fire is not a pleasant way to go).

Acute exacerbations

Acute exacerbations of COPD are treated with inhaled O_2 in a concentration (initially, at least) of 24%–28% O_2, that is, only just above atmospheric O_2 concentration (approximately 20%). The need for caution is because of the risk of precipitating CO_2 retention as a consequence of terminating the hypoxic drive to respiration. Blood gases and tissue oxygen saturation are monitored, and inspired O_2 subsequently is adjusted accordingly. Antibiotics such as aminopenicillins, macrolides or tetracyclines are recommended if there is evidence of infection. Inhaled bronchodilators (e.g.

salbutamol and ipratropium) are prescribed for symptomatic benefit.

A systemically active glucocorticoid (intravenous hydrocortisone or oral prednisolone) is also administered, although efficacy is modest.

Bronchiectasis

This is a chronic condition arising from persistent abnormalities and dilation of the bronchioles. Across the world, bronchiectasis can arise from a diverse range of lung pathologies such as COPD, tuberculosis and pneumonia. Cystic fibrosis, a genetic condition resulting in abnormal chloride ion movement, is an important cause in White populations, but rarely so in Asian or African people.

The clinical features of bronchiectasis include persistent cough, airflow limitation and recurrent chest infections that lead to permanent airway damage. The lung tissue is often colonised by antibiotic-resistant organisms, and treatment of such infections is both complex and challenging, involving nebulised as well as oral and intravenous agents (see **Ch. 52**).

Cystic Fibrosis

Patients with cystic fibrosis have an inherited (autosomal recessive) disorder in the cystic fibrosis transmembrane conductance regulator (CFTR) protein. This has a deleterious effect on chloride channels at the plasma membrane, with severe clinical consequences on fluid and ion composition at cell surfaces of the respiratory and GI tract. In particular, there is thickening and stasis of mucus secretions with impaired clearance of the airways and progressive lung damage.

Treatment options include recombinant human DNAse to break down the thick mucus secretion. More recently, specific therapeutic agents (known as CFTR modulators) have been developed to address the deficient CFTR protein in patients with specific mutations (for example, the *F508 deletion* mutation which is the most prevalent in the UK).

Channel potentiators (e.g. **ivacaftor**) are targeted at certain CFTR gating mutations, with the aim of enhancing chloride transport by promoting opening of the channels.

Channel correctors (**lumacaftor, elexacaftor, tezacaftor**) are used in patients affected by *F508 deletion*. The drugs aim to correct deficiencies in processing and movement or trafficking of the abnormal CFTR protein so that greater number of CFTR proteins can reach the surface of the cell.

Clinical trials have demonstrated that therapy using combinations of ivacaftor and channel correctors is more efficacious than single agents alone. Combination therapy is able to achieve greater improvements in ion transport at the plasma membrane because it remedies both the quantity as well as the physiological function of CFTR.

Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis is a chronic debilitating inflammatory disorder that results in scarring of lung tissue and loss of elasticity. Lung expansion and gaseous exchange in the alveoli are impaired due to the fibrosis and consequent increased stiffness in pulmonary tissues. In the absence of a known aetiological agent, treatment is focused on the use of anti-fibrotic agents.

Pirfenidone is an immunosuppressant that reduces fibroblast proliferation and production of fibrosis-related mediators. The exact mechanism of pirfenidone is not known, but it appears to reduce fibrosis-related protein and cytokines, prevent the accumulation of inflammatory cells and inhibit expansion of extracellular matrix that is stimulated by cytokine growth factors such as transforming growth factor-β and platelet-derived growth factor (**Borie et al., 2016**). Clinical trials have demonstrated that pirfenidone can slow the decline in lung function and exercise capacity caused by pulmonary fibrosis.

Nintedanib is a small-molecule tyrosine kinase inhibitor that is thought to reduce inflammatory and fibrotic change in the lung. The drug acts through inhibition of signalling cascades from platelet-derived and fibroblast-derived growth factor receptors that are involved in the proliferation and differentiation of pulmonary fibroblasts and myoblasts (**Borie et al., 2016**). Clinical trials have demonstrated the efficacy of nintedanib in slowing the progressive loss of lung function that is seen in pulmonary fibrosis.

Surfactants

Pulmonary surfactants act not by binding to specific targets but by lowering the surface tension of fluid lining the alveoli, allowing air to enter. They are effective in the prophylaxis and management of *respiratory distress syndrome* in newborn babies, especially premature babies in whom endogenous surfactant production is deficient. Examples include **beractant** and **poractant alpha**, which are derivatives of the physiological pulmonary surfactant protein. They are administered directly into the tracheobronchial

tree via an endotracheal tube. (The mothers of premature infants are sometimes treated with glucocorticoids before birth in an attempt to accelerate maturation of the fetal lung and minimise incidence of this disorder.)

Cough

Cough is a protective reflex that removes foreign material and secretions from the bronchi and bronchioles. It is a very common adverse effect of angiotensin-converting enzyme inhibitors, in which case the treatment is usually to substitute an alternative drug, often an angiotensin-receptor antagonist, less likely to cause this adverse effect (see **Ch. 21**). It can be triggered by inflammation in the respiratory tract, for example, by undiagnosed asthma or chronic reflux with aspiration, or by neoplasia. In these cases, cough suppressant (antitussive) drugs are sometimes useful, for example for the dry painful cough associated with bronchial carcinoma, but are to be avoided in cases of chronic pulmonary infection, as they can cause undesirable thickening and retention of sputum, and in asthma because of the risk of respiratory depression.

Drugs Used for Cough (Antitussive Drugs)

Opioid analgesics are sometimes prescribed but their efficacy is modest, and there are significant adverse effects (see **Ch. 43**). They act by inhibiting an ill-defined 'cough centre' in the brain stem and suppress cough in doses below those required for pain relief. Those used as cough suppressants have minimal analgesic actions and addictive properties.

Codeine (methylmorphine) is a weak opioid (see **Ch. 43**) with considerably less addiction liability than a strong opioid, and is a

mild cough suppressant. It decreases secretions in the bronchioles, which thickens sputum, and inhibits ciliary activity. Constipation is common. **Dextromethorphan** (a drug with many actions, including μ-receptor and sigma-1-receptor agonist, non-selective serotonin-uptake inhibitor) and **pholcodine** (μ-receptor agonist with weak analgesic effects) have less adverse effects than codeine. Respiratory depression is a risk with all centrally acting cough suppressants. **Morphine** is used for palliative care in cases of lung cancer associated with distressing cough.

Future research developments for refractory chronic cough (where no clear precipitating cause is found) include **gefapixant**, a selective antagonist of purinergic P2X3 receptors. These receptors are thought to have a key role in the activation of sensory neurons implicated in the cough reflex.

QUESTIONS

QUESTION 28.1

Respiration is controlled by spontaneous rhythmic discharges from the respiratory centre in the medulla, modulated by afferent sensory and efferent pathways, as well as the neural control networks in the brainstem.

Which of the following statements about airway innervation is incorrect?

OPTIONS:

A. Bronchoconstriction is largely mediated by acetylcholine (ACh) acting on M_3 receptors.

B. Relaxation of the airway is mediated by sympathetic innervation.

C. M_2 receptor activation leads to decreased ACh release from parasympathetic nerve terminals.

D. Vasoactive intestinal polypeptide released from non-adrenergic non-cholinergic (NANC) fibres mediates bronchodilation.

E. Irritant receptors are activated by cold air and cigarette smoke to cause bronchoconstriction.

QUESTION 28.2

Asthma is an inflammatory condition in which there is recurrent reversible airways obstruction in response to irritant stimuli and allergens.

Which of the following best describes the mechanism involved in the immediate phase of an allergic asthma attack?

OPTIONS:

A. Eosinophils become activated to release LTs, interleukins (ILs) and toxic proteins.

B. Eosinophils are attracted into the tissue by chemotaxins.

C. Allergen binds to circulating immunoglobulin E (IgE) and is then bound to mast cells to cause degranulation.

D. Adenosine release mediates broncho-hyperresponsiveness.

E. B cells are stimulated to 'switch' to IgE production.

QUESTION 28.3

β_2-Adrenoceptor agonists are first-line drugs in the treatment of asthma.

β2 agonists are effective therapeutics in asthma due to all of the following mechanisms, except…

OPTIONS:

A. Antagonism of bronchospasm induced by bronchoconstrictors

B. Inhibition of mediator release from mast cells

C. Reduction in the bronchial hyper-reactivity

D. Decrease tumour necrosis factor α (TNF-α) release from monocytes

E. Increase mucus clearance by an action on cilia

QUESTION 28.4

Glucocorticoids are the main anti-inflammatory drugs used in the treatment of asthma.

Glucocorticoids are proposed to act by all of the following mechanisms, except...

OPTIONS:

A. Restraining clonal proliferation of Th cells

B. Decreasing production of IgE and the expression of IgE receptors

C. Reducing the synthesis of IL-3

D. Generation of the vasodilators PGE_2 and PGI_2

E. Recruitment of *histone deacetylases* (HDACs)

ANSWERS

ANSWERS 28.1

RATIONALE:

A. M_3 receptors are pharmacologically the most important in airways disease. They are found on bronchial smooth muscle and gland cells, and mediate bronchoconstriction and mucus secretion.

B.

C. M_2 receptors are inhibitory autoreceptors mediating negative feedback on ACh release by postganglionic cholinergic nerves.

D. A distinct population of NANC nerves also regulates the airways releasing vasoactive intestinal polypeptide and nitric oxide which cause bronchodilation.

E. Physical or chemical stimuli, acting on irritant receptors on myelinated nerve fibres in the upper airways and/or C-fibre receptors in the lower airways, cause coughing, bronchoconstriction and mucus secretion.

CORRECT ANSWER WITH EXPLANATION:

B. Relaxation of the airway is mediated by sympathetic innervation.

Sympathetic nerves innervate tracheobronchial blood vessels and glands, but not human airway smooth muscle.

ANSWER 28.2

RATIONALE:

A. Activated eosinophils release cysteinyl leukotrienes, interleukins IL-3, IL-5 and IL-8, and the toxic proteins eosinophil cationic protein, major basic protein and eosinophil-derived neurotoxin. These play an important part in the events of the late phase of the attack.

B. Various chemotaxins and chemokines attract leukocytes – particularly eosinophils and mononuclear cells – setting the stage for the late phase.

C. Allergen interaction with mast cell-fixed IgE causes release of histamine, leukotriene B_4 and prostaglandin (PG)D_2.

D. Other putative mediators of the inflammatory process in the delayed phase are adenosine acting on the A_1 receptor.

E.

CORRECT ANSWER WITH EXPLANATION:

E. B cells are stimulated to 'switch' to IgE production.

Allergens activate Th2 cells which release cytokines (IL-4 and IL-13) to 'switch' B cells to IgE synthesis and cause expression of IgE receptors on mast cells and eosinophils.

ANSWER 28.3

RATIONALE:

A. β_2 agonists binding to adrenoceptors of smooth muscle are physiological antagonists of bronchoconstrictors and relax bronchial muscle whatever spasmogen is involved.

B. They inhibit mediator release, such as histamine, from mast cells.

C.

D. They decrease pro-inflammatory cytokine release from monocytes.

E. They increase mucus clearance by an action on cilia.

CORRECT ANSWER WITH EXPLANATION:

C. Reduction in the bronchial hyper-reactivity

β_2 agonists act as physiological antagonists of the spasmogenic mediators but have little or no effect on the bronchial hyper-reactivity.

ANSWER 28.4

RATIONALE:

A. By reducing the transcription of the gene for IL-2, corticosteroids reduce T-cell proliferation and clonal expansion.

B. They decrease the formation of Th2 cytokines that are responsible for promoting the production of IgE and the expression of IgE receptors.

C. IL-3 regulates mast cell production and so may explain why long-term steroid treatment eventually reduces the number of mast cells in the respiratory mucosa, and hence suppresses the early-phase response to allergens and exercise.

D.

E. HDACs suppress pro-inflammatory gene transcription and reduced activity of HDAC may be account for glucocorticoid resistance observed in in cigarette smokers.

CORRECT ANSWER WITH EXPLANATION:

D. Generation of the vasodilators PGE_2 and PGI_2

Glucocorticoids inhibit the generation of the vasodilators PGE_2 and PGI_2, by inhibiting induction of cyclo-oxygenase (COX)-2 so reducing the influx of inflammatory cells and mediators to the airways.

---

[1] Referred to as *Ondine curse*. Ondine was a water nymph who fell in love with a mortal. When he was unfaithful to her, the king of the water nymphs put a curse on him – that he must stay awake in order to breathe. When exhaustion finally supervened and he fell asleep, he died. Such patients are treated with mechanical ventilation. In less extreme forms, patients whose respiratory centre is relatively insensitive hypoventilate and become hypoxic when they fall asleep, leading to multiple awakenings during the night.

[2] William Osler, 19th-century doyen of American and British clinicians, wrote that ‘the asthmatic pants into old age’ – this at a time when the most effective drug that he could offer was to smoke stramonium cigarettes, a herbal remedy, the antimuscarinic effects of which were offset by direct irritation from the smoke. Its use persisted in English private schools into the 1950s, as one author can attest – much to the envy of his fellows!

[3] Over 200 years ago, William Withering recommended ‘coffee made very strong’ as a remedy for asthma. Coffee contains caffeine, a related methylxanthine.

[4] In 1900, Solis-Cohen reported that dried bovine adrenals had anti-asthma activity. He noted that the extract did not serve acutely ‘to cut short the paroxysm’ but was ‘useful in averting recurrence of paroxysms’. Mistaken for the first report on the effect of adrenaline, his astute observation was probably the first on the efficacy of steroids in asthma.

[5] Emphysema is a pathological condition sometimes associated with COPD, in which lung parenchyma is destroyed and replaced by air spaces that coalesce to form bullae – blister-like air-filled spaces in the lung tissue.

29: The kidney and urinary system

OVERVIEW

We set the scene with a brief outline of renal physiology based on the functional unit of the kidney – the nephron – before describing drugs that affect renal function. Emphasis is on diuretics – drugs that increase the excretion of Na^+ ions and water and reduce arterial blood pressure and cardiac work. We also mention drugs used to treat patients with renal failure and urinary tract disorders where these are not covered in other chapters.

Introduction

The main function of the kidneys is to maintain the constancy of the 'interior environment' by eliminating waste products and by regulating the volume, electrolyte content and pH of the extracellular fluid in the face of varying dietary intake and other environmental (e.g. climatic) demands. The kidneys receive approximately 20% of the cardiac output from which, in a young adult human, their glomeruli filter approximately 180 L of fluid per day, of which 99% is reabsorbed by the tubules. This results in a daily urine output of approximately 1.8 L (**Table 29.1**). The kidneys have important related endocrine functions including synthesis of

erythropoietin (see **Ch. 24**), renin (see **Ch. 21**) and of the active form of vitamin D (see **Ch. 36**), and are sites of action of mediators including aldosterone (Chs **21** and **33**) and antidiuretic hormone (ADH), which is also known as vasopressin (see **Ch. 33**).

The kidneys are targets of the familiar range of pathological processes – infectious, structural, immunological, malignant, toxic (including drug toxicities) and so on. The diverse diseases that result converge via impairment of renal function (reduced glomerular filtration rate) to a common end stage of renal failure which (if the pathological process is reversible) may be acute and recoverable or (if not) chronic and irreversible other than by transplantation. Lesser degrees of dysfunction, termed *renal impairment*, are diagnosed on the basis of reduced glomerular filtration rate which is estimated clinically from the plasma concentration of creatinine and age of the patient.

The main drugs that work on the kidney – the diuretics – are crucial in treating cardiovascular disease, especially hypertension and heart failure (**Ch. 21**), as well as in the management of patients with renal disease with an impaired ability to excrete salt and water. Immunosuppressant drugs (effective in several of the diseases that can cause renal failure, and crucial following renal transplantation) are covered in **Chapter 25** and antibacterial drugs (used to treat renal and urinary tract infections) in **Chapter 52**. Several drugs that act on the autonomic nervous system influence the muscle of the bladder (the detrusor muscle) and its sphincter, and some of these are used therapeutically to improve symptoms of detrusor instability or urinary obstruction ('prostatism') (Chs **14** and **15**).

The kidneys are the main organ by which drugs and their metabolites are eliminated from the body (see **Ch. 10**), so the dosing regimens of many drugs must be modified in patients with impaired renal function. A further challenge for clinical nephrologists is drug treatment of patients with renal failure who are being supported by artificial forms of dialysis. These are outside the scope of this book and interested readers are directed to the chapters by Golper, Udy and Lipman, and by Olyaei, Foster and Lermer in the *Oxford Textbook of Clinical* Nephrology (2015). Here we provide an introduction to renal physiology followed by coverage of the main classes of diuretics, and short sections on drugs used in renal failure and drugs used in urinary tract disorders.

Outline of Renal Function

The glomerular filtrate in health is similar in composition to plasma, apart from the absence of protein. As it passes through the renal tubule, about 99% of the filtered water, and much of the filtered Na^+, is reabsorbed, and some substances are secreted into it from the blood.

Each kidney consists of an outer cortex, an inner medulla and the renal pelvis, which empties into the ureter. The functional unit is the nephron, of which there are approximately 1.4×10^6 in each kidney (approximately half this number in people with hypertension), with considerable variation between individuals. Nephron number declines with age, even in healthy people, accompanied by a predictable decline in renal function.

The Structure and Function of the Nephron

Each nephron consists of a *glomerulus*, *proximal tubule*, *loop of Henle*, *distal convoluted tubule* and *collecting duct* (**Fig. 29.1**). The glomerulus comprises a tuft of capillaries projecting into Bowman's capsule, a cup-like sack draining into the proximal tubule. Most nephrons lie largely or entirely in the cortex. The remaining 12%, called the *juxtamedullary nephrons*, have their glomeruli and convoluted tubules next to the junction of the medulla and cortex, and their loops of Henle pass deep into the medulla.

The Blood Supply to the Nephron

Nephrons possess the special characteristic of having two capillary beds in series with each other (see **Fig. 29.1**). The afferent arteriole of each cortical nephron branches to form the glomerulus; glomerular capillaries coalesce into the efferent arteriole which supplies a second capillary network in the cortex, around the convoluted tubules and loops of Henle, before converging to form venules and then renal veins. By contrast, efferent arterioles of juxtamedullary nephrons lead to vessel loops (*vasa recta*) that pass deep into the medulla with the thin loops of Henle (see **Fig. 29.1**).

Table 29.1

[a] Typical values for a healthy young adult: renal blood flow, 1200 mL/min (20%–25% of cardiac output); renal plasma flow, 660 mL/min; glomerular filtration rate, 125 mL/min.

[b] These are typical figures for an individual eating a Western diet. The kidney excretes more or less of each of these substances to maintain the constancy of the internal milieu, so on a low-sodium diet (for instance in the Yanamami, indigenous people of the Amazonian rain forest), NaCl excretion may be reduced to below 10 mmol/day! At the other extreme, individuals living in some fishing communities in Japan eat (and excrete) several hundred mmol/day

The Juxtaglomerular Apparatus

A conjunction of afferent arteriole, efferent arteriole and distal convoluted tubule near the glomerulus forms the juxtaglomerular apparatus (**Fig. 29.2**). At this site, there are specialised cells in both the afferent arteriole and the tubule. The latter, termed *macula densa* cells, respond to changes in the rate of flow and the composition of tubule fluid, and they control, probably by purinergic signalling (see **Ch. 16**), *renin* release from specialised granular renin-containing cells in the afferent arteriole (see **Ch. 21**). These cells also release renin in response to decreased pressure in the afferent arteriole. Renin, named because of its discovery during the 19th century in extracts of kidney (renal) tissue, is an enzyme that cleaves angiotensin I from angiotensinogen. Angiotensin I is converted to angiotensin II via angiotensin converting enzyme (ACE) and acts on AT_1 receptors in vascular

smooth muscle to cause vasocontriction, and in the adrenal cortex to release aldosterone hence controlling vascular resistance, blood pressure, blood volume and Na^+ and K^+ balance. Renin is consequently of great importance in cardiovascular homeostasis. If it had been discovered more recently it might have been named from its biochemical action as 'angiotensinogenase'. Various chemical mediators also influence renin secretion, including β_2-adrenoceptor agonists, vasodilator prostaglandins and feedback inhibition from angiotensin II acting on AT_1 receptors (see **Fig. 21**.2). The role of the juxtaglomerular apparatus in the control of Na^+ balance is dealt with below.

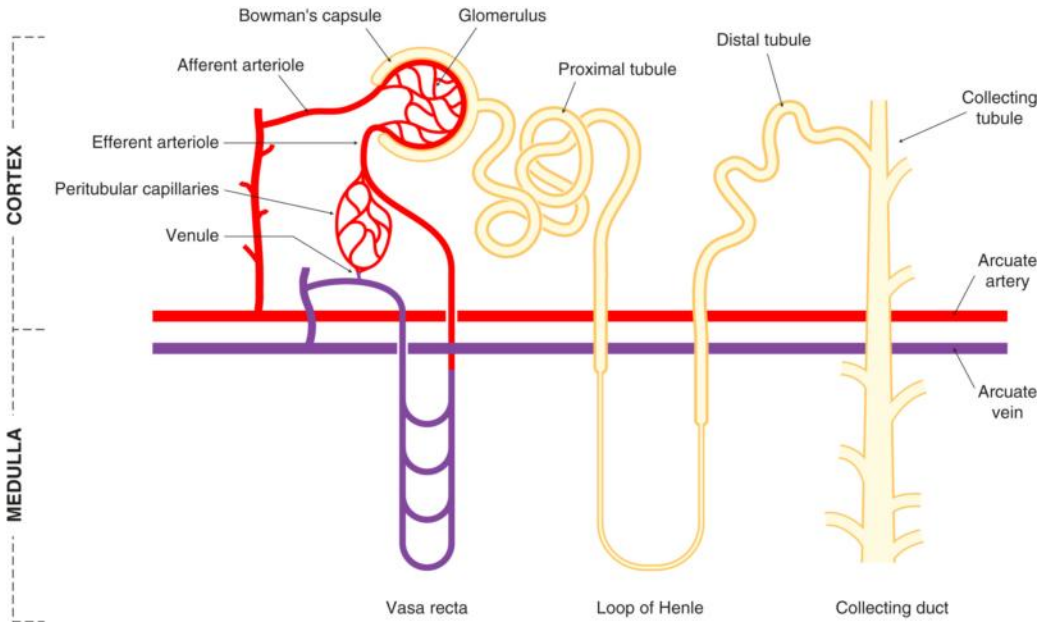

FIG. 29.1 Simplified diagram of a juxtamedullary nephron and its blood supply.The tubules and the blood vessels are shown separately for clarity. In the kidney, the peritubular capillary network surrounds the convoluted tubules, and the distal convoluted tubule passes close to the glomerulus, between the afferent and efferent arterioles. (This last is shown in more detail in Fig. 29.2.)

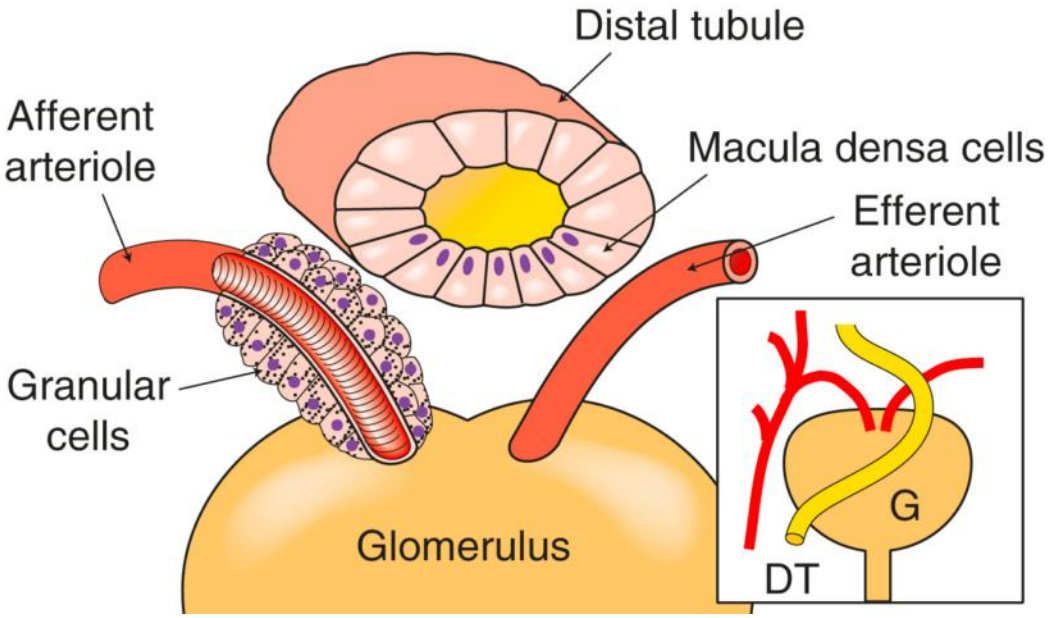

FIG. 29.2 The juxtaglomerular apparatus.The cutaway sections show the granular renin-containing cells around the afferent arteriole, and the macula densa cells in the distal convoluted tubule. The inset shows the general relationships between the structures. *DT*, Distal tubule; *G*, glomerulus.

Glomerular Filtration

Fluid is driven from the capillaries into Bowman's capsule by hydrodynamic force opposed by the oncotic pressure of the plasma proteins, to which healthy glomerular capillaries are impermeable. All the low-molecular-weight constituents of plasma appear in the filtrate, while albumin and larger proteins are retained in the blood.

Tubular Function

The apex (lumenal surface) of each tubular cell is surrounded by a tight junction, as in all epithelia. This is a specialised region of membrane that separates the intercellular space from the lumen. The movement of ions and water across the epithelium can occur *through* cells (the transcellular pathway) and *between* cells through the tight junctions (the paracellular pathway). A common theme is that energy is expended to pump Na^+ out of the cell by Na^+-K^+-ATPase situated in the basolateral cell membrane and the resulting gradient of Na^+ concentration drives the entry of Na^+ from the lumen via various transporters that facilitate Na^+ entry coupled with movement of other ions, either in the same direction as Na^+, in which case they are called *symporters* or *co-transporters*, or in the opposite direction, in which case they are called *antiporters*. These transporters vary in different parts of the nephron, as described later.

The proximal convoluted tubule

The epithelium of the proximal convoluted tubule is 'leaky'; i.e. the tight junctions in the proximal tubule are not so 'tight' after all, being permeable to ions and water, and permitting passive flow in either direction. This prevents the build-up of large concentration gradients; thus, although approximately 60%–70% of Na^+ reabsorption occurs in the proximal tubule, this transfer is accompanied by passive absorption of water so that fluid leaving the proximal tubule remains approximately isotonic to the glomerular filtrate.

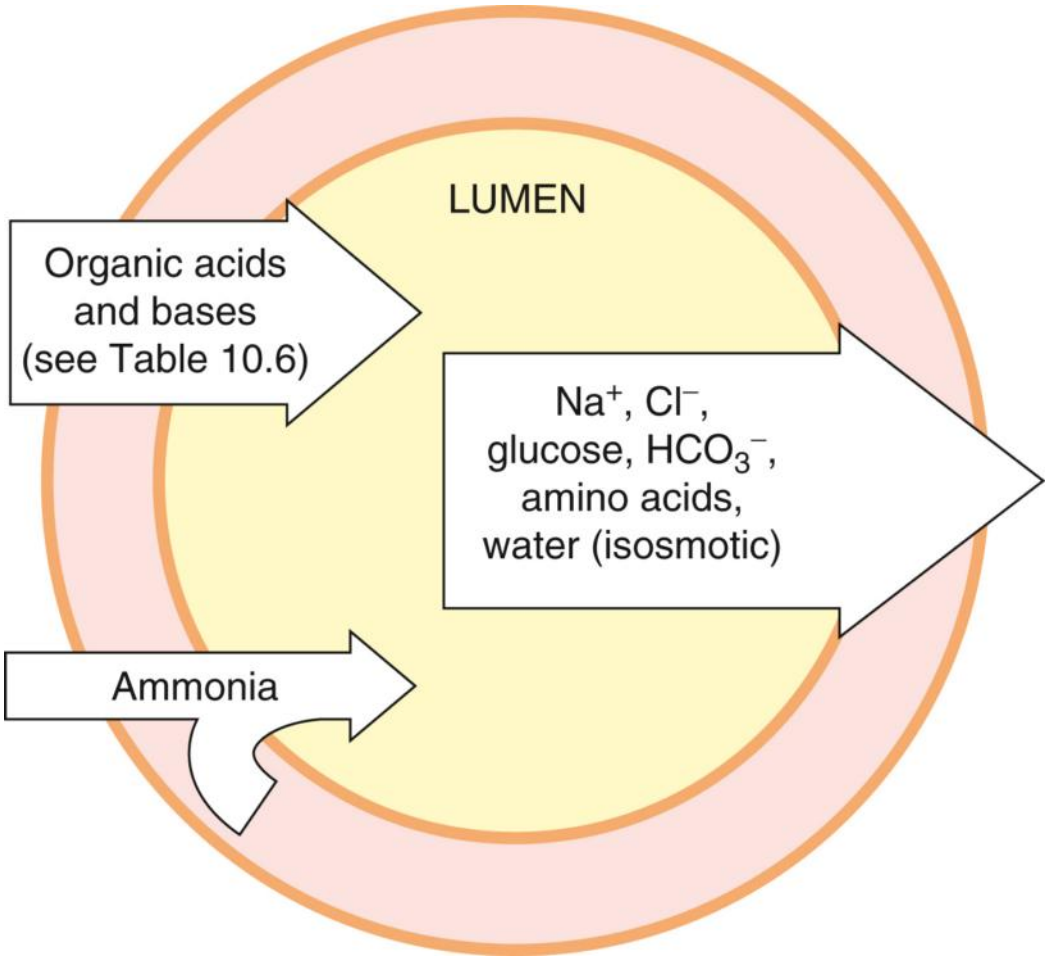

FIG. 29.3 Transport processes in the proximal convoluted tubule.The main driving force for the absorption of solutes and water from the lumen is the Na^+-K^+-ATPase in the basolateral membrane of the tubule cells. Many drugs are secreted into the proximal tubule (see **Ch. 10**). Redrawn from Burg, M.B., 1985. In: Brenner, B.M., Rector, F.C. (Eds), The Kidney, third ed. WB Saunders, Philadelphia, pp. 145–175.

Some of the transport processes in the proximal tubule are shown in Figs **29.3**–**29.5**. The most important mechanism for Na^+ entry into proximal tubular cells from the filtrate occurs by Na^+/H^+ exchange (see **Fig. 29.5**). Intracellular carbonic anhydrase is essential for production of H^+ for secretion into the lumen. Na^+ is reabsorbed from tubular fluid into the cytoplasm of proximal tubular cells in exchange for cytoplasmic H^+. It is then transported out of the cells into the interstitium by a Na^+-K^+-ATPase (sodium pump) in the basolateral membrane. This is the main active transport mechanism of the nephron in terms of energy consumption. Reabsorbed Na^+ then diffuses into blood vessels.

Bicarbonate is normally completely reabsorbed in the proximal tubule. This is achieved by combination with protons, yielding carbonic acid, which dissociates to form carbon dioxide and water – a reaction catalysed by carbonic anhydrase present in the lumenal brush border of the proximal tubule cells (see **Fig. 29.5A**) – followed by passive reabsorption of the dissolved carbon dioxide. [1] The selective removal of sodium bicarbonate, with accompanying water, in the early proximal tubule causes a secondary rise in the concentration of chloride ions. Diffusion of chloride down its concentration gradient via the paracellular shunt (see **Fig. 29.5A**) leads, in turn, to a lumen-positive potential difference that favours reabsorption of sodium. The other mechanism involved in movement via the paracellular route is that sodium ions are secreted by Na^+-K^+-ATPase into the lateral intercellular space, somewhat raising its osmolality because of the 3 Na^+:2 K^+ stoichiometry of the transporter. This leads to osmotic movement of water across the tight junction (see **Fig. 29.5A**), in turn causing

sodium and chloride ion reabsorption by convection (so-called solvent drag).

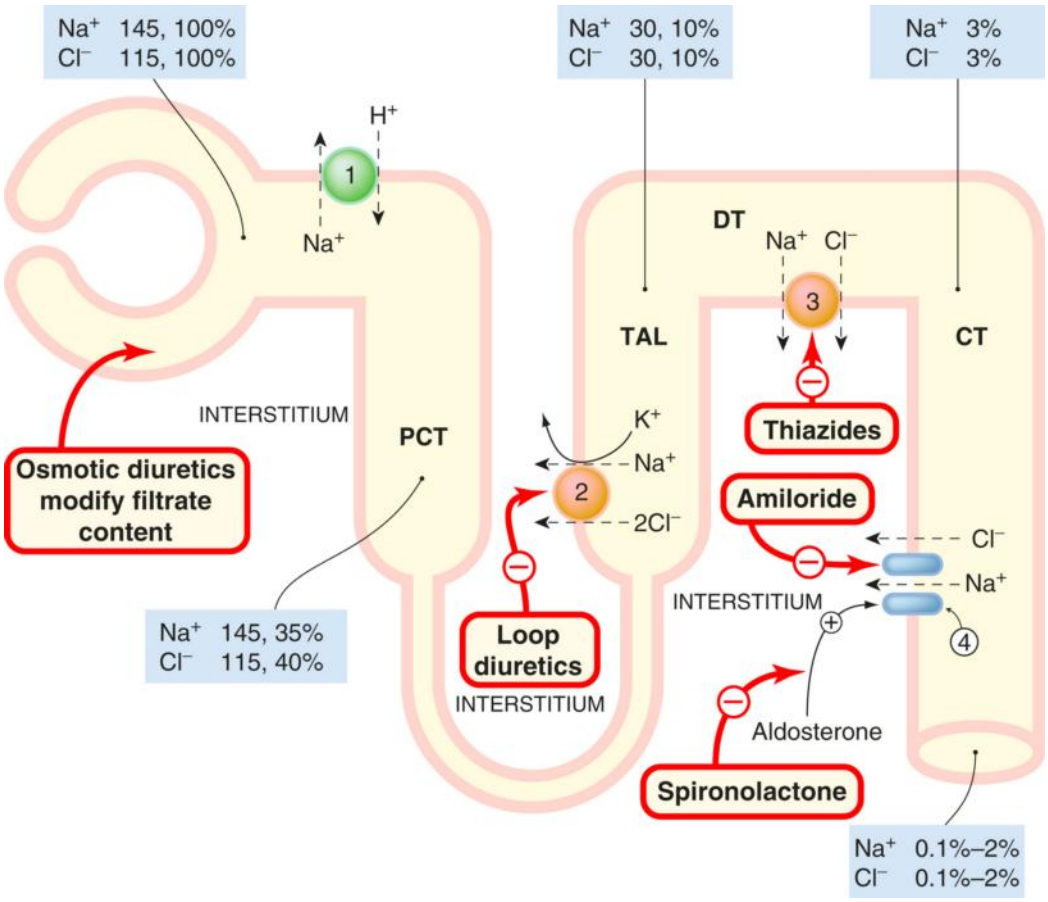

FIG. 29.4 Schematic showing the absorption of sodium and chloride in the nephron and the main sites of action of drugs.Cells are depicted as a *pink border* round the *yellow tubular lumen*. Mechanisms of ion absorption at the apical margin of the tubule cell: *(1)* Na^+/H^+ exchange; *(2)* $Na^+/K^+/2Cl^-$ co-transport; *(3)* Na^+/Cl^- co-transport; *(4)* Na^+ entry through sodium channels. Sodium is pumped out of the cells into the interstitium by the Na^+-K^+-ATPase in the basolateral margin of the tubular cells (not shown). The numbers in the boxes give the concentration of ions as millimoles per litre of

filtrate, and the percentage of filtered ions still remaining in the tubular fluid at the sites specified. *CT,* Collecting tubule; *DT,* distal tubule; *PCT,* proximal convoluted tubule; *TAL,* thick ascending loop. Data from **Greger, R., 2000**. Physiology of sodium transport. Am. J. Med. Sci. 319, 51–62.

Filtered glucose is reabsorbed in the proximal tubule, being co-transported with sodium ions by *a sodium/glucose cotransporter (SGLT)*. SGLT2 is expressed early in the proximal tubule; it accounts for the reabsorption of 80%–90% of the filtered glucose and is an important drug target. It is inhibited by the gliflozins (e.g. ***canagliflozin*** , ***dapagliflozin*** and ***empagliflozin***), which improve survival in appropriately selected patients with type 2 diabetes (see **Ch. 31**) and heart failure (see **Ch. 21**). Here it is worth noting that they also improve outcome in chronic renal disease.

SGLT1 is expressed further along the proximal tubule and accounts for the reabsorption of most of the remaining glucose.

Many organic acids and bases are actively secreted into the tubule from the blood by specific transporters (**Fig. 29.3** and see **Table 10.6**).

After passage through the proximal tubule, tubular fluid (now 30%–40% of the original volume of the filtrate) passes on to the loop of Henle.

The Loop of Henle, Medullary Counter-Current Multiplier and Exchanger

The loop of Henle consists of a descending and an ascending portion (see Figs **29.1** and **29.4**), the ascending portion having both thick and thin segments. This part of the nephron enables the kidney to excrete urine that is either more or less concentrated than plasma, and hence to regulate the osmotic balance of the body as a whole. The loops of Henle of the juxtamedullary nephrons function as counter-current multipliers, and the vasa recta as counter-current exchangers. NaCl is actively reabsorbed in the thick ascending limb, causing hypertonicity of the interstitium. The descending limb is permeable to water, and this interstitial hypertonicity causes water to move out, so that the tubular fluid becomes progressively more concentrated as it approaches the bend.

In juxtamedullary nephrons with long loops, there is extensive movement of water out of the tubule so that the fluid eventually reaching the tip of the loop has a high osmolality – normally approximately 1200 mOsmol/kg, but up to 1500 mOsmol/kg under conditions of dehydration – compared with plasma and extracellular fluid, which is approximately 300 mOsmol/kg. [2] The hypertonic milieu of the medulla, through which the collecting ducts of all nephrons pass on the way to the renal pelvis, is important in providing a mechanism by which the osmolarity of the urine is controlled.

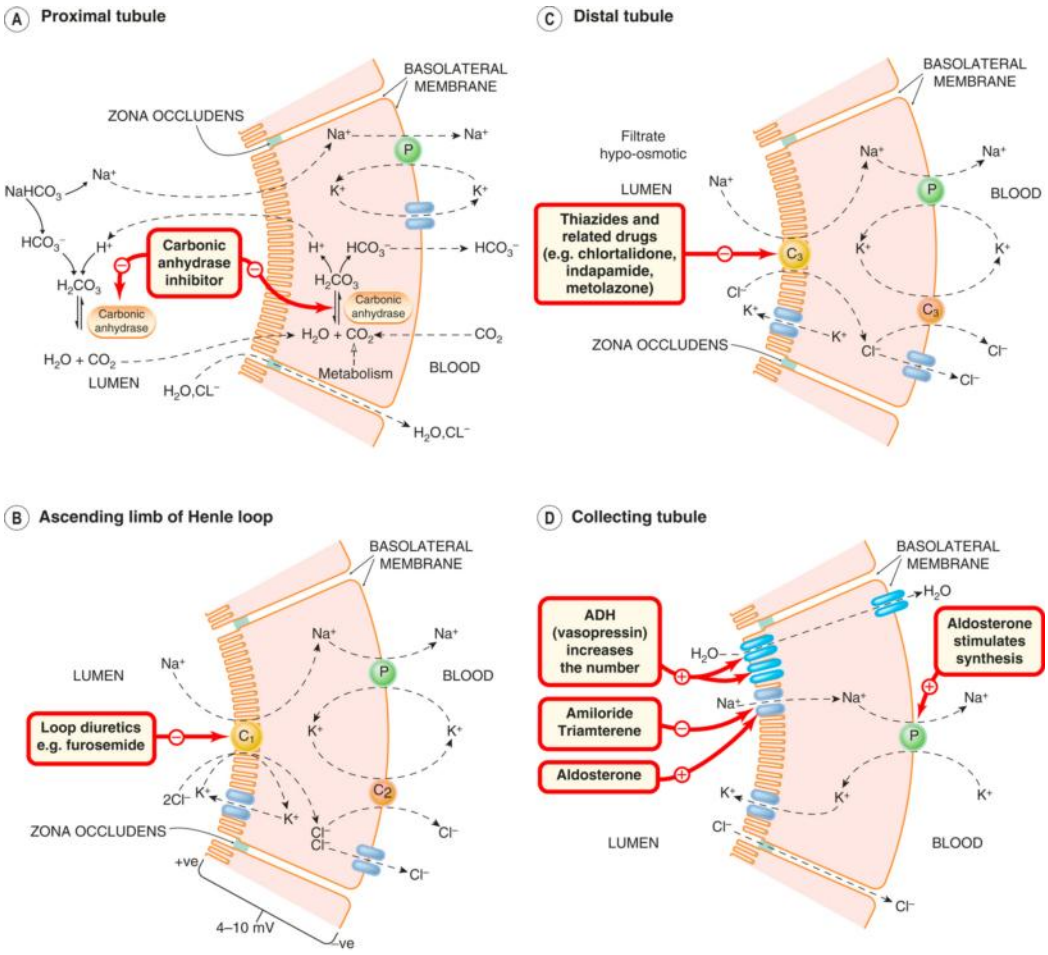

FIG. 29.5 Drug effects on renal tubular ion transport.The primary active transport mechanism is the Na^+/K^+ pump *(P)* in the basolateral membrane of cells in each location; the diagrams are simplified in that the pump exchanges three Na^+ for two K^+ ions. (A) Bicarbonate ion reabsorption in the proximal convoluted tubule, showing the action of carbonic anhydrase inhibitors. (B) Ion transport in the thick ascending limb of Henle loop, showing the site of action of loop diuretics, namely the $Na^+/K^+/2Cl^-$ co-transporter *(C_1)*.

Chloride ions leave the cell both through basolateral chloride channels and by an electroneutral K^+/Cl^- co-transporter *(C_2)* which are also present in the distal tubule. (C) Salt transport in the distal convoluted tubule, showing the site of action of thiazide diuretics, namely the Na^+/Cl^- co-transporter *(C_3)*. (D) Actions of hormones and drugs on the collecting tubule. The cells are impermeable to water in the absence of antidiuretic hormone (ADH), and to Na^+ in the absence of aldosterone. Aldosterone acts on a nuclear receptor within the tubule cell and on membrane receptors. Adapted from **Greger, R., 2000**. Physiology of sodium transport. Am. J. Med. Sci. 319, 51–62.

The *ascending limb* has very low permeability to water; i.e. the tight junctions really are tight, enabling the build-up of a substantial concentration gradient across the wall of the tubule. It is here, in the thick ascending limb of the loop of Henle, that 20%–30% of filtered Na^+ is reabsorbed. There is active reabsorption of NaCl, unaccompanied by water, reducing the osmolality of the tubular fluid and making the interstitial fluid of the medulla hypertonic. The osmotic gradient in the medullary interstitium is the key consequence of the counter-current multiplier system, the main principle being that small horizontal osmotic gradients stack up to produce a large vertical gradient. Urea contributes to the gradient because it is more slowly reabsorbed than water and may be added to fluid in the descending limb, so its concentration rises along the

nephron until it reaches the collecting tubules, where it diffuses out into the interstitium. It is thus trapped in the inner medulla.

Ions move into cells of the thick ascending limb of the loop of Henle across the apical membrane by a $Na^+/K^+/2Cl^-$ co-transporter, driven by the Na^+ gradient produced by Na^+-K^+-ATPase in the basolateral membrane (see **Fig. 29.5B**). Most of the K^+ taken into the cell by the $Na^+/K^+/2Cl^-$ co-transporter returns to the lumen through apical potassium channels, but some K^+ is reabsorbed, along with Mg^{2+} and Ca^{2+}.

Reabsorption of salt from the thick ascending limb is not balanced by reabsorption of water, so tubular fluid is hypotonic with respect to plasma as it enters the distal convoluted tubule (see **Fig. 29.4**). The thick ascending limb is therefore sometimes referred to as the 'diluting segment'.

The Distal Tubule

In the early distal tubule, NaCl reabsorption, coupled with impermeability of the *zonula occludens* to water, further dilutes the tubular fluid. Transport is driven by Na^+-K^+-ATPase in the basolateral membrane. This lowers cytoplasmic Na^+ concentration, and consequently Na^+ enters the cell from the lumen down its concentration gradient, accompanied by Cl^-, by means of a Na^+/Cl^- co-transporter (see **Fig. 29.5C**).

The apical surfaces (lumen side) of distal tubular cells are permeable to Ca^{2+} via the TRPV5 channel. On the basolateral surface there is an active Na^+/Ca^{2+} transporter, and the basolateral ATP-dependent Na^+/K^+ pump produces the gradient for Ca^{2+} to be reabsorbed via a separate Na^+/Ca^{2+} basolateral antiporter. The

excretion of Ca^{2+} is regulated in this part of the nephron, by *parathormone (PTH)* and *calcitriol,* both of which increase Ca^{2+} reabsorption and phosphate excretion by increasing the synthesis of several of these transporters (see **Ch. 36**).

The Collecting Tubule and Collecting Duct

Distal convoluted tubules empty into collecting tubules, which coalesce to form collecting ducts (see **Fig. 29.1**). Collecting tubules include principal cells, which reabsorb Na^+ and secrete K^+ (see **Fig. 29.5D**), and two populations of intercalated cells, α and β, which secrete acid and base, respectively.

The tight junctions in this portion of the nephron are impermeable to water and cations. The movement of ions and water in this segment is under independent hormonal control: absorption of NaCl by *aldosterone* (Chs **21** and **33**) and absorption of water by ADH (see **Ch. 33**).

Aldosterone enhances Na^+ reabsorption and promotes K^+ excretion (see **Fig. 29.5D**). It promotes Na^+ reabsorption by:

- a rapid effect, up-regulating epithelial sodium channels in the collecting duct, increasing apical membrane permeability and hence reabsorption of sodium ions by an action on membrane aldosterone receptors. [3]
- delayed effects, via nuclear receptors (see **Ch. 3**), directing the synthesis of a specific protein mediator up-regulating and activating the basolateral Na^+/K^+ pump, which pumps three sodium ions out of the cell, into the interstitial fluid and two potassium ions into the cell from the interstitial fluid and stimulates synthesis of the epithelial sodium ion

channel in addition to its rapid effect via the membrane receptor mentioned earlier.

ADH, diabetes insipidus and inappropriate ADH secretion (syndrome of inappropriate ADH [SIADH*]*)

ADH is secreted by the posterior pituitary (see **Ch. 33**) and acts on V_2 receptors ('V' for 'vasopressin' – the alternative name for ADH) in the basolateral membranes of cells in the collecting tubules and ducts, increasing the expression of *aquaporin* (water channels; see **Ch. 9**) in the apical membranes (see **Fig. 29.5D**). This renders this part of the nephron permeable to water, allowing passive reabsorption of water as the collecting duct traverses the hyperosmotic region of the medulla, and hence the excretion of concentrated urine. Conversely, in the absence of ADH, collecting duct epithelium is impermeable to water, so hypotonic fluid that leaves the distal tubule remains hypotonic as it passes down the collecting ducts, leading to the excretion of dilute urine. Defective ADH secretion (see **Ch. 33**) or impaired action of ADH on the kidney results in *diabetes insipidus*, an uncommon disorder in which patients excrete large volumes of dilute urine. Excessive ADH secretion can result from various neurological disorders or from ectopic secretion by various malignant tumours. Assays for ADH in plasma are not routinely available in the clinic, so this condition is usually inferred indirectly from its characteristic effects on plasma and urine which include hyponatraemia, the production of a concentrated urine despite a low plasma osmolarity and persistent loss of Na^+ ions in the urine and referred to as the 'syndrome of inappropriate ADH' or 'SIADH'. Hyponatraemia is driven by

continued drinking (from habit) despite renal water retention and can result in seizures, so dietary fluid restriction is a mainstay of management.

Ethanol (see **Ch. 50**) inhibits the secretion of ADH, causing a water diuresis (possibly familiar to some of our readers) as a kind of transient diabetes insipidus. **Nicotine** enhances ADH secretion (perhaps contributing to the appeal of an after-dinner cigar?).

Several drugs inhibit the action of ADH: **lithium** (used in psychiatric disorders; see **Ch. 48**), **demeclocycline** (a tetracycline used not as an antibiotic, but rather to treat SIADH), **colchicine** (see **Ch. 25**) and *vinca alkaloids* (see **Ch. 57**). Recently, more specific antagonists of ADH (e.g. **conivaptan**, **tolvaptan**) have been introduced for management of hyponatraemia. Any of these drugs, given in excess, can cause acquired forms of *nephrogenic* diabetes insipidus, caused by a failure of the renal collecting ducts to respond to ADH. Nephrogenic diabetes insipidus can also be caused by genetic disorders affecting the V_2 receptor or aquaporin.

Renal tubular function

- Protein-free glomerular filtrate enters via Bowman's capsule.
- Na^+-K^+-ATPase in the basolateral membrane is the main active transporter. It provides the Na^+-gradients (low cytoplasmic Na^+ concentrations) for passive transporters in the apical membranes which facilitate Na^+ entry (reabsorption) from the tubular fluid down a concentration gradient and in exchange for hydrogen ions (H^+).

- 60%–70% of the filtered Na^+ and >90% of HCO_3^- are absorbed in the proximal tubule.
- Glucose is reabsorbed in the proximal tubule, mainly by SGLT2. Gliflozins inhibit SGLT2 and improve survival in appropriately selected patients with type 2 diabetes mellitus (see **Ch. 31**) and with heart failure (see **Ch. 21**).
- Carbonic anhydrase is key for $NaHCO_3$ reabsorption in the proximal tubule and also for distal tubular urine acidification.
- The thick ascending limb of Henle loop is impermeable to water; 20%–30% of the filtered NaCl is actively reabsorbed in this segment.
- Ions are reabsorbed from tubular fluid by a $Na^+/K^+/2Cl^-$ co-transporter in the apical membranes of the thick ascending limb.
- $Na^+/K^+/2Cl^-$ co-transport is inhibited by loop diuretics.
- Filtrate is diluted as it traverses the thick ascending limb as ions are reabsorbed, so that it is hypotonic when it leaves.
- The tubular counter-current multiplier actively generates a concentration gradient – small horizontal differences in solute concentration between tubular fluid and interstitium are multiplied vertically. The deeper in the medulla, the more concentrated is the interstitial fluid.
- Medullary hypertonicity is preserved passively by counter-current exchange in the vasa recta.
- Na^+/Cl^- co-transport (inhibited by thiazide diuretics) reabsorbs 5%–10% of filtered Na^+ in the distal tubule.

- K^+ is secreted into tubular fluid in the distal tubule and the collecting tubules and collecting ducts.
- In the absence of ADH, the collecting tubule and collecting duct have low permeability to salt and water. ADH increases water permeability.
- Na^+ is reabsorbed from the collecting duct through epithelial sodium channels.
- These epithelial Na^+ channels are activated by aldosterone and inhibited by **amiloride** and by **triamterene.** K^+ or H^+ is secreted into the tubule in exchange for Na^+ in this distal region.

Acid–Base Balance

The kidneys (together with the lungs; see **Ch. 28**) regulate the H^+ concentration of body fluids. Acid or alkaline urine can be excreted according to need, the usual requirement being to form acid urine to eliminate phosphoric and sulfuric acids generated during the metabolism of nucleic acids and of sulfur-containing amino acids consumed in the diet. Consequently, metabolic acidosis is a common accompaniment of renal failure. Altering urine pH to alter drug excretion is mentioned later.

Potassium Balance

Extracellular K^+ concentration – critically important for excitable tissue function (see **Ch. 4**) – is tightly controlled through regulation of K^+ excretion by the kidney. Urinary K^+ excretion

matches dietary intake, usually approximately 50–100 mmol in 24 h in Western countries. Many diuretics cause K^+ loss (see later).

Potassium ions are transported into collecting duct and collecting tubule cells from interstitial fluid by an Na^+-K^+-ATPase in the basolateral membrane which is under the control of aldosterone (see earlier), and leak into the lumen through a K^+-selective ion channel. Na^+ passes from tubular fluid through sodium channels in the apical membrane down the electrochemical gradient created by the Na^+-K^+-ATPase; a lumen-negative potential difference across the cell results, increasing the driving force for K^+ secretion into the lumen. Thus K^+ secretion is coupled to Na^+ reabsorption.

Consequently, K^+ is lost when:

- more Na^+ reaches the collecting duct, as occurs with any diuretic acting proximal to the collecting duct;
- Na^+ reabsorption in the collecting duct is increased directly (e.g. in hyperaldosteronism).

Conversely, K^+ is retained when:

- Na^+ reabsorption in the collecting duct is decreased, for example by **amiloride** or **triamterene**, which block the sodium channel in this part of the nephron, or **spironolactone**, **eplerenone**, or **finerenone**, which antagonise aldosterone (see later).

Excretion of Organic Molecules

There are distinct mechanisms (see **Ch. 10**, **Table 10.7**) for secreting organic anions and cations into the proximal tubular

lumen. Secreted anions include several important drugs, for example, *thiazides*, **furosemide** and most *penicillins* and *cephalosporins* (see **Ch. 52**). Similarly, several secreted organic cations are important drugs, for example, **triamterene**, **amiloride**, **atropine** (see **Ch. 14**), **morphine** (see **Ch. 43**) and **quinine** (see **Ch. 55**). Both anion and cation transport mechanisms are, like other renal ion transport processes, indirectly powered by active transport of Na^+ and K^+, the energy being derived from Na^+-K^+-ATPase in the basolateral membrane.

Organic anions in the interstitial fluid are exchanged with cytoplasmic α-ketoglutarate by an antiport (i.e. an exchanger that couples uptake and release of α-ketoglutarate with, in the opposite direction, uptake and release of a different organic anion) in the basolateral membrane, and

diffuse passively into the tubular lumen (see **Fig. 29.3**).

Organic cations diffuse into the cell from the interstitium and are then actively transported into the tubular lumen in exchange for H^+.

Natriuretic Peptides

Endogenous A, B and C natriuretic peptides (ANP, BNP and CNP; see Chs **20** and **21**) are involved in the regulation of Na^+ excretion. They are released from the heart in response to stretch (A and B) and from endothelium (C). They activate membrane-bound guanylyl cyclase (see **Ch. 3**), and cause natriuresis both by renal haemodynamic effects (increasing glomerular capillary pressure by dilating afferent and constricting efferent arterioles) and by direct tubular actions. The tubular actions include the inhibition of angiotensin II–stimulated Na^+ and water reabsorption in the

proximal convoluted tubule, and of the action of ADH in promoting water reabsorption in the collecting tubule. Therapeutically, this effect has been harnessed via the inhibition of *neprilysin*, a membrane endopeptidase, by the active metabolite of **sacubitril**. Neprilysin inactivates ANP and BNP (along with other peptides, see **Ch. 17**), so its inhibition promotes natriuresis and sacubitril is used in combination with valsartan in the management of heart failure (see **Ch. 21**).

Within the kidney, the post-translational processing of ANP prohormone differs from that in other tissues, resulting in an additional four amino acids being added to the amino terminus of ANP to yield a related peptide, *urodilatin*, that promotes Na^+ excretion by acting on natriuretic peptide A receptors.

Prostaglandins and Renal Function

Prostaglandins (PGs; see **Ch. 17**) generated in the kidney influence its haemodynamic and excretory functions. The main renal prostaglandins in humans are vasodilator and natriuretic, namely PGE_2 in the medulla and PGI_2 (prostacyclin) in glomeruli. Factors that stimulate their synthesis include ischaemia, angiotensin II, ADH and bradykinin.

Prostaglandin biosynthesis is low under basal conditions. However, when vasoconstrictors (e.g. angiotensin II, noradrenaline) are released, local release of PGE_2 and PGI_2 compensates, preserving renal blood flow by their vasodilator action.

The influence of renal prostaglandins on salt balance and haemodynamics can be inferred from the effects of non-steroidal anti-inflammatory drugs (NSAIDs; which inhibit prostaglandin

production by inhibiting cyclo-oxygenase; see **Ch. 25**). NSAIDs have little or no effect on renal function in healthy people, but predictably cause acute renal failure in clinical conditions in which renal blood flow depends on vasodilator prostaglandin biosynthesis. These include cirrhosis of the liver, heart failure, nephrotic syndrome, glomerulonephritis and extracellular volume contraction (see **Ch. 58**, **Table 58.1**). NSAIDs increase blood pressure in patients treated for hypertension by impairing PG-mediated vasodilatation and salt excretion. They exacerbate salt and water retention in patients with heart failure (see **Ch. 21**), partly by this same direct mechanism. [4]

Drugs Acting on the Kidney

Diuretics

Diuretics increase the excretion of Na^+ and water. They decrease the reabsorption of Na^+ and an accompanying anion (usually Cl^-) from the filtrate, increased water loss being secondary to the increased excretion of NaCl (natriuresis). This can be achieved:

- by a direct action on the cells of the nephron
- indirectly, by modifying the content of the filtrate

Because a very large proportion of salt (NaCl) and water that passes into the tubule via the glomerulus is reabsorbed (see **Table 29.1**), even a small decrease in reabsorption can cause a marked increase in Na^+ excretion. A summary diagram of the mechanisms and sites of action of various diuretics is given in **Fig. 29.4** and

more detailed information on different classes of drugs in **Fig. 29.5**.

Most diuretics with a direct action on the nephron act from within the tubular lumen and reach their sites of action by being secreted into the proximal tubule (**spironolactone** is an exception).

Diuretics Acting Directly On Cells Of The Nephron

The main therapeutically useful diuretics act on the:

- thick ascending loop of Henle
- early distal tubule
- collecting tubules and ducts

For a more detailed review of the actions and clinical uses of the diuretics, see **Ellison and Subramanya (2015)**.

Loop diuretics

Loop diuretics (see **Fig. 29.5B**) are the most powerful diuretics (see **Fig. 29.6** for a comparison with thiazides), capable of causing the excretion of 15%–25% of filtered Na^+. Their action is often described – in a phrase that conjures up a rather uncomfortable picture – as causing 'torrential urine flow'. The main example is **furosemide**; **bumetanide** and **torasemide** are alternative agents. These drugs act on the thick ascending limb, inhibiting the $Na^+/K^+/2Cl^-$ carrier in the lumenal membrane by combining with its Cl^- binding site.

Loop diuretics also have incompletely understood vascular actions. Intravenous administration of furosemide to patients with

pulmonary oedema caused by acute heart failure (see **Ch. 21**) causes a therapeutically useful vasodilator effect independent of the onset of diuresis. Possible mechanisms that have been invoked include decreased vascular responsiveness to vasoconstrictors such as angiotensin II and noradrenaline; increased formation of vasodilating prostaglandins (see earlier); decreased production of the endogenous ouabain-like natriuretic hormone (Na^+-K^+-ATPase inhibitor; see **Ch. 20**); and potassium-channel opening effects in resistance arteries (see **Ellison and Subramanya, 2015**).

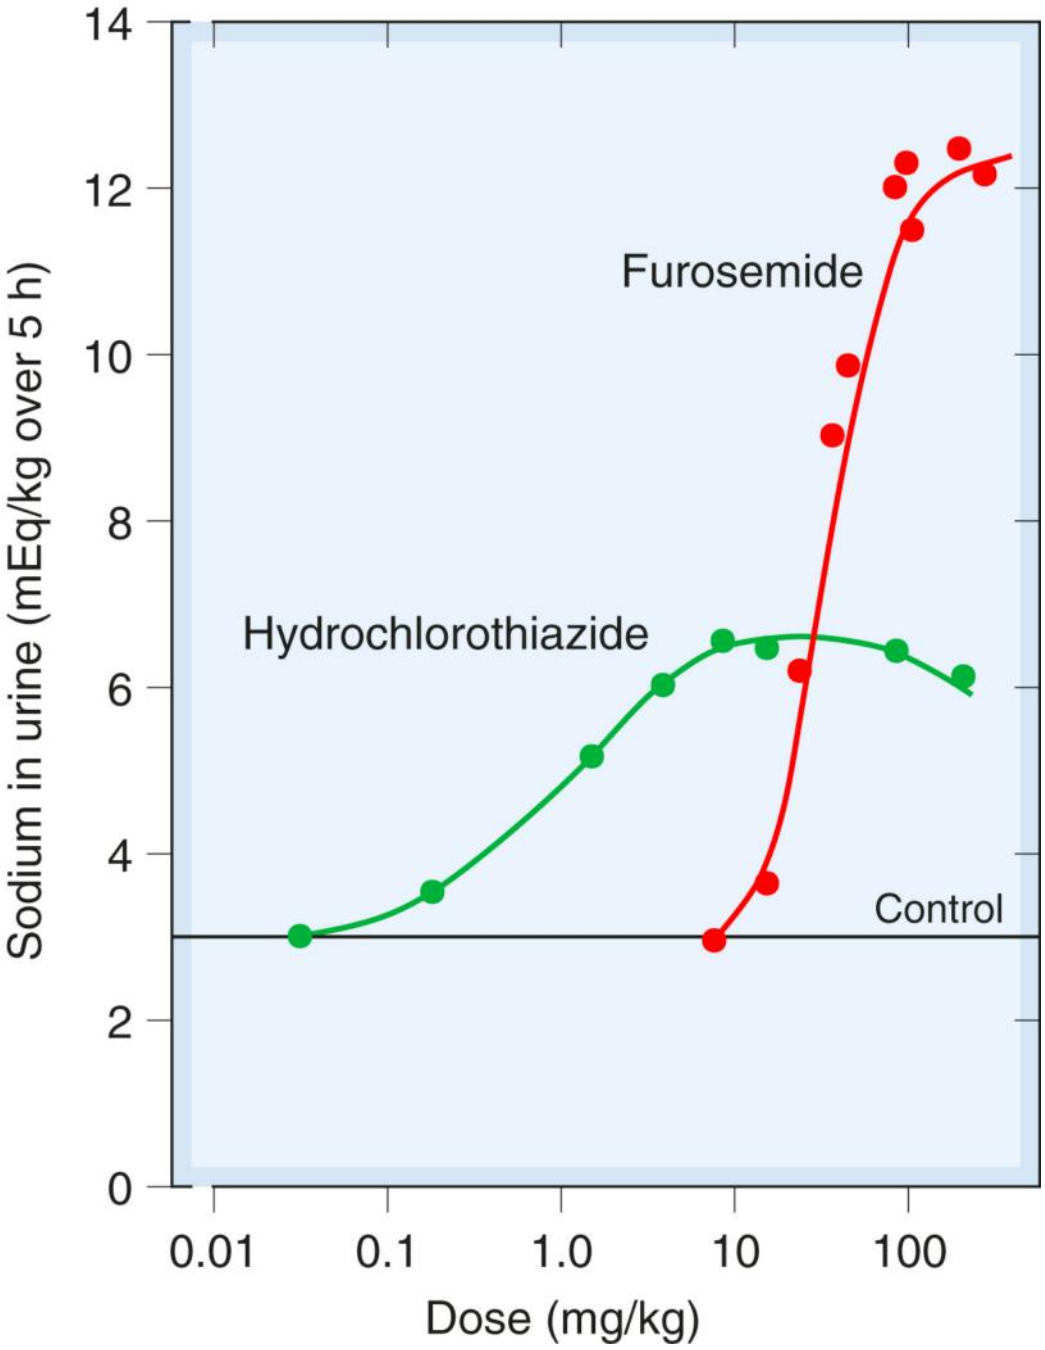

FIG. 29.6 Dose–response curves for furosemide and hydrochlorothiazide, showing differences in potency and maximum effect 'ceiling' in rat.Note that these doses are not used

clinically in humans. Adapted from Timmerman, R.J., et al., 1964. Curr. Ther. Res. 6, 88.

Loop diuretics increase the delivery of Na^+ to the distal nephron, causing loss of H^+ and K^+. Because Cl^- but not HCO_3^- is lost in the urine, the plasma concentration of HCO_3^- increases as plasma volume is reduced – a form of metabolic alkalosis therefore referred to as 'contraction alkalosis'.

Loop diuretics increase excretion of Ca^{2+} and Mg^{2+} and decrease excretion of uric acid.

Pharmacokinetic aspects

Loop diuretics are well but variably absorbed from the gastrointestinal tract and are predominantly given by mouth. They may also be given intravenously in urgent situations (e.g. acute pulmonary oedema) or when intestinal absorption is impaired, for example, as a result of reduced intestinal perfusion in patients with severe chronic congestive heart failure, who can become resistant to the action of orally administered diuretics. Given orally, they act within 1 h; given intravenously, they produce a peak effect within 30 min. Bumetanide and torasemide have greater bioavailability than furosemide, but the effect of all these drugs depends on C_{max} exceeding a threshold value, which varies markedly both within as well as between individuals, rather than on mean exposure (AUC). Patients who have a high threshold are said to be 'diuretic resistant'. Such resistance depends on multiple disease-related factors such as renal function (glomerular filtration rate), acid–base status, drug competition for the organic anion transporter (OAT) and proteinuria. Consequently, in practice physicians adjust dose on the

basis of clinical response (judged by fluid intake/output charts and regular weighing of the patient among other cardiovascular and biochemical measures) rather than on mean PK parameters. Similarly, when a patient is switched from intravenous to oral loop diuretic, while it might be expected that on the basis of oral bioavailability the dose of bumetanide or torsemide should be maintained whereas the dose of furosemide should be doubled, in practice a fixed intravenous/oral conversion cannot be given. Loop diuretics are strongly bound to plasma protein, and so do not pass directly into the glomerular filtrate. They reach their site of action – the lumenal membrane of the cells of the thick ascending limb – by being secreted in the proximal convoluted tubule by the organic acid transport mechanism; the fraction thus secreted is excreted in the urine.

In nephrotic syndrome, [5] loop diuretics become bound to albumin in the tubular fluid, and consequently are not available to act on the $Na^+/K^+/2Cl^-$ carrier – another cause of diuretic resistance.

The fraction of the diuretic not excreted in the urine is metabolised, mainly in liver – **bumetanide** by cytochrome P450 pathways and **furosemide** by glucuronidation. The plasma half-life of both these drugs is approximately 90 min (longer in renal failure), and the duration of action 3–6 h. The clinical use of loop diuretics is given in the box.

Clinical uses of loop diuretics (e.g. furosemide)

- Loop diuretics are used (cautiously!), in conjunction with dietary salt restriction and often with other classes of diuretic, in the treatment of salt and water overload associated with:
  - *acute pulmonary oedema*
  - *chronic heart failure*
  - *cirrhosis of the liver complicated by ascites*
  - *nephrotic syndrome*
  - *renal failure.*
- Treatment of *hypertension* complicated by renal impairment (thiazides are preferred if renal function is preserved).
- Treatment of *hypercalcaemia* after replacement of plasma volume with intravenous NaCl solution.

Unwanted effects

Unwanted effects directly related to the renal action of loop diuretics are common. [6] Excessive Na^+ and water loss, especially in elderly patients, can cause hypovolaemia and hypotension. Potassium loss, resulting in low plasma K^+ (hypokalaemia), and metabolic alkalosis are common. Hypokalaemia increases the effects and toxicity of several drugs (e.g. **digoxin** and type III antidysrhythmic drugs, see **Ch. 20**), so this is potentially a clinically important source of drug interaction. If necessary, hypokalaemia can be averted or treated by concomitant use of K^+-sparing diuretics (see later), or supplementary potassium replacement. Hypomagnesaemia is less often recognised but can also be clinically important. Hyperuricaemia is common and can

precipitate acute gout (see **Ch. 25**). Excessive diuresis leads to reduced renal perfusion and consequent impairment of renal function (an early warning of this is a rise in plasma urea concentration).

Unwanted effects *unrelated to the renal actions* of the drugs are infrequent. Dose-related hearing loss (compounded by concomitant use of other ototoxic drugs such as aminoglycoside antibiotics) can result from impaired ion transport by the basolateral membrane of the stria vascularis in the inner ear. It occurs only at much higher doses than usually needed to produce diuresis. Adverse reactions unrelated to the main pharmacological effect (e.g. rashes, bone marrow depression) can occur.

Diuretics acting on the distal tubule

Diuretics acting on the distal tubule include thiazides (e.g. **bendroflumethiazide**, **hydrochlorothiazide**) – the class 'thiazides' being defined by possessing this chemical structure – and so-called 'thiazide-like' drugs (e.g. **chlortalidone**, **indapamide** and **metolazone**; see **Fig. 29.5C**) which act on the same molecular target but are structurally distinct. All of these agents are best thought of collectively as a single group irrespective of chemical structure, but there are pharmacokinetic differences between individual drugs, the thiazide-like drugs being cleared more slowly and hence acting throughout more of a 24-h dosing interval.

Thiazides are less powerful than loop diuretics, at least in terms of peak increase in rate of urine formation, and are preferred in treating uncomplicated hypertension (see **Ch. 21**). They are better tolerated than loop diuretics, and in clinical trials have been shown

to reduce risks of stroke and heart attack associated with hypertension. In the largest trial (**ALLHAT, 2002**), chlortalidone performed as well as an angiotensin-converting enzyme (ACE) inhibitor and a calcium antagonist (see **Ch. 21**). Thiazides bind the Cl^- site of the distal tubular Na^+/Cl^- co-transporter, inhibiting its action and causing natriuresis with loss of sodium and chloride ions in the urine. The resulting contraction in blood volume stimulates renin secretion, leading to angiotensin formation and aldosterone secretion (see **Ch. 21**, see **Fig. 21.9**). This homeostatic mechanism limits the effect of the diuretic on blood pressure, resulting in an in vivo dose–hypotensive response relationship with only a gentle gradient during chronic dosing.

The effects of thiazides on Na^+, K^+, H^+ and Mg^{2+} balance are qualitatively similar to those of loop diuretics, but smaller in magnitude. In contrast to loop diuretics, however, thiazides reduce Ca^{2+} excretion, possibly advantageous in older patients at risk of osteoporosis and favouring thiazides over loop diuretics in this setting (**Aung and Htay, 2011**).

Although thiazides are milder than loop diuretics when used alone, co-administration with loop diuretics has a synergistic effect, because the loop diuretic delivers a greater fraction of the filtered load of Na^+ to the site of action of the thiazide in the distal tubule.

Thiazide diuretics have a vasodilator action. When used in the treatment of hypertension (see **Ch. 21**), the initial fall in blood pressure results from the decreased blood volume caused by diuresis, but vasodilatation contributes to the later phase.

Thiazide diuretics have a paradoxical effect in diabetes insipidus, where they *reduce* the volume of urine by interfering with the

production of hypotonic fluid in the distal tubule, and hence reduce the ability of the kidney to excrete hypotonic urine (i.e. they reduce free water clearance).

Pharmacokinetic aspects

Thiazides and thiazide-related drugs are effective orally. All are excreted in the urine, mainly by tubular secretion, and they compete with uric acid for the OAT (see **Ch. 9**). Bendroflumethiazide has its maximum effect at about 4–6 h and duration is 8–12 h. Chlortalidone has a longer duration of action.

The clinical use of thiazide diuretics is given in the clinical box.

Clinical uses of thiazide/thiazide-like diuretics (e.g. bendroflumethiazide/chlortalidone)

- *Hypertension*.
- Mild heart *failure* (loop diuretics are usually preferred).
- Severe resistant *oedema* (**metolazone**, especially, is used, together with loop diuretics).
- To prevent recurrent stone formation in idiopathic *hypercalciuria*.
- *Nephrogenic diabetes insipidus*.

Unwanted effects

Apart from an increase in *urinary frequency*, the commonest unwanted effect of thiazides is *erectile dysfunction*. This emerged in an analysis of reasons given by patients for withdrawing from

blinded treatment in the Medical Research Council mild hypertension trial, where (to the surprise of the investigators) erectile dysfunction was substantially more common than in men allocated to a β-adrenoceptor antagonist or to placebo. Thiazide-associated erectile dysfunction is reversible; it is less common with the low doses used in current practice but remains a problem. *Potassium loss* can be important, as can loss of Mg^{2+}. Excretion of uric acid is decreased, and hypochloraemic alkalosis can occur.

Impaired glucose tolerance (see **Ch. 31**), due to inhibition of insulin secretion, is thought to result from activation of K_{ATP} channels in pancreatic islet beta-cells. [7] **Diazoxide**, a non-diuretic thiazide, also activates K_{ATP} channels, causing vasodilatation and impaired insulin secretion. **Indapamide** is said to lower blood pressure with less metabolic disturbance than related drugs, possibly because it is marketed at a lower equivalent dose.

Hyperuricaemia is common as a consequence of competition with urate for the OAT and can precipitate acute gout as with loop diuretics (see **Ch. 25**).

Hyponatraemia is potentially serious, especially in the elderly. Hypokalaemia can be a cause of adverse drug interaction (see previously under Loop diuretics) and can precipitate encephalopathy in patients with severe liver disease.

Adverse reactions unrelated to the main pharmacology (e.g. rashes, blood dyscrasias) are not common but can be serious.

Aldosterone antagonists

Spironolactone, **eplerenone** and **finerenone** have limited diuretic action when used singly, because distal Na^+/K^+ exchange –

the site on which they act – accounts for reabsorption of only 2% of filtered Na^+. They do, however, have marked antihypertensive effects (see **Ch. 21**), prolong survival in selected patients with heart failure (see **Ch. 21**) and, in the case of finerenone (**Bakris et al., 2020**; **Pitt et al., 2021**), preserve renal function and reduce cardiovascular death in type 2 diabetic patients with chronic kidney disease (CKD). They can prevent hypokalaemia when combined with loop diuretics or with thiazides. They compete with aldosterone for the intracellular mineralocorticoid receptor (MR, see **Ch. 33**), thereby inhibiting distal Na^+ retention and K^+ secretion (see **Fig. 29.5D**).

Pharmacokinetic aspects

Spironolactone is well absorbed from the gut. Its plasma half-life is only 10 min, but its active metabolite, **canrenone**, has a plasma half-life of 16 h. The action of spironolactone is largely attributable to canrenone. This, in addition to the slow turnover of membrane transporters, results in a slow onset of action, occurring over several days. Eplerenone has a shorter elimination half-life than canrenone and has no active metabolites. It is administered by mouth once daily. Finerenone is administered by mouth once daily; it is inactivated by metabolism, primarily by CYP3A4.

Unwanted effects

Aldosterone antagonists predispose to hyperkalaemia, which is potentially fatal. Potassium supplements should not be co-prescribed other than in exceptional circumstances and then with close monitoring of plasma creatinine and electrolytes. Such monitoring is also needed if these drugs are used for patients with

impaired renal function, especially if other drugs that can increase plasma potassium, such as *ACE inhibitors*, *angiotensin receptor antagonists* (sartans) (see **Ch. 21**) or *β-adrenoceptor antagonists* (see **Ch. 15**), are also prescribed – as they often are for patients with heart failure. Gastrointestinal upset is quite common. The actions of spironolactone/canrenone on progesterone and androgen receptors in tissues other than the kidney can cause gynaecomastia, menstrual disorders and testicular atrophy. Eplerenone has lower affinity for these receptors, and such oestrogen-like adverse effects are less common. Finerenone is a nonsteroidal MR antagonist: it has high potency and selectivity for the MR but no relevant affinity for androgen, progesterone, oestrogen and glucocorticoid receptors.

The clinical use of potassium-sparing diuretics is given in the clinical box.

Clinical uses of potassium-sparing diuretics

- With K^+-losing (i.e. loop or thiazide) diuretics to prevent K^+ loss, where hypokalaemia is especially hazardous (e.g. patients requiring **digoxin** or **amiodarone**; see **Ch. 20**).
- **Spironolactone** or **eplerenone** is used in:
  - *heart failure*, to improve survival (see **Ch. 20**)
  - *primary hyperaldosteronism* (Conn's syndrome)
  - *resistant essential hypertension* (especially low-renin hypertension)
  - *secondary hyperaldosteronism* caused by hepatic cirrhosis complicated by ascites.

- **Finerenone**, a non-steroidal MR antagonist, was recently approved by the FDA for use in type 2 diabetic patients with CKD to:
  - reduce the risk of *progressive renal impairment, cardiovascular death*, nonfatal *myocardial infarction*, and *hospitalisation* for heart failure.

Triamterene and amiloride

Like aldosterone antagonists, **triamterene** and **amiloride** have only limited diuretic efficacy, because they also act in the distal nephron, where only a small fraction of Na^+ reabsorption occurs. They act on the collecting tubules and collecting ducts, inhibiting Na^+ reabsorption by blocking lumenal sodium channels, thereby indirectly decreasing K^+ excretion (see **Fig. 29.5D**).

They can be given with loop diuretics or thiazides in order to maintain potassium balance.

Pharmacokinetic aspects

Triamterene is well absorbed in the gastrointestinal tract. Its onset of action is within 2 h, and its duration of action is 12–16 h. It is partly metabolised in the liver and partly excreted unchanged in the urine. Amiloride is less well absorbed and has a slower onset, with a peak action at 6 h and duration of about 24 h. Most of the drug is excreted unchanged in the urine.

Unwanted effects

The main unwanted effect, hyperkalaemia, is related to the pharmacological action of these drugs and can be dangerous,

especially in patients with renal impairment or receiving other drugs that can increase plasma K^+ (see above). Gastrointestinal disturbances have been reported but are infrequent. Idiosyncratic reactions, for example, rashes, are uncommon.

Carbonic anhydrase inhibitors

Carbonic anhydrase inhibitors (see **Fig. 29.5A**) – for example, **acetazolamide** – increase excretion of bicarbonate with accompanying Na^+, K^+ and water, resulting in an increased flow of an alkaline urine and metabolic acidosis. These agents, although not now used as diuretics, are still used in the treatment of glaucoma to reduce the formation of aqueous humour (see **Ch. 27**), in some types of infantile epilepsy (see **Ch. 46**) and to accelerate acclimatisation to high altitude.

Urinary loss of bicarbonate depletes extracellular bicarbonate, and the diuretic effect of carbonic anhydrase inhibitors is consequently self-limiting. Acetazolamide is a sulfonamide and off-target unwanted effects such as rashes, blood dyscrasias and interstitial nephritis can occur as with other sulfonamides (see **Ch. 52**).

Diuretics that Act Indirectly by Modifying the Content of the Filtrate

Osmotic diuretics

Osmotic diuretics are pharmacologically inert substances (e.g. **mannitol**) that are filtered in the glomerulus but not reabsorbed (see **Fig. 29.4**). [8] Their main effect is exerted in those parts of the nephron that are freely permeable to water: the proximal tubule,

descending limb of the loop and (in the presence of ADH; see earlier) the collecting tubules. Passive water reabsorption is reduced by the presence of non-reabsorbable solute within the tubule; consequently, a larger volume of fluid remains within the proximal tubule. This has the secondary effect of reducing Na^+ reabsorption.

The main effect of osmotic diuretics is to increase the amount of water excreted, with a smaller increase in Na^+ excretion. They are sometimes used in acute renal failure, which can occur as a result of haemorrhage, injury or systemic infections. In acute renal failure, glomerular filtration rate is reduced, and absorption of NaCl and water in the proximal tubule becomes almost complete, so that more distal parts of the nephron virtually 'dry up', and urine flow ceases. Protein is deposited in the tubules and may impede the flow of fluid. Osmotic diuretics (e.g. **mannitol** given intravenously in multiple-gram doses) can limit these effects, at least if given in the earliest stages, albeit while increasing intravascular volume and cardiac pre-load.

Osmotic diuretics are also used for the emergency treatment of acutely raised intracranial or intraocular pressure. Such treatment has nothing to do with the kidney but relies on the increase in plasma osmolarity by solutes that do not enter the brain or eye, which results in efflux of water from these compartments.

Unwanted effects include transient expansion of the extracellular fluid volume (with a risk of precipitating left ventricular failure) and hyponatraemia. Headache, nausea and vomiting can occur.

- Normally <1% of filtered Na^+ is excreted.
- Diuretics increase the excretion of salt (NaCl or $NaHCO_3$) and water.
- Loop diuretics, thiazides and K^+-sparing diuretics are the main therapeutic drugs.
- Loop diuretics (e.g. **furosemide**) cause copious urine production. They inhibit the $Na^+/K^+/2Cl^-$ co-transporter in the thick ascending loop of Henle. They are used to treat heart failure and other diseases complicated by salt and water retention. Hypovolaemia and hypokalaemia are important unwanted effects.
- Thiazides and thiazide-like drugs (e.g. **bendroflumethiazide/chlortalidone**) have a less dramatic diuretic effect than loop diuretics. They inhibit the Na^+/Cl^- co-transporter in the distal convoluted tubule. They are used to treat hypertension, working partly through an indirect vasodilator action. Erectile dysfunction is an important adverse effect. Hypokalaemia and other metabolic effects (e.g. hyperuricaemia, hyperglycaemia) can occur, especially with high doses.
- Potassium-sparing diuretics:
  - act in the distal nephron and collecting tubules; they are weak diuretics but effective in some forms of hypertension and heart failure, and they can prevent hypokalaemia caused by loop diuretics or thiazides.
  - canrenone, the active metabolite of **spironolactone**, **eplerenone** and the nonsteroidal MR antagonist **finerenone** compete with aldosterone for the MR.

– **amiloride** and **triamterene** act by blocking the sodium channels controlled by aldosterone's protein mediator.

Drugs that Alter the pH of the Urine

It is possible, using pharmacological agents, to produce urinary pH values ranging from approximately 5 to 8.5.

Carbonic anhydrase inhibitors increase urinary pH by blocking bicarbonate reabsorption (see earlier). **Citrate** (given by mouth as a mixture of sodium and potassium salts) is metabolised via the Krebs cycle with the generation of bicarbonate, which is excreted, alkalinising the urine. This may have some antibacterial effects, as well as improving dysuria (a common symptom of bladder infection, consisting of a burning sensation while passing urine). Additionally, some citrate is excreted in the urine as such and inhibits urinary stone formation. Alkalinisation is important in preventing certain weak acid drugs with limited aqueous solubility, such as *sulfonamides* (see **Ch. 52**), from crystallising in the urine; it also decreases the formation of uric acid and cystine stones by favouring the charged anionic form that is more water-soluble (see **Ch. 9**).

Alkalinising the urine increases the excretion of drugs that are weak acids (e.g. salicylates and some barbiturates). Sodium bicarbonate is sometimes used to treat salicylate overdose (see **Ch. 10**).

Urinary pH can be decreased with **ammonium chloride**, but this is now rarely, if ever, used clinically.

Drugs that Alter the Excretion of Organic Molecules

Uric acid metabolism and excretion are relevant in the treatment and prevention of gout (see **Ch. 25**), and a few points about its excretion are made here. Normal plasma urate concentration is approximately 0.24 mmol/L, higher concentrations predisposing to gout (see **Ch. 25**)

Uric acid is derived from the catabolism of purines and is present in plasma mainly as ionised urate. In humans, it passes freely into the glomerular filtrate, and most is then reabsorbed in the proximal tubule while a small amount is secreted into the tubule by the anion-secreting mechanism. The net result is excretion of approximately 8%–12% of filtered urate. The secretory mechanism is generally inhibited by low doses of drugs that affect uric acid transport (see later), whereas higher doses are needed to block reabsorption. Such drugs therefore tend to cause retention of uric acid at low doses, while promoting its excretion at higher doses. Drugs that increase the elimination of urate (*uricosuric agents*, e.g. **probenecid** and **sulfinpyrazone**) may be useful in such patients, although these have largely been supplanted by **allopurinol**, which inhibits urate synthesis (see **Ch. 25**).

Probenecid inhibits the anion transporter responsible for the reabsorption of urate in the proximal tubule, increasing its excretion. It has the opposite effect on penicillin, inhibiting its secretion into the tubules and raising its plasma concentration (an effect still sometimes exploited during antibiotic therapy, see Chs **10** and **52**). Given orally, probenecid is well absorbed in the gastrointestinal tract, maximal concentrations in the plasma

occurring in about 3 h. Approximately 90% is bound to plasma albumin. Free drug passes into the glomerular filtrate but more is actively secreted into the proximal tubule, whence it may diffuse back because of its high lipid solubility (see also **Ch. 10**). Sulfinpyrazone acts similarly, but additionally inhibits cyclo-oxygenase.

The main effect of uricosuric drugs is to block urate reabsorption and lower plasma urate concentration. Both probenecid and sulfinpyrazone inhibit the secretion as well as the reabsorption of urate and, if given in subtherapeutic doses, can actually increase plasma urate concentrations.

Drugs Used in Renal Failure

Many drugs used in chronic renal failure (e.g. antihypertensives, vitamin D preparations and **epoetin**) are covered in other chapters. Electrolyte disorders are particularly important in renal failure, notably *hyperphosphataemia* and *hyperkalaemia*, and may require drug treatment which is described briefly here.

Hyperphosphataemia

Phosphate metabolism is closely linked with that of calcium and is discussed in **Chapter 36**.

The antacid **aluminium hydroxide** (see **Ch. 30**) binds phosphate in the gastrointestinal tract, reducing its absorption, but may increase plasma aluminium in patients with end-stage kidney failure receiving haemodialysis treatment. [9] Calcium-based phosphate-binding agents (e.g. calcium carbonate) are widely used to treat hyperphosphatemia. They are contraindicated in

hypercalcaemia or hypercalciuria but until recently have been believed to be otherwise safe. However, calcium salts may predispose to tissue calcification (including of artery walls), and calcium-containing phosphate binders may actually contribute to the very high death rates from cardiovascular disease in dialysis patients.

An anion exchange resin, **sevelamer**, lowers plasma phosphate, and is less likely than calcium carbonate to cause arterial calcification (**Tonelli et al., 2010**). Sevelamer is not absorbed from the gut and has an additional effect in lowering low-density lipoprotein cholesterol. It is given in gram doses by mouth three times a day with meals. Its adverse effects are gastrointestinal disturbance, and it is contraindicated in bowel obstruction.

Hyperkalaemia

Severe hyperkalaemia is life-threatening. Its prevalence is increased in patients with kidney failure, and by drugs that inhibit the renin–angiotensin–aldosterone axis which are widely used to slow the progression of renal impairment. Cardiac K^+-toxicity is counteracted by administering calcium chloride intravenously (see **Table 20.2**), and by measures that shift K^+ into the intracellular compartment, for example glucose plus insulin (see **Ch. 31**). **Salbutamol**, administered intravenously or by inhalation, also causes cellular K^+ uptake and is used for this indication including in children (**Murdoch et al., 1991**); it acts synergistically with insulin. Intravenous sodium bicarbonate moves potassium ions into cells in exchange for intracellular protons that emerge to buffer the extracellular fluid, but can paradoxically lower intracellular and

transcellular pH. Removal of excessive potassium from the body can be achieved by cation exchange resins such as **sodium** or **calcium polystyrene sulfonate** administered by mouth (in combination with **sorbitol** to prevent constipation) or as an enema. There are two exchange resins (**sodium zirconium cyclosilicate** and **patiromer calcium**) licensed for alleviating hyperkalaemia in patients with CKD who require continued treatment with renin–angiotensin–aldosterone system inhibitors for comorbid hypertension or heart failure. Unlike the other resins which act mainly in the colon, sodium zirconium cyclosilicate can capture potassium ions along the entire gastrointestinal tract, with onset of action within an hour of ingestion (thus making it suitable for emergency management of hyperkalaemia). The long-term tolerability of cation exchange resins is questionable because these agents are associated with gastrointestinal upset and electrolyte abnormalities.

Drugs Used in Urinary Tract Disorders

Bed wetting (enuresis) is normal in young children and persists in around 5% of 10-year-olds. Nocturnal enuresis in children aged 10 years or more may warrant treatment with **desmopressin** (an analogue of ADH, given by mouth or by nasal spray for the treatment of diabetes insipidus caused by ADH deficiency due to disease of the posterior pituitary gland – see earlier discussion and **Ch. 33**), combined with restricting fluid intake in the evening.

Disordered micturition is also common in adults. Symptoms from benign prostatic hyperplasia may be improved by α_1-adrenoceptor antagonists, for example **doxazosin** or **tamsulosin** (see **Ch. 15**),

or by an inhibitor of androgen synthesis such as **finasteride** (see **Ch. 35**).

Muscarinic receptor antagonists (see **Ch. 14**) such as **oxybutynin** are used for neurogenic detrusor muscle instability ('overactive bladder'), but the dose is limited by their adverse effects. A selective β_3 agonist (**mirabegron**) is also licensed for this indication (see **Ch. 15**) but can cause tachycardia and atrial fibrillation.

QUESTIONS

QUESTION 29.1

One of the main functions of the kidneys is to regulate Na^+ reabsorption with concomitant water reabsorption to maintain homeostasis.

Which of the following statements about the mechanism and site of Na^+ reabsorption is correct?

OPTIONS:

A. Na^+ reabsorption from the tubules is largely driven by the expression of Na^+/K^+ ATPases on apical membranes.

B. The majority of filtered Na^+ is reabsorbed in the distal tubule.

C. In the ascending loop of Henle, Na^+ is transported across the apical membrane by a Na^+/Cl^- antiport.

D. Na^+/H^+ exchange facilitates the reabsorption of bicarbonate.

E. Na^+ absorption in the distal tubule is accompanied by water reabsorption.

QUESTION 29.2

The kidneys have important related endocrine functions including synthesis of renin which is great importance in regulating blood pressure and cardiovascular homeostasis.

Which of the following statements about the renin–angiotensin function is incorrect?

OPTIONS:

A. Renin is released following a decrease in tubular flow.

B. Renin is released from the macula densa cells in the distal tubule.

C. Renin converts angiotensinogen to angiotensin I.

D. Renin triggers aldosterone release from the adrenal glands.

E. Angiotensin II acts on AT_1 receptors to cause vasoconstriction.

QUESTION 29.3

Blood pressure and electrolyte balance is maintained through the regulation of electrolyte (Na^+) and water reabsorption. Factors affecting water reabsorption will alter the volume and concentration of the urine.

Which of the following would lead to the excretion of more diluted urine?

OPTIONS:

A. Ethanol

B. An increase in antidiuretic hormone (ADH) secretion

C. Nicotine

D. Thiazides

E. Increased aquaporin expression

QUESTION 29.4

Diuretics increase the excretion of Na^+ and H_2O, reducing blood volume and pressure, and hence are of value in the treatment of a range of cardiovascular and hypertensive disorders.

Which of the statements about the therapeutic use of diuretics is correct?

OPTIONS:

A. Furosemide is beneficial in acute pulmonary oedema as it inhibits the Na^+/Cl^- co-transporter in the distal tubule to increase Na^+ and H_2O excretion.

B. Bendroflumethiazide is the drug of choice in chronic heart failure, as it is milder in action than a loop diuretic.

C. Hydrochlorothiazide is the drug of choice for treating hypertension in the elderly at risk of osteoporosis, due to its Ca^{2+}-sparing effects.

D. Non-steroidal anti-inflammatory drugs (NSAIDs) reduce the effectiveness of loop diuretics in the treatment of heart failure.

E. Aldosterone antagonists should be co-prescribed with potassium supplements in patients with heart failure.

ANSWERS

ANSWER 29.1

RATIONALE:

A. Na^+ reabsorption from the lumen is largely mediated by Na^+/H^+ exchange, drawn by the concentration gradient created by Na^+/K^+ ATPases on the basolateral membranes.

B. The majority of filtered Na^+ is reabsorbed in the proximal tubule.

C. In the ascending loop, Na^+ is reabsorbed via a $Na^+/K^+/Cl^-$ co-transporter.

D.

E. The distal tubule is largely impermeable to water.

CORRECT ANSWER WITH EXPLANATION:

D. Na^+/H^+ exchange facilitates the reabsorption of bicarbonate. The exchanged H^+ combines with HCO_3^- in the lumen to form carbonic acid, which dissociates to water and carbon dioxide that

can be absorbed. Recombination to carbonic acid in the tubular cells and ionisation enables the reabsorption of bicarbonate ions.

ANSWER 29.2

RATIONALE:

A. Renin release is triggered by a decrease in blood pressure and tubular flow.

B.

C. Renin is an enzyme that cleaves angiotensin I from angiotensinogen and perhaps should be more appropriately named angiotensinogenase (Ang I to II is mediated by angiotensin-converting enzymes (ACEs)).

D. Angiotensin II produced as a result of the increase in renin acts on the adrenal cortex to release aldosterone hence controlling vascular resistance, blood pressure, blood volume and Na^+ and K^+ balance.

E. Angiotensin II acts on AT_1 receptors in vascular smooth muscle to cause vasoconstriction.

CORRECT ANSWER WITH EXPLANATION:

B. Renin is released from the macula densa cells in the distal tubule.

Renin is released from specialised granular renin-containing cells in the afferent arteriole in response to purinergic signals from the macula densa cells in the distal convoluted tubule.

ANSWER 29.3

RATIONALE:

A.

B. ADH increases the expression of aquaporin channels and hence water reabsorption.

C. Nicotine enhances ADH secretion, so enhancing water reabsorption.

D. Thiazides decrease the reabsorption of Na^+ and Cl^- in the distal tubule maintaining a high electrolyte concentration in the excreted urine.

E. The expression of aquaporin channels in the collecting tubules and ducts facilitates water reabsorption, so concentrating the excreted urine.

CORRECT ANSWER WITH EXPLANATION:

A. Ethanol

Ethanol inhibits the release of ADH, so decreasing water reabsorption resulting in increased quantities of dilute urine.

ANSWER 29.4

RATIONALE:

A. Furosemide is effective in acute pulmonary oedema but acts on the thick ascending limb to inhibit the $Na^+/K^+/2Cl^-$ carrier.

B. Thiazides are milder in action than loop diuretics and are therefore used in mild hypertension when a more limited diuresis is required.

C. Compared with loop diuretics, thiazides cause a reduced level of Ca^{2+} excretion.

D.

E. Aldosterone antagonists pose a high risk of hyperkalaemia and potassium-containing supplements should therefore not be given.

CORRECT ANSWER WITH EXPLANATION:

D. NSAIDs reduce the effectiveness of loop diuretics in the treatment of heart failure.

NSAIDs make loop diuretics less effective by competing with them for the organic anion transport (OAT) mechanism. Loop diuretics act from within the lumen by inhibiting exchange mechanisms so blocking their secretion into the lumen reduces their effectiveness by reducing their concentrations at their sites of action.

---

[1] The reaction is reversible, and the enzyme (as any catalyst) does not alter the equilibrium, just speeds up the rate with which it is attained. The concentrations inside the cell are such that carbon dioxide combines with water to produce carbonic acid: the same enzyme (carbonic anhydrase) catalyses this as well (see Fig. 29.5A).

[2] These figures are for humans; some other species, notably the desert rat, can do much better, with urine osmolalities up to 5000 mOsmol/kg.

[3] A mechanism distinct from regulation of gene transcription, which is the classical transduction mechanism for steroid hormones (see Ch. 3).

[4] Additionally, NSAIDs make many of the diuretics used to treat heart failure less effective by competing with them for the organic anion transport (OAT) mechanism mentioned earlier; loop diuretics and thiazides act from within the lumen by inhibiting exchange mechanisms – see later in this chapter – so blocking their secretion into the lumen reduces their effectiveness by reducing their concentrations at their sites of action.

[5] Several diseases that damage renal glomeruli impair their ability to retain plasma albumin, causing massive loss of albumin in the urine and a reduced concentration of albumin in the plasma, which can in turn cause peripheral oedema. This is referred to as nephrotic syndrome.

[6] Such unwanted effects are re-enacted in extreme form in Bartter syndrome type 1, a rare loss-of-function genetic disorder of the $Na^+/K^+/2Cl^-$transporter, the features of which include polyhydramnios – caused by fetal polyuria – and, postnatally, renal salt loss, low blood pressure, hypokalaemic metabolic alkalosis and hypercalciuria.

[7] The chemically related sulfonylurea group of drugs used to treat type 2 diabetes mellitus (Ch. 31) act in the opposite way, by closing K_{ATP} channels and enhancing insulin secretion.

[8] In hyperglycaemia, glucose acts as an osmotic diuretic once plasma glucose exceeds the renal reabsorptive capacity (usually approximately 12 mmol/L), accounting for the cardinal symptom of polyuria in diabetes mellitus; see Chapter 31.

[9] Before Kerr identified the cause, the use of alum to purify municipal water supplies in Newcastle led to a horrible and untreatable neurodegenerative condition known as ‘dialysis dementia’, and also to a particularly painful and refractory form of bone disease.

30: The gastrointestinal tract

OVERVIEW

In addition to its main function of digestion and absorption of food, the gastrointestinal (GI) tract is one of the major endocrine systems in the body. It also has its own integrative neuronal network, the enteric nervous system (see **Ch. 13**), which contains almost the same number of neurons as the spinal cord. It is the site of many common pathologies, ranging from simple dyspepsia to complex autoimmune conditions such as Crohn's disease, and medicines for treating GI disorders comprise some 8% of all prescriptions. In this chapter, we briefly review the physiological control of GI function and then discuss the pharmacological characteristics of drugs affecting gastric secretion and motility, and those used to treat intestinal inflammatory disease.

The Innervation and Hormones of the Gastrointestinal Tract

The blood vessels and the glands (exocrine, endocrine and paracrine) of the GI tract are under both neuronal and hormonal control.

Neuronal Control

There are two principal intramural plexuses in the tract: the *myenteric plexus* (*Auerbach's plexus*) lies between the outer, longitudinal and the middle, circular muscle layers, and the *submucous plexus* (*Meissner's plexus*) lies on the lumenal side of the circular muscle layer. These plexuses are interconnected and their ganglion cells receive preganglionic parasympathetic fibres from the vagus. These are mostly cholinergic and excitatory, although a few are inhibitory. Incoming sympathetic fibres are largely postganglionic. In addition to innervating blood vessels, smooth muscle and some glandular cells directly, some sympathetic fibres terminate in these plexuses, where they inhibit acetylcholine secretion (see **Ch. 13**).

The neurons within the plexuses constitute the *enteric nervous system* and secrete not only acetylcholine and noradrenaline (norepinephrine), but also 5-hydroxytryptamine (5-HT), purines, nitric oxide and a variety of pharmacologically active peptides (see Chs **13**–**19**). The enteric plexus also contains sensory neurons, which respond to mechanical and chemical stimuli.

Hormonal Control

The hormones of the GI tract include both endocrine and paracrine secretions. The endocrine secretions (i.e. substances released into the bloodstream) are mainly peptides synthesised by endocrine cells in the mucosa. Important examples include *gastrin* and *cholecystokinin* (CCK). The paracrine secretions include many regulatory peptides released from special cells found throughout the wall of the tract. These hormones act on nearby cells, and in the

stomach the most important of these is *histamine*. Some of these paracrine factors also function as neurotransmitters.

Orally administered drugs are, of course, absorbed during their passage through the GI tract (see **Ch. 9**). Other functions of the GI tract that are important from the viewpoint of pharmacological intervention are:

- gastric secretion
- vomiting (emesis) and nausea
- gut motility and defecation
- the formation and excretion of bile

Gastric Secretion

The stomach secretes about 2.5 L of gastric juice daily. The principal exocrine components are proenzymes such as *prorennin* and *pepsinogen* elaborated by the *chief* or *peptic* cells, and *hydrochloric acid* (HCl) and *intrinsic factor* (see **Ch. 24**) secreted by the *parietal* or *oxyntic* cells. The production of acid is important for promoting proteolytic digestion of foodstuffs, iron absorption and killing pathogens. Mucus-secreting cells also abound in the gastric mucosa. Bicarbonate ions are secreted and trapped in the mucus, creating a gel-like protective barrier that maintains the mucosal surface at a pH of 6–7 in the face of a much more acidic environment (pH 1–2) in the lumen. Alcohol and bile can disrupt this protective layer. Locally produced 'cytoprotective' prostaglandins (PGs) stimulate the secretion of both mucus and bicarbonate.

Disturbances in these secretory and protective mechanisms are thought to be involved in the pathogenesis of *peptic ulcer*, and

indeed in other types of gastric damage such as *gastro-oesophageal reflux disease* (GORD [1]) and injury caused by non-steroidal anti-inflammatory drugs (NSAIDs).

The Regulation of Acid Secretion by Parietal Cells

Disturbances of acid secretion are important in the pathogenesis of peptic ulcer and constitute a particular target for drug action. The secretion of the parietal cells is an isotonic solution of HCl (150 mmol/L) with a pH less than 1, the concentration of hydrogen ions being more than a million times higher than that in the plasma. To produce this, Cl^- is actively transported into *canaliculi* in the cells that communicate with the lumen of the gastric glands and thus with the stomach itself. This is accompanied by K^+ secretion, which is then exchanged for H^+ from within the cell by a K^+-H^+-ATPase (the 'proton pump', **Fig. 30.1**). Within the cell, carbonic anhydrase catalyses the combination of carbon dioxide and water to give carbonic acid, which dissociates into H^+ and bicarbonate ions. The latter exchanges across the basal membrane of the parietal cell for Cl^-. The principal mediators that directly – or indirectly – control parietal cell acid output are:

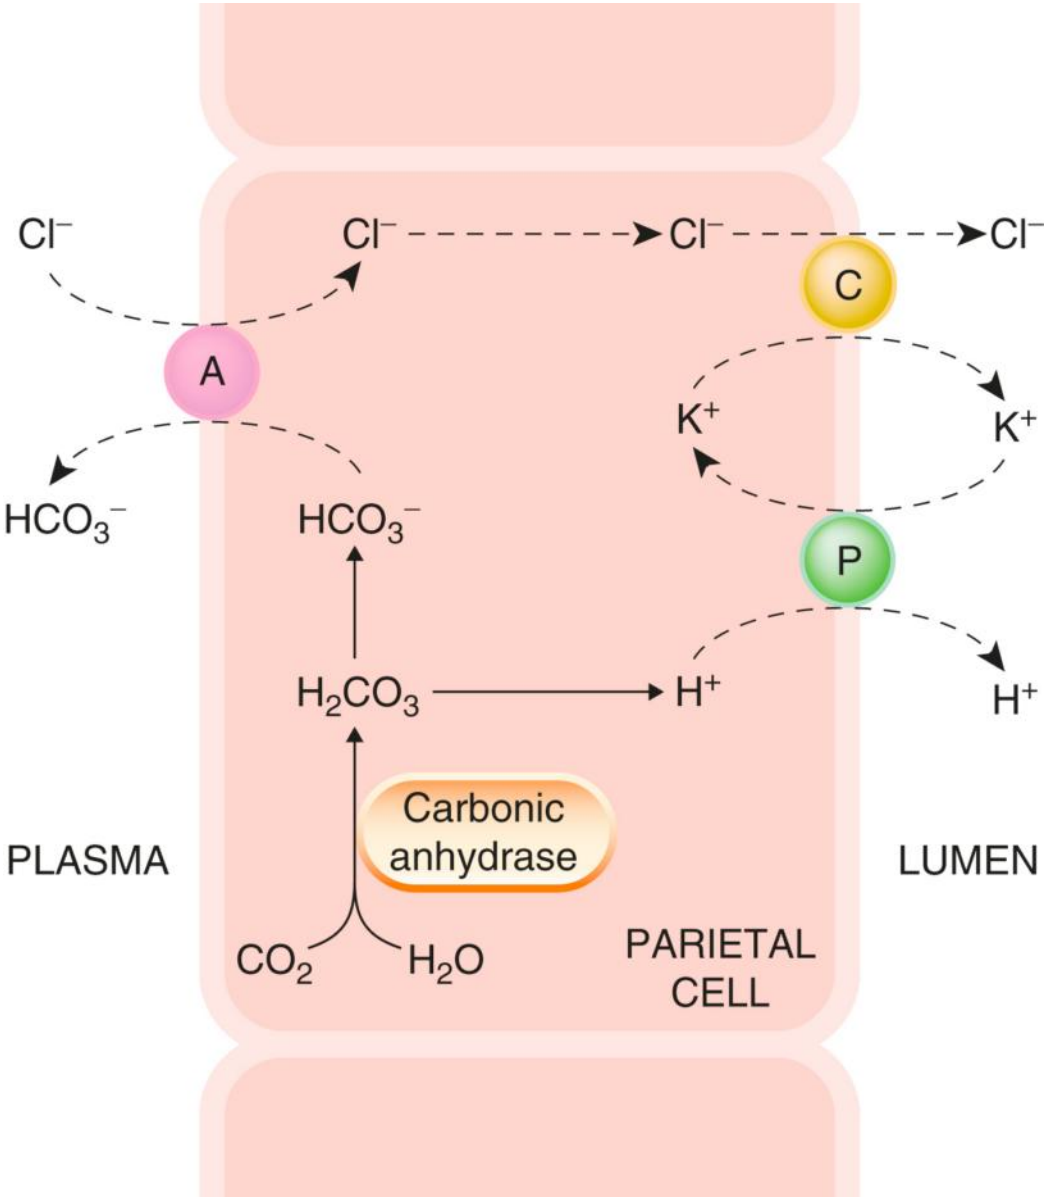

FIG. 30.1 A schematic illustration of the secretion of hydrochloric acid by the gastric parietal cell.Secretion involves a proton pump *(P)*, which is an H^+-K^+-ATPase; a symport carrier *(C)* for K^+ and Cl^-; and an antiport *(A)*, which exchanges Cl^- and HCO_3^-. An additional Na^+/H^+ antiport situated at the interface with the plasma may also have a role (not shown).

- histamine (a stimulatory local hormone)
- gastrin (a stimulatory peptide hormone)
- acetylcholine (a stimulatory neurotransmitter)
- PGE_2 and PGI_2 (local hormones that inhibit acid secretion)
- somatostatin (an inhibitory peptide hormone)

Histamine

Histamine is discussed in **Chapter 17**, and only those aspects of its pharmacology relevant to gastric secretion will be dealt with here. Neuroendocrine cells abound in the stomach and the dominant type is the *ECL cell* (enterochromaffin-like). These are histamine-containing cells similar to mast cells, which lie close to the parietal cells. They sustain a steady basal release of histamine, which is further increased by gastrin and acetylcholine. Histamine acts in a paracrine fashion on parietal cell H_2 receptors, increasing intracellular cAMP. These cells are responsive to histamine concentrations that are below the threshold required for vascular H_2 receptor activation.

Gastrin

Gastrin is a polypeptide of 34 residues but also exists in shorter forms. It is synthesised by *G cells* in the gastric antrum and secreted into the portal blood, acting as a circulating hormone. Its main action is stimulation of acid secretion by ECL cells through its action at gastrin/CCK_2 receptors, [2] which elevate intracellular Ca^{2+}. Gastrin receptors also occur on the parietal cells but their significance in the control of physiological secretion is controversial. CCK_2 receptors are blocked by **proglumide** and

netazepide, both of which are undergoing clinical trials in gastrointestinal disease (**Fig. 30.2**).

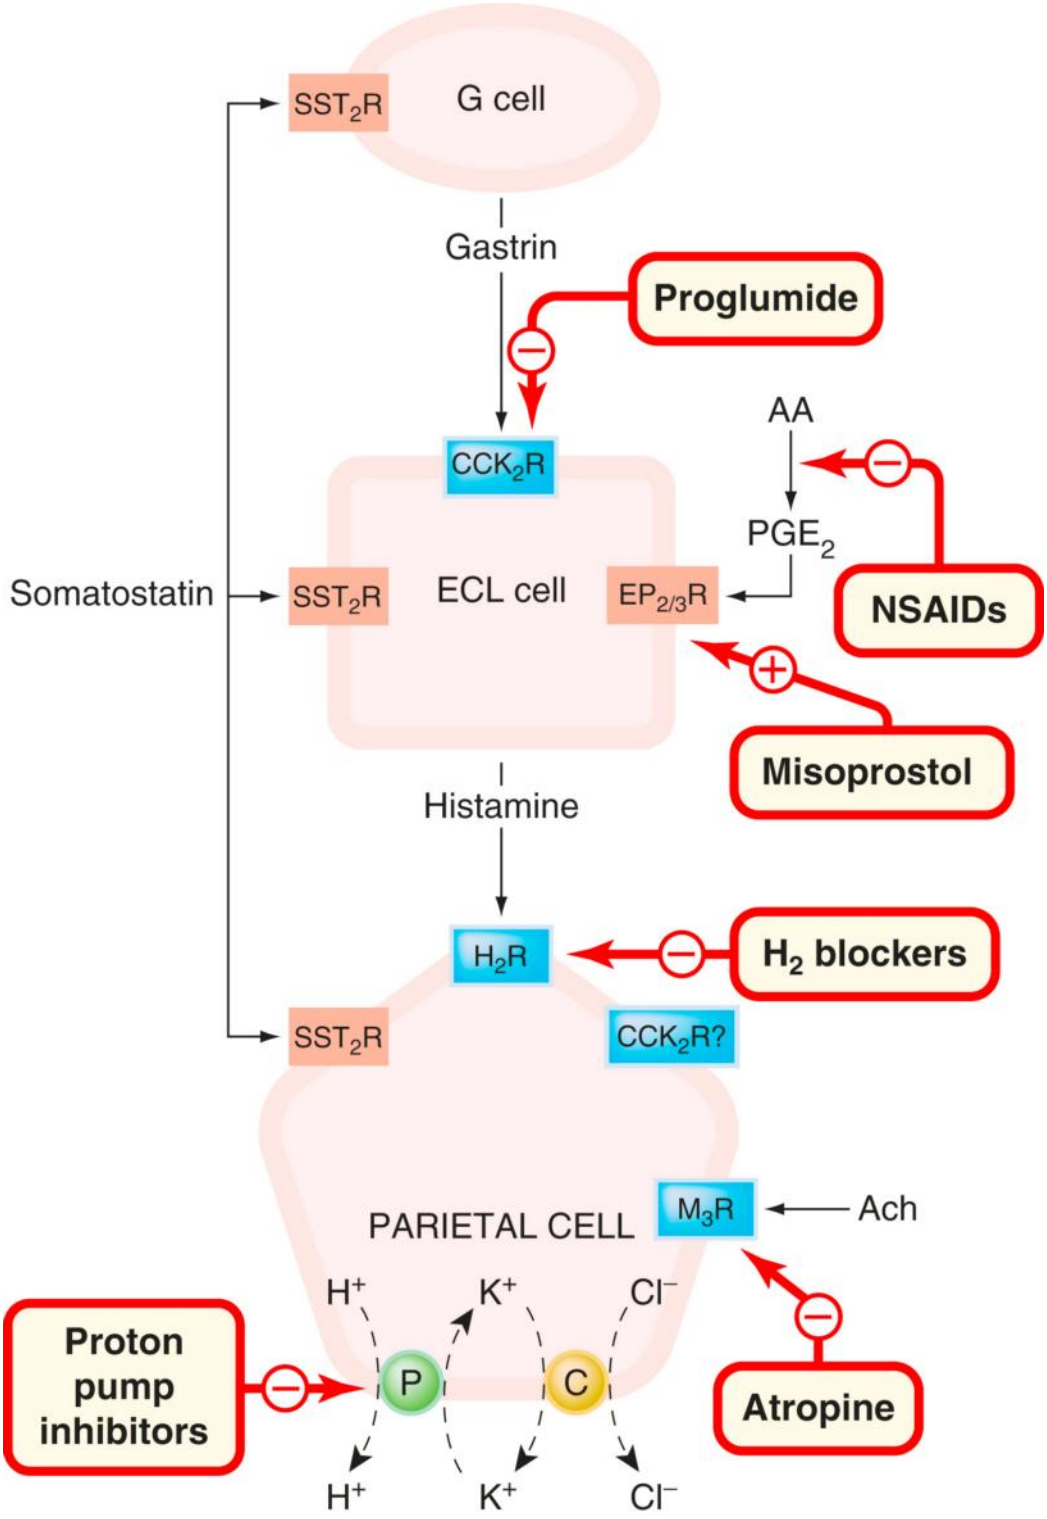

FIG. 30.2 Schematic diagram showing the regulation of the acid-secreting gastric parietal cell, illustrating the site of action of drugs

influencing acid secretion.The initial step in controlling physiological secretion is the release of gastrin from G cells. This acts through its gastrin/cholecystokinin (CCK_2) receptor on mast cell-like histamine-secreting enterochromaffin (ECL) cells to release histamine and may also have a secondary direct effect on parietal cells themselves, although this is not entirely clear. Histamine acts on parietal cell H_2 receptors to elevate cAMP that activates the secretion of acid by the proton pump. Direct vagal stimulation also provokes acid secretion and released acetylcholine directly stimulates M_3 receptors on parietal cells. The influence of somatostatin on G cells, ECL cells and parietal cells is inhibitory. Local (or therapeutically administered) prostaglandins exert inhibitory effects predominately on ECL cell function. Receptors depicted in *red* have inhibitory effects on cell secretion, whilst those in *blue* stimulate cell secretion. *AA,* Arachidonic acid; *ACh,* acetylcholine; *C,* symport carrier for K^+ and Cl^-; *CCK_2,* gastrin/cholecystokinin receptor; *NSAIDs,* non-steroidal anti-inflammatory drugs; *P,* proton pump (H^+-K^+-ATPase); *PGE_2,* prostaglandin E_2.

Gastrin also stimulates histamine synthesis by ECL cells and indirectly increases pepsinogen secretion, stimulates blood flow and

increases gastric motility. Release of gastrin is controlled by both neuronal transmitters and blood-borne mediators, as well as by the chemistry of the stomach contents. Amino acids and small peptides directly stimulate the gastrin-secreting cells, as do milk and solutions of calcium salts, explaining why it is inappropriate to use calcium-containing salts as antacids.

Acetylcholine

Acetylcholine, released (together with a battery of other neurotransmitters and peptides) from postganglionic cholinergic neurons, stimulates specific muscarinic M_3 receptors on the surface of the parietal cells (see **Ch. 14**), thereby elevating intracellular Ca^{2+} and stimulating acid secretion. It also has complex effects on other cell types; by inhibiting somatostatin release from *D cells*, it potentiates its action on parietal cell acid secretion.

Prostaglandins

Most cells of the GI tract produce PGs (see **Ch. 17**), the most important being PGE_2 and PGI_2. PGs exert 'cytoprotective' effects on many aspects of gastric function including increasing bicarbonate secretion ($EP_{1/2}$ receptors), increasing the release of protective mucin (EP_4 receptor), reducing gastric acid output, probably by acting on $EP_{2/3}$ receptors on ECL cells and preventing the vasoconstriction (and thus damage to the mucosa) that follows injury or insult. The latter is probably an action mediated through $EP_{2/4}$ receptors. **Misoprostol** (see later) is a synthetic PG that probably exploits many of these effects to bring about its therapeutic action.

Somatostatin

This peptide hormone is released from *D cells* at several locations within the stomach. By acting at its somatostatin $(SST)_2$ receptor, it exerts paracrine inhibitory actions on gastrin release from G cells, histamine release from ECL cells, as well as directly on parietal cell acid output.

The Coordination of Factors Regulating Acid Secretion

The regulation of the parietal cell is complex, and many local hormones probably play a role in the fine-tuning of the secretory response. The generally accepted model today is that the *gastrin–ECL–parietal cell axis* is the dominant mechanism for controlling acid secretion. According to this idea (see **Fig. 30.2**), which is supported by the majority of genetically altered mouse studies, the initial step in controlling physiological secretion is the release of gastrin from G cells. This acts through its CCK_2 receptor on ECL cells to release histamine and may also have a secondary direct effect on parietal cells themselves, although this has been disputed. Histamine acts on H_2 receptors on parietal cells to elevate cAMP and to activate the secretion of protons as described.

Direct vagal stimulation can also provoke acid secretion (the basis for 'stress ulcers') through a release of acetylcholine, which directly stimulates M_3 receptors on parietal cells. Somatostatin probably exerts a tonic inhibitory influence on G cells, ECL and parietal cells, and local (or therapeutically administered) PGs, acting through $EP_{2/3}$ receptors, exert inhibitory effects predominantly on ECL cell function.

This control system is clearly complex, but prolonged exposure of tissues to excess acid secretion is dangerous and must be tightly regulated (see **Schubert and Peura, 2008**).

Secretion of gastric acid, mucus and bicarbonate

The control of the GI tract is through nervous and humoural mechanisms.

- Acid is secreted from gastric parietal cells by a proton pump (K^+-H^+-ATPase).
- The three endogenous secretagogues for acid are histamine, acetylcholine and gastrin.
- PGE_2 and PGI_2 inhibit acid, stimulate mucus and bicarbonate secretion, and dilate mucosal blood vessels.
- Somatostatin inhibits all phases of parietal cell activation.

The genesis of peptic ulcers involves:

- infection of the gastric mucosa with *Helicobacter pylori*;
- an imbalance between mucosal-damaging (acid, pepsin) and mucosal-protecting (mucus, bicarbonate, PGE_2 and PGI_2 and nitric oxide) agents.

Drugs Used to Inhibit or Neutralise Gastric Acid Secretion

The principal clinical indications for reducing acid secretion are *peptic ulceration* (both duodenal and gastric), *GORD* (in which gastric secretion causes damage to the oesophagus) and the *Zollinger–Ellison syndrome* (a rare hypersecretory condition caused by a gastrin-producing tumour). If untreated, GORD can cause a dysplasia of the oesophageal epithelium which may progress to a potentially dangerous pre-cancerous condition called *Barrett oesophagus*.

The reasons why peptic ulcers develop are not fully understood, although infection of the stomach mucosa with *Helicobacter pylori* [3] – a Gram-negative bacillus that causes chronic gastritis – is now generally considered to be a major cause (especially of duodenal ulcer) and forms the usual basis for therapy. Treatment of *H. pylori* infection is discussed later.

Many non-specific NSAIDs (see **Ch. 25**) cause gastric bleeding and erosions by inhibiting cyclo-oxygenase I, the enzyme responsible for synthesis of protective PGs. More selective cyclo-oxygenase II inhibitors such as **celecoxib** appear to cause less stomach damage (but see **Ch. 25** for a discussion of this issue).

Therapy of peptic ulcer and reflux oesophagitis aims to decrease the secretion of gastric acid with H_2 receptor antagonists or proton pump inhibitors, and/or to neutralise secreted acid with antacids. These treatments are often coupled with measures to eradicate *H. pylori*.

Histamine H_2 Receptor Antagonists

The discovery and development of histamine H_2-blocking drugs by Black and his colleagues in 1972 was a major breakthrough in the

treatment of gastric ulcers – a condition that could hitherto only be treated by (sometimes rather heroic) surgery. [4] Indeed, the ability to distinguish between histamine receptor subtypes using pharmacological agents was, in itself, a major intellectual achievement since there was no direct evidence for the existence of these receptors until the advent of selective antagonists. H_2 receptor antagonists competitively inhibit histamine actions at all H_2 receptors, but their main clinical use is as inhibitors of gastric acid secretion. They can inhibit histamine- and gastrin-stimulated acid secretion; pepsin secretion also falls with the reduction in volume of gastric juice. These agents not only decrease both basal and food-stimulated acid secretion by 90% or more, but numerous clinical trials indicate that they also promote healing of gastric and duodenal ulcers. However, relapses are likely to follow cessation of treatment.

The main drugs used are **cimetidine**, **ranitidine** (sometimes in combination with **bismuth**), **nizatidine** and **famotidine**. There is little clinically relevant difference between them. The effect of cimetidine on gastric secretion in human subjects is shown in **Fig. 30.3**. The clinical use of H_2 receptor antagonists is explained in the clinical box.

Clinical use of agents affecting gastric acidity

- Histamine H_2 receptor antagonists (e.g. **famotidine**):
  - peptic ulcer
  - reflux oesophagitis.

- Proton pump inhibitors (e.g. **omeprazole**, **lansoprazole**):
  - peptic ulcer
  - reflux oesophagitis
  - as one component of therapy for *H. pylori* infection
  - *Zollinger–Ellison* syndrome (a rare condition caused by gastrin-secreting tumours).
- Antacids (e.g. magnesium trisilicate, aluminium hydroxide, alginates):
  - dyspepsia
  - symptomatic relief in *peptic ulcer* or (**alginate**) *oesophageal reflux.*
- **Bismuth chelate**:
  - as one component of therapy for *H. pylori* infection.

Pharmacokinetic aspects and unwanted effects

The drugs are generally given orally and are well absorbed, although preparations for intramuscular and intravenous use are also available (except **famotidine**). Dosage regimens vary depending on the condition under treatment. Low-dosage over-the-counter formulations of **cimetidine**, **ranitidine** and **famotidine** are available from pharmacies for short-term use, without prescription.

FIG. 30.3 The effect of cimetidine on betazole-stimulated gastric acid and pepsin secretion in humans.Either cimetidine or a placebo was given orally 60 min prior to a subcutaneous injection (1.5 mg/kg) of betazole, a relatively specific histamine H_2-receptor agonist that stimulates gastric acid secretion. Modified from Binder, H.J., Donaldson, R.M., Jr., 1978. Effect of cimetidine on intrinsic factor and pepsin secretion in man. Gastroenterology 74, 371–375.

Unwanted effects are rare. Diarrhoea, dizziness, muscle pains, alopecia, transient rashes, confusion in the elderly and hypergastrinaemia have been reported. **Cimetidine** sometimes causes gynaecomastia in men and, rarely, a decrease in sexual function. This is probably caused by a modest affinity for androgen receptors. **Cimetidine** (but not other H_2 receptor antagonists) also inhibits cytochrome P450 and can retard the metabolism (and thus potentiate the action) of a range of drugs including oral anticoagulants and tricyclic antidepressants.

Proton Pump Inhibitors

The first proton pump inhibitor was **omeprazole**, which irreversibly inhibits the H^+-K^+-ATPase (the proton pump), the terminal step in the acid secretory pathway (see Figs **30.1** and **30.2**). Both basal and stimulated gastric acid secretion (**Fig. 30.4**) is reduced. The drug comprises a racemic mixture of two enantiomers. As a weak base, it accumulates in the acid

environment of the canaliculi of the stimulated parietal cell where it is converted into an achiral form and is then able to react with, and inactivate, the ATPase. This preferential accumulation means that it has a specific effect on these cells. Other proton pump inhibitors (all of which have a similar mode of activation and pharmacology) include **esomeprazole** (the [S] isomer of omeprazole), **lansoprazole**, **pantoprazole** and **rabeprazole**. The clinical indication for these drugs is given in the clinical box (see earlier).

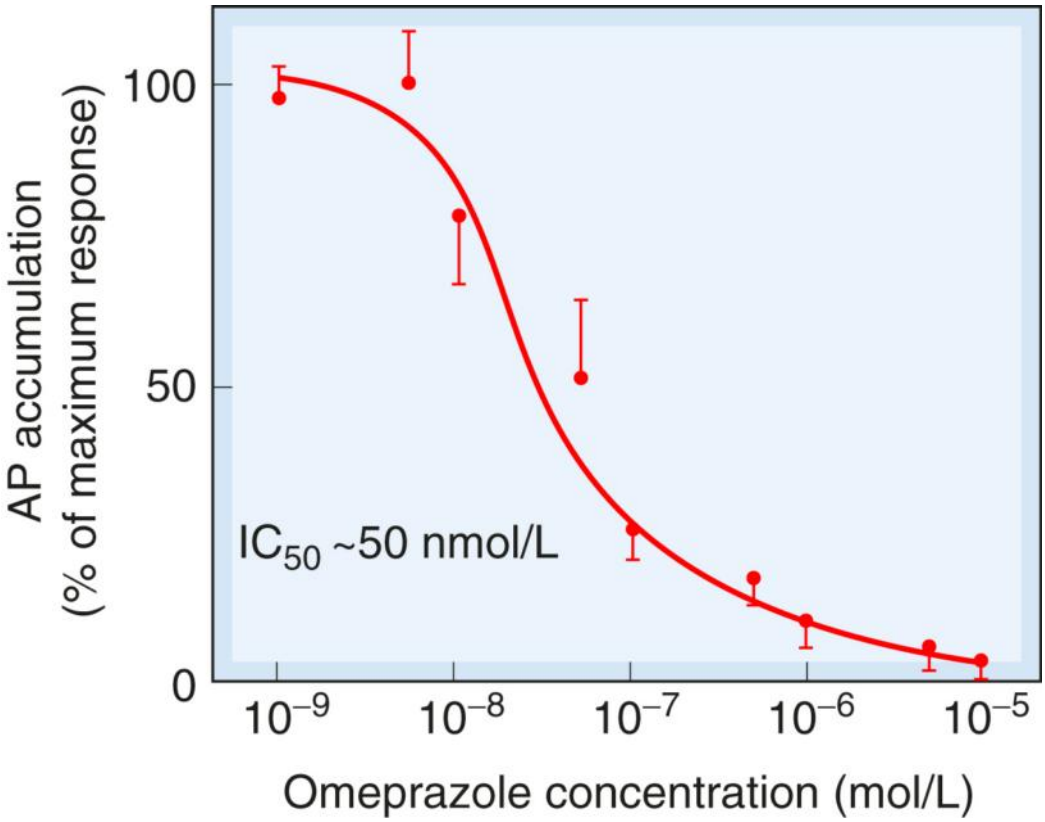

FIG. 30.4 The inhibitory action of omeprazole on acid secretion from isolated human gastric glands stimulated by 50 µmol/L histamine.Acid secretion was measured by the accumulation of a radiolabelled weak base, aminopyrine (AP), in the secretory channels. The data represent the mean and standard error of measurements from eight patients. Adapted from Lindberg, P., et al., 1987. Trends Pharmacol. Sci. 8, 399–402.

Pharmacokinetic aspects and unwanted effects

Oral administration is the most common route of administration, although some injectable preparations are available. **Omeprazole** is given orally, but as it degrades rapidly at low pH, it is

administered as capsules containing enteric-coated granules. Following absorption in the small intestine, it passes from the blood into the parietal cells and then into the canaliculi where it exerts its effects. Increased doses give disproportionately higher increases in plasma concentration (possibly because its inhibitory effect on acid secretion improves its own bioavailability). Although its half-life is about 1 h, a single daily dose affects acid secretion for 2–3 days, partly because of the accumulation in the canaliculi and partly because it inhibits the H^+-K^+-ATPase irreversibly. With daily dosage, there is an increasing antisecretory effect for up to 5 days, after which a plateau is reached.

Unwanted effects of this class of drugs are uncommon. They may include headache, diarrhoea (both sometimes severe) and rashes. Acid suppression with proton pump inhibitors is associated with increased risk of *Clostridium difficile* diarrhoea, particularly in patients who are immunosuppressed or have been receiving antibiotics. Dizziness, somnolence, mental confusion, impotence, gynaecomastia and pain in muscles and joints have been reported. Proton pump inhibitors should be used with caution in patients with liver disease, or in women who are pregnant or breastfeeding. The use of these drugs may ‘mask’ the symptoms of gastric cancer.

Antacids

Antacids are the simplest way to treat the symptoms of excessive gastric acid secretion. They directly neutralise acid and this also has the effect of inhibiting the activity of peptic enzymes, which practically ceases at pH 5. Given in sufficient quantity for long

enough, they can produce healing of duodenal ulcers, but are less effective for gastric ulcers.

Most antacids in common use are salts of magnesium and aluminium. Magnesium salts cause diarrhoea and aluminium salts, constipation – so mixtures of these two can, happily, be used to preserve normal bowel function. Preparations of these substances (e.g. **magnesium trisilicate** mixtures and some proprietary aluminium preparations) containing high concentrations of sodium should not be given to patients on a sodium-restricted diet. Numerous antacid preparations are available; a few of the more significant are given later.

Magnesium hydroxide is an insoluble powder that forms magnesium chloride in the stomach. It does not produce systemic alkalosis, because Mg^{2+} is poorly absorbed from the gut. Another salt, magnesium trisilicate, is an insoluble powder that reacts slowly with the gastric juice, forming magnesium chloride and colloidal silica. This agent has a prolonged antacid effect, and it also adsorbs pepsin. **Magnesium carbonate** is also used.

Aluminium hydroxide gel forms aluminium chloride in the stomach; when this reaches the intestine, the chloride is released and is reabsorbed. Aluminium hydroxide raises the pH of the gastric juice to about 4, and also adsorbs pepsin. Its action is gradual, and its effect continues for several hours. [5] Colloidal aluminium hydroxide combines with phosphates in the GI tract and the increased excretion of phosphate in the faeces that occurs results in decreased excretion of phosphate via the kidney. This effect has been used in treating patients with chronic renal failure (see Ch.

30). Other preparations such as **hydrotalcite** contain mixtures of both aluminium and magnesium salts.

Alginates or **simeticone** are sometimes combined with antacids. Alginates are believed to increase the viscosity and adherence of mucus to the oesophageal mucosa, forming a protective barrier, whereas **simeticone** is an anti-foaming agent, intended to relieve bloating and flatulence.

Treatment of *Helicobacter Pylori* Infection

H. pylori infection has been implicated as a causative factor in the production of gastric and, more particularly, duodenal ulcers, as well as a risk factor for gastric cancer. Indeed, some would argue that infectious gastroduodenitis is actually the chief clinical entity associated with ulcers, and gastric cancer its prominent sequela. Certainly, eradication of *H. pylori* infection promotes rapid and long-term healing of ulcers, and it is routine practice to test for the organism in patients presenting with suggestive symptoms. If the test is positive, then the organism can generally be eradicated with a 1- or 2-week regimen of 'triple therapy', comprising a proton pump inhibitor in combination with the antibacterials **amoxicillin** and **metronidazole** or **clarithromycin** (see **Ch. 52**); other combinations are also used. Bismuth-containing preparations (see later) are sometimes added. While elimination of the bacillus can produce long-term remission of ulcers, reinfection with the organism can occur.

Drugs that Protect the Mucosa

Some agents, termed *cytoprotective*, are said to enhance endogenous mucosal protection mechanisms and/or to provide a physical barrier over the surface of the ulcer.

Bismuth chelate

Bismuth chelate (tripotassium dicitratobismuthate) is sometimes used in combination regimens to treat *H. pylori*. It has toxic effects on the bacillus and may also prevent its adherence to the mucosa or inhibit its bacterial proteolytic enzymes. It is also believed to have other mucosa-protecting actions, by mechanisms that are unclear, and is widely used as an over-the-counter remedy for mild GI symptoms. Very little is absorbed, but if renal excretion is impaired, the raised plasma concentrations of bismuth can result in encephalopathy.

Unwanted effects include nausea and vomiting and blackening of the tongue and faeces.

Sucralfate

Sucralfate is a complex of aluminium hydroxide and sulfated sucrose, which releases aluminium in the presence of acid. The residual complex carries a strong negative charge and binds to cationic groups in proteins, glycoproteins, etc. It can form complex gels with mucus, an action that is thought to decrease the degradation of mucus by pepsin and to limit the diffusion of H^+ ions. Sucralfate can also inhibit the action of pepsin and stimulate secretion of mucus, bicarbonate and PGs from the gastric mucosa. All these actions contribute to its mucosa-protecting action.

Sucralfate is given orally and about 30% is still present in the stomach 3 h after administration. In the acid environment, the

polymerised product forms a tenacious paste, which can sometimes produce an obstructive lump (known as a *bezoar* [6]) that gets stuck in the stomach. It reduces the absorption of a number of other drugs, including fluoroquinolone antibiotics, **theophylline**, **tetracycline**, **digoxin** and **amitriptyline**. Because it requires an acid environment for activation, antacids given concurrently or prior to its administration will reduce its efficacy.

Unwanted effects are few, the most common being constipation. Less common effects apart from bezoar formation include dry mouth, nausea, vomiting, headache and rashes.

Misoprostol

PGs of the E and I series have a generally homeostatic protective action in the GI tract, and a deficiency in endogenous production (after ingestion of an NSAID, for example) may contribute to ulcer formation. **Misoprostol** is a stable analogue of PGE_1. It is given orally and is used to promote the healing of ulcers or to prevent the gastric damage that can occur with chronic use of NSAIDs. It exerts a direct action on the ECL cell (and possibly parietal cell also; see **Fig. 30.2**), inhibiting the basal secretion of gastric acid as well as the stimulation of production seen in response to food, pentagastrin and caffeine. It also increases mucosal blood flow and augments the secretion of mucus and bicarbonate.

Unwanted effects include diarrhoea and abdominal cramps; uterine contractions can also occur, so the drug should not be given during pregnancy (unless deliberately to induce a therapeutic abortion; see **Ch. 35**). PGs and NSAIDs are discussed more fully in Chapter **25**.

Vomiting

Nausea and vomiting are unwanted side effects of many clinically used drugs, notably those used for cancer chemotherapy but also opioids, general anaesthetics and digoxin. They also occur in motion sickness, [7] during early pregnancy and in numerous disease states (e.g. migraine) as well as bacterial and viral infections.

The Reflex Mechanism of Vomiting

Vomiting is a defensive response intended to rid the organism of toxic or irritating material. Poisonous compounds, bacterial toxins and many cytotoxic drugs (as well as mechanical distension) trigger the release, from enterochromaffin cells in the lining of the GI tract, of mediators such as 5-HT. These transmitters trigger signals in vagal afferent fibres. The physical act of vomiting is co-ordinated centrally by the *vomiting* (or *emetic*) *centre* in the medulla (**Fig. 30.5**). Actually, this is not a discrete anatomical location but a network of neural pathways that integrate signals arriving from other locations. One of these, in the *area postrema*, is known as the *chemoreceptor trigger zone* (CTZ). The CTZ receives inputs from the labyrinth in the inner ear through the *vestibular nuclei* (which explains the mechanism of motion sickness) and vagal afferents arising from the GI tract. Toxic chemicals in the bloodstream can also be detected directly by the CTZ because the blood–brain barrier is relatively permeable in this area. The CTZ is therefore a primary site of action of many emetic and antiemetic drugs (**Table 30.1**).

The vomiting centre also receives signals directly from vagal afferents, as well as those relayed through the CTZ. In addition, it receives input from higher cortical centres, explaining why

unpleasant or repulsive sights or smells, or strong emotional stimuli, can sometimes induce nausea and vomiting.

The main neurotransmitters involved in this neurocircuitry are acetylcholine, histamine, 5-HT, dopamine and substance P and receptors for these transmitters have been demonstrated in the relevant areas (see Chs **13**–**17**). It has been hypothesised that enkephalins (see **Ch. 43**) are also implicated in the mediation of vomiting, acting possibly at δ (CTZ) or μ (vomiting centre) opioid receptors. Substance P (see **Ch. 17**) acting at neurokinin-1 receptors in the CTZ, and endocannabinoids (see **Ch. 18**), may also be involved.

The neurobiology of nausea is much less well understood. Nausea and vomiting may occur together or separately and may subserve different physiological functions (see **Andrews and Horn, 2006**). From the pharmacologist's viewpoint, it is easier to control vomiting than nausea, and many effective antiemetics (e.g. 5-HT_3 antagonists) are much less successful in this regard.

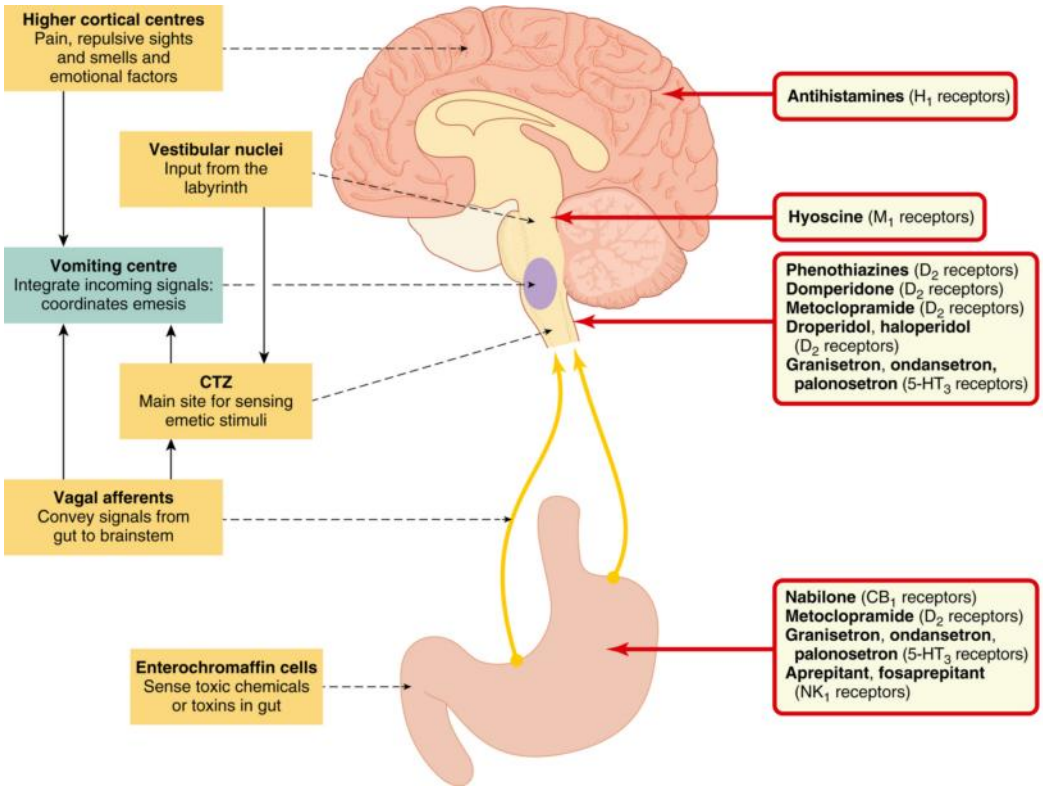

FIG. 30.5 Schematic diagram of the factors involved in the control of vomiting, with the probable sites of action of antiemetic drugs.There are three important centres located in the medulla. The chemoreceptor trigger zone (CTZ), the vomiting centre and the vestibular nuclei. The vomiting centre receives inputs from the CTZ, the gastrointestinal (GI) tract (through vagal afferent connections) and higher cortical centres and coordinates the physical act of emesis. Vagal afferents arising from the GI tract also feed into the CTZ directly as does input from the vestibular nuclei, which in turn receive inputs from the labyrinth. Based partly on a diagram from Rojas, C., Slusher, B.S., 2012.

Pharmacological mechanisms of 5-HT(3) and tachykinin NK(1) receptor antagonism to prevent chemotherapy-induced nausea and vomiting. Eur. J. Pharmacol. 684, 1–7.

The reflex mechanism of vomiting

Emetic stimuli include:

- chemicals or drugs in the blood or intestine;
- neuronal input from the GI tract, labyrinth and central nervous system (CNS).

Pathways and mediators include:

- impulses from the CTZ and various other CNS centres relayed to the vomiting centre;
- chemical transmitters such as histamine, acetylcholine, dopamine, 5-HT and substance P, acting on H_1, muscarinic, D_2, 5-HT_3 and NK_1 receptors, respectively.

Antiemetic drugs include:

- H_1 receptor antagonists (e.g. **cinnarizine**);
- muscarinic antagonists (e.g. **hyoscine**);
- 5-HT_3 receptor antagonists (e.g. **ondansetron**);
- D_2 receptor antagonists (e.g. **metoclopramide**);
- cannabinoids (e.g. **nabilone**);
- neurokinin-1 antagonists (e.g. **aprepitant**, **fosaprepitant**).

Main side effects of principal antiemetics include:

- drowsiness and antiparasympathetic effects (**hyoscine**, **nabilone** > **cinnarizine**);
- dystonic reactions (**metoclopramide**);
- general CNS disturbances (**nabilone**);
- headache, GI tract upsets (**ondansetron**).

Table 30.1

5-*HT*, 5-Hydroxytryptamine; *CINV,* cytotoxic drug-induced vomiting; *CNS,* central nervous system; *CTZ,* chemoreceptor trigger zone; *GI,* gastrointestinal; *PONV,* postoperative nausea and vomiting; *RS,* radiation sickness.

Antiemetic Drugs

Several antiemetic agents are available, and these are generally used for specific conditions, although there may be some overlap. Such drugs are of particular importance as an adjunct to cancer chemotherapy, where the nausea and vomiting produced by many cytotoxic drugs (see **Ch. 57**) can be almost unendurable. [8] In using drugs to treat the morning sickness of pregnancy, the problem of potential damage to the fetus has always to be borne in mind. In general, all drugs should be avoided during the first 3 months of pregnancy, if possible. Details of the main categories of antiemetics are given later, and their main clinical uses are summarised in the box. The clinical box and **Table 30.1** give an overview of their likely sites of action and their clinical utility.

Clinical use of antiemetic drugs

- Histamine H_1 receptor antagonists (see also clinical box in Ch. 25):
  - **Cyclizine**: motion sickness, vestibular disorders, nausea and vomiting associated with surgery and postoperative narcotic analgesic use.
  - **Cinnarizine**: motion sickness, vestibular disorders (e.g. Menière's disease).
  - **Promethazine**: severe morning sickness of pregnancy, motion sickness, vestibular disorders.
- Muscarinic receptor antagonists:
  - **Hyoscine**: motion sickness.
- Dopamine D_2 receptor antagonists:
  - Phenothiazines (e.g. **prochlorperazine**): vomiting caused by migraine, vestibular disorders, radiation, viral gastroenteritis, severe morning sickness of pregnancy.
  - **Metoclopramide**: vomiting caused by migraine, radiation, GI disorders, cytotoxic drugs, prevention of nausea and vomiting in the postoperative period.
  - **Domperidone** is less liable to cause CNS side effects in patients with Parkinson's disease as it penetrates the blood–brain barrier poorly.
- 5-HT_3 receptor antagonists (e.g. **ondansetron**): cytotoxic drugs or radiation, postoperative vomiting.
- Cannabinoids (e.g. **nabilone**): cytotoxic drugs (see Ch. 18).
- NK_1 receptor antagonists (e.g. fosaprepitant): cytotoxic drugs.

Receptor Antagonists

Many H_1 (see **Ch. 25**), muscarinic (see **Ch. 14**), 5-HT_3 (see **Ch. 16**), dopamine (see **Ch. 47**) and neurokinin NK_1 receptor antagonists exhibit clinically useful antiemetic activity.

H_1 receptor antagonists

Cinnarizine, **cyclizine** and **promethazine** are the most commonly employed; they are effective against nausea and vomiting arising from many causes, including motion sickness (even in NASA space journeys!), and the presence of irritants in the stomach. They are less effective against substances that act directly on the CTZ. Promethazine or **doxylamine** are used for morning sickness of pregnancy (on the rare occasions when this is so severe that drug treatment is required). Drowsiness and sedation, while possibly contributing to their clinical efficacy, are the chief unwanted effects.

Betahistine has complicated effects on histamine action, antagonising H_3 receptors but having a weak agonist activity on H_1 receptors. It is used to control the nausea and vertigo associated with *Menière's disease*. [9]

Muscarinic receptor antagonists

Hyoscine (scopolamine) is employed principally for prophylaxis and treatment of motion sickness and may be administered orally or as a transdermal patch. Dry mouth and blurred vision are the most common unwanted effects. Drowsiness also occurs, but the drug has less sedative action than the antihistamines because of poor CNS penetration.

5-HT_3 receptor antagonists

Granisetron, **ondansetron** and **palonosetron** (see **Ch. 16**) are of particular value in preventing and treating the vomiting and, to a lesser extent the nausea, commonly encountered postoperatively as well as that caused by radiation therapy or administration of cytotoxic drugs such as **cisplatin**. The primary site of action of these drugs is the CTZ. They may be given orally or by injection (sometimes helpful if nausea is already present). Unwanted effects such as headache and GI upsets are relatively uncommon.

Dopamine antagonists

Antipsychotic phenothiazines (see **Ch. 47**), such as **chlorpromazine**, **perphenazine**, **prochlorperazine** and **trifluoperazine**, are effective antiemetics commonly used for treating the more severe nausea and vomiting associated with cancer, radiation therapy, cytotoxic drugs, opioids, anaesthetics and other drugs. They can be administered orally, intravenously or by suppository. They act mainly as antagonists of the dopamine D_2 receptors in the CTZ (see **Fig. 30.5**) but they also block histamine and muscarinic receptors.

Unwanted effects are common and include sedation (especially chlorpromazine), hypotension and extrapyramidal symptoms including dystonias and tardive dyskinesia (see **Ch. 47**).

Other antipsychotic drugs, such as **haloperidol**, the related compound **droperidol** and **levomepromazine** (see **Ch. 47**), also act as D_2 antagonists in the CTZ and can be used for acute chemotherapy-induced emesis.

Metoclopramide and domperidone

Metoclopramide is a D_2 receptor antagonist (see **Fig. 30.5**), closely related to the phenothiazine group, that acts centrally on the CTZ and also has a peripheral action on the GI tract itself, increasing the motility of the oesophagus, stomach and intestine. This not only adds to the antiemetic effect but explains its use in the treatment of gastro-oesophageal reflux and hepatic and biliary disorders. As **metoclopramide** also blocks dopamine receptors elsewhere in the CNS, it produces a number of unwanted effects including disorders of movement (more common in children and young adults), fatigue, motor restlessness, spasmodic torticollis (involuntary twisting of the neck) and oculogyric crises (involuntary upward eye movements). It stimulates prolactin release (see Ch. **35**) causing galactorrhoea and disorders of menstruation.

Domperidone is a similar drug used to treat vomiting due to cytotoxic therapy as well as GI symptoms. Unlike **metoclopramide**, it does not readily penetrate the blood–brain barrier and is consequently less prone to producing central side effects. However, **domperidone** is associated with a small increased risk of serious cardiac adverse effects (particularly at higher doses and in older patients), and its use is now restricted.

Both drugs are given orally, have plasma half-lives of 4–5 h and are excreted in the urine.

NK_1 receptor antagonists

Substance P causes vomiting when injected intravenously and is released by GI vagal afferent nerves as well as in the vomiting centre itself. **Aprepitant** blocks substance P (NK_1) receptors in the CTZ and vomiting centre. **Aprepitant** is given orally and is effective

in controlling the late phase of emesis caused by cytotoxic drugs, with few significant unwanted effects. **Fosaprepitant** is a prodrug of **aprepitant**, which is administered intravenously.

Other Antiemetic Drugs

Anecdotal evidence originally suggested the possibility of using cannabinoids (see **Ch. 18**) as antiemetics (see **Pertwee, 2001**). The synthetic cannabinol **nabilone** has been found to decrease vomiting caused by agents that stimulate the CTZ and is sometimes effective where other drugs have failed. The antiemetic effect is antagonised by **naloxone**, which implies that opioid receptors may be important in the mechanism of action. Nabilone is given orally; it is well absorbed from the GI tract and is metabolised in many tissues. Its plasma half-life is approximately 120 min, and its metabolites are excreted in the urine and faeces.

Unwanted effects are common, especially drowsiness, dizziness and dry mouth. Mood changes and postural hypotension are also fairly frequent. Some patients experience hallucinations and psychotic reactions, resembling the effect of other cannabinoids (see **Ch. 18**).

High-dose glucocorticoids (particularly **dexamethasone**; see Chs **25** and **33**) can also control emesis, especially when this is caused by cytotoxic drugs. The mechanism of action is not clear. **Dexamethasone** is typically deployed in combination with **metoclopramide** or **ondansetron** in patients receiving cytotoxics, or in postoperative nausea and vomiting.

The Motility of the GI Tract

Drugs that alter the motility of the GI tract include:

- purgatives, which accelerate the passage of food through the intestine;
- agents that increase the motility of the GI smooth muscle without causing purgation;
- antidiarrhoeal drugs, which decrease motility;
- antispasmodic drugs, which decrease smooth muscle tone.

Clinical uses of drugs that affect the motility of the GI tract are summarised in the clinical box.

Drugs and GI tract motility

- Purgatives include:
  - bulk laxatives (e.g. **ispaghula husk**, first choice for slow action);
  - osmotic laxatives (e.g. **lactulose**);
  - faecal softeners (e.g. **docusate**);
  - stimulant purgatives (e.g. **senna**).
- Drugs used to treat diarrhoea:
  - oral rehydration with isotonic solutions of NaCl plus glucose and starch-based cereal (important in infants);
  - antimotility agents, e.g. **loperamide** (unwanted effects: drowsiness and nausea).

Purgatives

The transit of food through the intestine may be hastened by several different types of drugs, including laxatives, faecal softeners and stimulant purgatives. The latter agents may be used to relieve constipation or to clear the bowel prior to surgery or examination.

Bulk and Osmotic Laxatives

The *bulk laxatives* include **methylcellulose** and certain plant extracts such as **sterculia**, **agar**, **bran** and **ispaghula husk**. These agents are polysaccharide polymers that are not digested in the upper part of the GI tract. They form a bulky hydrated mass in the gut lumen promoting peristalsis and improving faecal consistency. They may take several days to work but have no serious unwanted effects.

The *osmotic laxatives* consist of poorly absorbed solutes – the saline purgatives – and **lactulose**. The main salts in use are magnesium sulfate and magnesium hydroxide. By producing an osmotic load, these agents trap increased volumes of fluid in the lumen of the bowel, accelerating the transfer of the gut contents through the small intestine. This results in an abnormally large volume entering the colon, causing distension and purgation within about an hour. Abdominal cramps can occur. The amount of magnesium absorbed after an oral dose is usually too small to have adverse systemic effects, but these salts should be avoided in small children and in patients with poor renal function, in whom they can cause heart block, neuromuscular block or CNS depression. While isotonic or hypotonic solutions of saline purgatives cause purgation, hypertonic solutions can cause vomiting. Sometimes, other sodium

salts of phosphate and citrate are given rectally, by suppository, to relieve constipation.

Lactulose is a semisynthetic disaccharide of fructose and galactose. It is poorly absorbed and produces an effect similar to that of the other osmotic laxatives. It takes 2–3 days to act. Unwanted effects, seen with high doses, include flatulence, cramps, diarrhoea and electrolyte disturbance. Tolerance can develop. Another agent, **macrogol**, which consists of inert ethylene glycol polymers, acts in the same way, and is sometimes formulated together with electrolyte ions to ensure that the laxative effect does not cause marked changes in sodium, potassium and water balance.

Faecal Softeners

Docusate sodium is a surface-active compound that acts in the GI tract in a manner similar to a detergent and produces softer faeces. It is also a weak stimulant laxative. Other agents that achieve the same effect include **arachis oil**, which is given as an enema, and **liquid paraffin**, although this is now seldom used.

Stimulant Laxatives

The stimulant laxative drugs act mainly by increasing electrolyte and hence water secretion by the mucosa, and by increasing peristalsis – possibly by stimulating enteric nerves. Abdominal cramping may be experienced as a side effect with almost any of these drugs.

Bisacodyl may be given by mouth but is often given by suppository. In the latter case, it stimulates the rectal mucosa, inducing defecation in 15–30 min. Glycerol suppositories act in the same manner. **Sodium picosulfate** and docusate sodium have

similar actions. The former is given orally and is often used in preparation for intestinal surgery or colonoscopy.

Senna and **dantron** are **anthraquinone** laxatives. The active principle (after hydrolysis of glycosidic linkages in the case of the plant extract, senna) directly stimulates the myenteric plexus, resulting in increased peristalsis and thus defecation. **Dantron** is similar. As this drug is a skin irritant and may be carcinogenic, it is generally used only in the terminally ill.

Laxatives of any type should not be used when there is obstruction of the bowel. Overuse can lead to an atonic colon where the natural propulsive activity is diminished. In these circumstances, the only way to achieve defecation is to take further amounts of laxatives, so a sort of dependency arises.

Drugs that Increase Gastrointestinal Motility

Domperidone is primarily used as an antiemetic (as described previously), but it also increases GI motility (although the mechanism is unknown).

Metoclopramide (also an antiemetic) stimulates gastric motility, causing a marked acceleration of gastric emptying. It is useful in gastro-oesophageal reflux and in disorders of gastric emptying but is ineffective in paralytic ileus.

Prucalopride is a selective 5-HT_4 receptor agonist that has marked prokinetic properties on the gut. It is generally only used when other types of laxative treatment have failed. Similarly, **tegaserod** is used to treat symptoms of constipation in those with irritable bowel syndrome (IBS) (see later).

Lubiprostone is a chloride channel-2 activator that acts on cells in the apical membrane of the small intestine to promote chloride and fluid secretion into the lumen, with associated improvements in gut motility and softer stool. It has regulatory approval for treatment of constipation due to opioids, in IBS and in patients who have failed to respond to non-drug treatment of constipation.

Naloxegol is a μ opioid-receptor antagonist that is similar to naloxone, but with the addition of a pegylated portion to prevent penetration into the CNS. **Naloxegol** counteracts the reduced GI motility and hypertonicity that is seen in opioid-induced constipation, but without exerting any adverse effect on the analgesic properties of opioid agonists centrally.
Methylnaltrexone is a peripheral opioid-receptor antagonist that is licensed for opioid-induced constipation, and **naldemedine** is a similar compound (**Nelson and Camilleri, 2016**).

Elobixibat is licensed in Japan for treatment of chronic idiopathic constipation. It is an inhibitor of the ileal bile acid transporter which is responsible for re-absorption of bile salts from the terminal ileum. The suppression of bile salt reabsorption leads to greater bile acid progress into the colon, with increased water secretion and motility.

Antidiarrhoeal Agents

There are numerous causes of diarrhoea, including underlying disease, infection, toxins and even anxiety. It may also arise as a side effect of drug or radiation therapy. The consequences range from mild discomfort and inconvenience to a medical emergency requiring hospitalisation, parenteral fluid and electrolyte

replacement therapy. Globally, acute diarrhoeal disease is one of the principal causes of death in malnourished infants, especially in developing countries where medical care is less accessible and 1–2 million children die each year for want of simple counter-measures.

During an episode of diarrhoea, there is an increase in the motility of the GI tract, accompanied by an increased secretion, coupled with a decreased absorption, of fluid. This leads to a loss of electrolytes (particularly Na^+) and water. Cholera toxins and some other bacterial toxins produce a profound increase in electrolyte and fluid secretion by irreversibly activating the G proteins that couple the surface receptors of the mucosal cells to adenylyl cyclase (see **Ch. 3**).

There are three approaches to the treatment of severe acute diarrhoea:

- maintenance of fluid and electrolyte balance;
- use of anti-infective agents;
- use of spasmolytic or other antidiarrhoeal agents.

The maintenance of fluid and electrolyte balance by means of oral rehydration is the first priority. Wider application of this cheap and simple remedy could save the lives of many infants in the developing world. Indeed, many patients require no other treatment.

In the ileum, as in the nephron, there is co-transport of Na^+ and glucose across the epithelial cell. The presence of glucose (and some amino acids) therefore enhances Na^+ absorption and thus water uptake. Preparations of sodium chloride and glucose for oral

rehydration are available in powder form, ready to be dissolved in water before use.

Many GI infections are viral in origin. Those that are bacterial generally resolve fairly rapidly, so the use of anti-infective agents is usually neither necessary nor useful. Other cases may require more aggressive therapy, however. *Campylobacter* spp. is the commonest cause of bacterial gastroenteritis in the United Kingdom, and severe infections may require **ciprofloxacin**. The most common bacterial organisms encountered by travellers include *Escherichia coli*, *Salmonella* and *Shigella*, as well as protozoa such as *Giardia* and *Cryptosporidium* spp. Drug treatment (Chs **52** and **55**) may be necessary in these and other more serious infections.

Traveller's Diarrhoea

Millions of people cross international borders each year. Many travel hopefully, but some return with GI symptoms such as diarrhoea, having encountered enterotoxin-producing *E. coli* (the most common cause) or other organisms. Most infections are mild and self-limiting, requiring only oral replacement of fluid and salt, as detailed previously. The general principles for the drug treatment of traveller's diarrhoea are detailed by **Leung et al. (2019)**.Recent guidelines on the role of drug treatments such as antimotility agents, bismuth and antibiotics for more severe cases are listed in the Further Reading section.

Antimotility and Spasmolytic Agents

The main pharmacological agents that decrease motility are opioids (see **Ch. 43**) and muscarinic receptor antagonists (see **Ch. 14**). Agents in this latter group are seldom employed as primary therapy

for diarrhoea because of their actions on other systems, but small doses of **atropine** are sometimes used, combined with **diphenoxylate**. The action of **morphine**, the archetypal opiate, on the alimentary tract is complex; it increases the tone and rhythmic contractions of the intestine but diminishes propulsive activity. The pyloric, ileocolic and anal sphincters are contracted, and the tone of the large intestine is markedly increased. Its overall effect is constipating.

The main opioids used for the symptomatic relief of diarrhoea are **codeine** (a morphine congener), diphenoxylate and **loperamide** (both **pethidine** congeners that do not readily penetrate the blood–brain barrier and are used only for their actions in the gut). All may have unwanted effects, including constipation, abdominal cramps, drowsiness and dizziness. Complete loss of intestinal motility (paralytic ileus) can also occur. They should not be used in young (<4 years of age) children.

Loperamide is the drug of first choice for pharmacotherapy of traveller's diarrhoea and is a component of several proprietary antidiarrhoeal medicines. It has a relatively selective action on the GI tract and undergoes significant enterohepatic cycling. It reduces the frequency of abdominal cramps, decreases the passage of faeces and shortens the duration of the illness.

Diphenoxylate also lacks morphine-like activity in the CNS, although large doses (25-fold higher) produce typical opioid effects. Preparations of diphenoxylate usually contain atropine as well. **Codeine** and **loperamide** have antisecretory actions in addition to their effects on intestinal motility.

'Endogenous opioids', enkephalins (see **Ch. 43**), also play a role in regulation of intestinal secretion. **Racecadotril** is a prodrug of **thiorphan**, an inhibitor of enkephalinase. By preventing the breakdown of enkephalins, this drug reduces the excessive intestinal secretion seen during episodes of diarrhoea. It is used in combination with rehydration therapy.

Cannabinoid receptor agonists also reduce gut motility in animals, most probably by decreasing acetylcholine release from enteric nerves. There have been anecdotal reports of a beneficial effect of cannabis against dysentery and cholera.

Drugs that reduce GI motility are also useful in IBS and diverticular disease. Muscarinic receptor antagonists (see **Ch. 14**) used for this purpose include atropine, hyoscine, **propantheline** and **dicycloverine**. The last named is thought to have some additional direct relaxant action on smooth muscle. All produce antimuscarinic side effects such as dry mouth, blurred vision and urinary retention. **Mebeverine**, a derivative of **reserpine**, has a direct relaxant action on GI smooth muscle. Unwanted effects are few.

Adsorbents

Adsorbent agents are used in the symptomatic treatment of some types of diarrhoea, although properly controlled trials proving efficacy have not been carried out. The main preparations used contain kaolin, pectin, chalk, charcoal, methylcellulose and activated attapulgite (magnesium aluminium silicate). It has been suggested that these agents may act by adsorbing microorganisms or toxins, by altering the intestinal flora or by coating and protecting

the intestinal mucosa, but there is no hard evidence for this. Kaolin is sometimes given as a mixture with morphine (e.g. kaolin and morphine mixture BP).

Drugs for Chronic Bowel Disease

This category comprises *IBS* and *inflammatory bowel disease* (IBD). IBS is characterised by bouts of diarrhoea (IBS-D), constipation (IBS-C) or abdominal pain, and some patients may have a mixture of symptoms (IBS-M) recurring periodically. The aetiology of IBS is uncertain, but alterations in the gut–brain axis, visceral hypersensitivity and psychological factors may play a part. Treatment is symptomatic, with a high-residue diet, **loperamide** for diarrhoea symptoms or a laxative (such as **isphagula** husk) if needed for constipation.

The serotoninergic or 5-HT pathway is thought to be one of the drivers leading to excess GI motility and secretion in IBS. Treatment of IBS-D includes the 5-HT_3 receptor antagonists **alosetron** and **ramosetron** which decrease gut motility, thus allowing more time for water reabsorption and reduction of watery stools. The opposing effect is seen with **tegaserod**, a 5-HT_4 agonist which stimulates GI motility to reduce bloating and constipation. Use of serotoninergic drugs in IBS has faced major regulatory hurdles, with both **alosetron** and **tegaserod** having been withdrawn from the US market, and then subsequently re-instated with stringent conditions.

Eluxadoline is a mixed μ and κ opioid-receptor agonist and δ-receptor antagonist that has recently been licensed for treatment of IBS with diarrhoea. The drug acts on opioid receptors in enteric

neurons that regulate motility and visceral sensation in the GI tract, resulting in slowing of intestinal transit and improved stool consistency. **Eluxadoline** has low oral bioavailability and is considered to have limited potential for adverse effects on opioid receptors in the CNS (see **Corsetti and Whorwell, 2016**).

Linaclotide is used for symptomatic treatment of moderate to severe IBS with constipation in adults. It is a synthetic peptide that is structurally related to endogenous guanylin peptides. Linaclotide is an agonist at the guanylate cyclase-C receptor on the luminal surface of intestinal epithelium and increases the concentration of cyclic guanosine monophosphate in the intestinal cells. This results in greater secretion of chloride and bicarbonate ions and intestinal fluid, as well as more rapid intestinal transit. Clinical trials have demonstrated improvements in bowel movements and reduction in abdominal discomfort, although diarrhoea is a recognised adverse effect (see **Corsetti and Whorwell, 2016**). **Plecanatide** is a uroguanylin analogue that works in a similar way to **linaclotide**.

An alternative method of promoting softer stools and increasing stool frequency is to block sodium reabsorption in the small intestine. This can be achieved by inhibiting the sodium/hydrogen exchanger isoform 3, which is an antiporter found in the apical membrane of intestinal cells. **Tenapanor** (licensed in the United States) acts locally on the gut to promote sodium excretion and increased frequency of bowel movements in those with IBS-C.

Ulcerative colitis and *Crohn's disease* are forms of IBD, affecting the colon or ileum. They are autoimmune inflammatory disorders, which can be severe and progressive, requiring long-term drug treatment with anti-inflammatory and immunosuppressant drugs

(see **Ch. 25**), and occasionally surgical resection. The following agents are commonly used.

Glucocorticoids

Glucocorticoids are potent anti-inflammatory agents and are dealt with in **Chapters 25** and **33**. The drugs of choice are generally **prednisolone** or **budesonide** (although others can be used). They are administered orally or locally into the bowel by suppository or enema.

Aminosalicylates

While glucocorticoids are useful for the acute attacks of IBDs, they are not ideal for long-term treatment because of their side effects. Maintenance of remission in both ulcerative colitis and Crohn's disease is generally achieved with aminosalicylates, although they are less useful in the latter condition.

Sulfasalazine consists of the sulfonamide **sulfapyridine** linked to 5-aminosalicylic acid (5-ASA). The latter forms the active moiety when it is released in the colon. Its mechanism of action is obscure. It may reduce inflammation by scavenging free radicals, by inhibiting PG and leukotriene production and/or by decreasing neutrophil chemotaxis and superoxide generation. Its unwanted effects include diarrhoea, salicylate sensitivity and interstitial nephritis. **5-ASA** is not absorbed, but the **sulfapyridine** moiety, which seems to be therapeutically inert in this instance, is absorbed, and its unwanted effects are those associated with the sulfonamides (see **Ch. 52**).

Newer compounds in this class, which presumably share a similar mechanism of action, include **mesalazine** (**5-ASA** itself),

olsalazine (a **5-ASA** dimer linked by a bond that is hydrolysed by colonic bacteria) and **balsalazide** (a prodrug from which **5-ASA** is also released following hydrolysis of a diazo linkage).

Other Drugs

Methotrexate and the immunosuppressants **ciclosporin**, **tacrolimus**, **azathioprine** and **6-mercaptopurine** (see **Ch. 25**) are also sometimes used in patients with severe IBD. The biopharmaceuticals **infliximab, adalimumab** and **golimumab**, monoclonal antibodies directed against tumour necrosis factor (TNF)-α (see **Ch. 25**), have also been used with success. These drugs are expensive, and their principal indication is for moderate and severe IBD that is unresponsive to glucocorticoids or immunomodulators.

Newer biopharmaceutical agents have been developed towards alternative targets in the inflammatory pathway. **Vedolizumab** is a humanised monoclonal antibody with specific binding properties for α4β7 integrin on T-helper lymphocytes that migrate to the gut. The inhibition of α4β7 integrin stops the interaction of these lymphocytes with mucosal addressin cell adhesion molecule-1 on gut epithelial cells, thus reducing the inflammatory effects in the bowel tissue that arise from trans-migration of T lymphocytes. In contrast, **ustekinumab** is targeted at the p40 protein subunit of interleukin (IL)-12 and IL-23 and prevents these cytokines from binding to IL-12Rβ1 receptors on immune cells. **Vedolizumab** and **ustekinumab** are indicated in those with moderately to severely active IBD, who have not responded to or cannot tolerate conventional treatment and other biopharmaceuticals.

The antiallergy drug sodium **cromoglicate** (see **Ch. 28**) is sometimes used for treating GI symptoms associated with food allergies.

Drugs Affecting the Biliary System

The commonest pathological condition of the biliary tract is *cholesterol cholelithiasis* – the formation of gallstones with high cholesterol content. Surgery is generally the preferred option in patients who are troubled by symptoms such as pain and infection. There are orally active drugs that dissolve non-calcified 'radiolucent' cholesterol gallstones. The principal agent is **ursodeoxycholic acid**, a minor constituent of human bile (but the main bile acid in the bear, hence *urso*-) but there is little evidence of therapeutic benefit. Diarrhoea is the main unwanted effect.

Biliary colic, the pain produced by the passage of gallstones through the bile duct, can be very intense, and immediate relief may be required. Clinical trials have demonstrated the efficacy of NSAIDs in relieving the pain of biliary colic, whilst opioid analgesics such as **morphine** and **pethidine** can also be used. Previous suggestions that morphine may have an undesirable local effect because it constricts the sphincter of Oddi and raises the pressure in the bile duct have not been borne out in clinical practice. Anticholinergic drugs (such as **dicyclomine**) are commonly employed to relieve biliary spasm and may be used in conjunction with morphine. **Glyceryl trinitrate** (see **Ch. 19**) can produce a marked fall of intrabiliary pressure and may be used to relieve biliary spasm.

Future Directions

The quest for novel antisecretory drugs is an ongoing task. Among the newer agents that have undergone evaluation are gastrin/CCK-2 receptor antagonists (with little success) and potassium competitive acid-blocking drugs (**Inatomi et al., 2016**). The latter agents work because potassium ions are exchanged for protons by the proton pump (see **Fig. 30.1**) and so potassium antagonists with rapid onset of action and sustained effect would represent a promising modality for inhibiting the secretion of acid. Unfortunately, the agents produced so far have not been proven conclusively to be superior to proton pump inhibitors, and currently, the available agents (**revaprazan**, **vonoprazan, tegoprazan**) are use in a limited number of conditions such as gastritis, erosive oesophagitis, and *H.pylori* eradication. The pharmacological therapy of IBS also remains a major challenge because of the complex interconnected networks of the gut–brain axis.

QUESTIONS

QUESTION 30.1

Parietal cells of the stomach secrete hydrochloric acid to aid digestion and kill pathogens.

Which of the following mediators provides the main stimulus for gastric acid secretion?

OPTIONS:

A. Acetylcholine acting on M_2 receptors

B. Histamine acting on H_2 receptors

C. Gastrin acting on cholecystokinin $(CCK)_1$ receptors

D. Somatostatin (SST) acting on SST_2 receptors

E. Prostaglandin (PG)E_2 acting on $EP_{2/3}$ receptors

QUESTION 30.2

Parietal cells secrete an isotonic solution of HCl, involving several different transporters and enzymes to facilitate the uptake and secretion of the H^+ and Cl^- ions.

Which of the following statements about the mechanism of acid production is incorrect?

OPTIONS:

A. Acid production involves the enzyme carbonic anhydrase.

B. Cl^- is actively transported into *canaliculi* in the cells.

C. The K^+ is exchanged for H^+ from within the cell by a K^+-H^+-ATPase.

D. Acid is secreted from gastric parietal cells by a proton pump.

E. Chloride ions are transported across the membrane with bicarbonate ions using a Cl^-/HCO_3^- symport.

ANSWERS

ANSWER 30.1

RATIONALE:

A. Acetylcholine activation of M_3 receptors on parietal cells increases gastric acid secretion.

B.

C. Gastrin acts on CCK_2 receptors on enterochromaffin-like (ECL) cells to stimulate acid secretion.

D. SST inhibits various components of the pathway, reducing parietal cell acid secretion.

E. Prostaglandins exert 'cytoprotective' effects on many aspects of gastric function including reducing gastric acid output, probably by acting on $EP_{2/3}$ receptors on ECL cells.

CORRECT ANSWER WITH EXPLANATION:

B. Histamine acting on H_2 receptors

Histamine released from ECL binding to H_2 receptors on the parietal cells causes an increase in cAMP to activate the secretion of protons.

ANSWER 30.2

RATIONALE:

A. This enzyme catalyses the combination of CO_2 and water to carbonic acid, which dissociates to release a proton (required for acid production) and a bicarbonate ion (exchanged across the membrane for Cl^-).

B. Cl^- is actively transported into *canaliculi* in the cells that communicate with the lumen of the gastric glands and thus with the stomach itself. This is accompanied by K^+ secretion.

C. This is the proton pump required to transport H^+ ions from the parietal cells into the lumen where they combine with Cl^- ions to form HCl.

D. Acid is secreted from gastric parietal cells by a proton pump (K^+-H^+-ATPase) stimulated by histamine, acetylcholine and gastrin.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Chloride ions are transported across the membrane with bicarbonate ions using a Cl^-/HCO_3^- symport.

HCO_3^- generated in the parietal cells is exchanged for Cl^- via an antiport, enabling transport of Cl^- across the cell into the lumen.

[1] Or GERD in the United States, to reflect the different spelling of *esophageal*.

[2] These two peptides share the same, biologically active, C-terminal pentapeptide sequence.

[3] *H. pylori* infection in the stomach has also been classified as a class 1 (definite) carcinogen for gastric cancer.

4 This era has been referred to as the 'BC' – before cimetidine – era of gastroenterology (Schubert and Peura, 2008)! It is an indication of the clinical importance of the development of this drug.

5 There was a suggestion – no longer widely believed – that aluminium could trigger Alzheimer's disease. In fact, aluminium is not absorbed to any significant extent following oral administration of aluminium hydroxide, although when introduced by other routes (e.g. during renal dialysis with aluminium-contaminated solutions) it is extremely toxic.

6 From the Persian word meaning 'a cure for poisoning'. It refers to the belief that a concoction made from lumps of impacted rubbish retrieved from the stomach of goats would protect against poisoning by one's enemies.

7 In fact, the word *nausea* is derived from the Greek word meaning 'boat', with the obvious implication of associated motion sickness. *Vomiting* is derived from a Latin word and a *vomitorium* was the 'fast exit' passageway in ancient theatres. It has a certain resonance, as we think you will agree!

8 It was reported that a young, medically qualified patient being treated by combination chemotherapy for sarcoma stated that 'the severity of vomiting at times made the thought of death seem like a welcome relief'.

9 A disabling condition named after the eponymous French physician who discovered that the nausea and vertigo that characterise this condition were associated with a disorder of the inner ear.

31: The control of blood glucose and drug treatment of diabetes mellitus

OVERVIEW

In this chapter we describe the endocrine control of blood glucose by pancreatic hormones, especially *insulin* but also *glucagon* and *somatostatin*, and the gut hormones (*incretins*) *glucagon-like peptide-1* (GLP-1) and *gastric inhibitory peptide* (GIP, also known as glucose-dependent insulinotropic peptide). This underpins coverage of diabetes mellitus and its treatment with insulin preparations (including insulin analogues), and other hypoglycaemic agents – metformin, sulfonylureas, α-glucosidase inhibitors, incretin mimetics such as the GLP-1 receptor agonists and gliptins (which potentiate incretins by blocking their degradation), and renal tubular sodium–glucose co-transport (SGLT) inhibitors, notably the SGLT2 inhibitors.

Introduction

Insulin is the main hormone controlling intermediary metabolism. Its most striking acute effect is to lower blood glucose. Reduced or absent secretion of insulin causes *diabetes mellitus*. It is often coupled with reduced sensitivity to its action, 'insulin resistance',

which is closely related to obesity. Diabetes mellitus, recognised since ancient times, is named for the production of sugary urine in copious volumes (due to the osmotic diuretic action of the high urine glucose concentration). Diabetes is rapidly increasing to epidemic proportions (in step with obesity, see **Ch. 32**), and its consequences are dire – especially accelerated atherosclerosis (myocardial and cerebral infarction, gangrene or limb amputation), kidney failure, neuropathy and blindness.

In this chapter, we first describe the control of blood sugar. The second part of the chapter is devoted to the different kinds of diabetes mellitus and the role of drugs in their treatment. Diabetes, along with obesity (see **Ch. 32**), hypertension (see **Ch. 21**), dyslipidaemia (see **Ch. 22**), and fatty infiltration of the liver, comprise a 'metabolic syndrome', a common pathological cluster and a rapidly growing problem that is associated with many life-threatening conditions. Drugs that act on some of the many mechanisms that become deranged in metabolic syndrome, including several directed at controlling blood sugar, have been developed, but clinical success has been modest so far.

Control of Blood Glucose

Glucose is the obligatory source of energy for the adult human brain, and physiological control of blood glucose reflects the need to maintain adequate fuel supplies in the face of intermittent food intake and variable metabolic demands. More fuel is made available by feeding than is required immediately, and excess calories are stored as glycogen or fat. During fasting, these energy stores need to be mobilised in a regulated manner. The most important regulatory

hormone is *insulin*, the actions of which are described later. Increased blood glucose stimulates insulin secretion (**Fig. 31.1**), whereas reduced blood glucose reduces insulin secretion. The effect of glucose on insulin secretion depends on whether the glucose load is administered intravenously or by mouth. Glucose administered by mouth is more effective in stimulating insulin secretion because it stimulates release from the gut of *incretin* hormones which promote insulin secretion (see **Fig. 31.1**). Glucose is less effective in stimulating insulin secretion in patients with diabetes (**Fig. 31.2**). *Hypoglycaemia*, caused by excessive exogenous insulin, not only reduces endogenous insulin secretion but also elicits secretion of an array of 'counter-regulatory' hormones, including *glucagon*, *adrenaline* (see **Ch. 15**), *glucocorticoids* (see **Ch. 33**) and *growth hormone* (see **Ch. 33**), all of which increase blood glucose. Their main effects on glucose uptake and carbohydrate metabolism are summarised and contrasted with those of insulin in **Table 31.1**.

The kidneys also have an important role in glucose regulation. Substantial amounts of glucose (approximately 900 mmol or 160 g) are filtered each day from the plasma into the renal tubules (**Abdul-Ghani et al., 2015**). However, in those with normal glucose homeostasis, very little or no glucose is excreted in the urine because renal tubular SGLTs reclaim all the filtered glucose. The co-transporters are large transmembrane proteins (670 amino acids) that actively transport glucose against the concentration gradient through a mechanism that involves coupling with sodium transport (**Abdul-Ghani et al., 2011**). There are two SGLT variants in the kidney – SGLT2 (located in the early convoluted segment of the proximal tubule) has low affinity but high capacity

and is responsible for reclaiming about 90% of the filtered renal glucose, whilst the remaining 10% is reclaimed by high-affinity, low-capacity SGLT1 (located further on in the distal straight segment of the proximal tubule; **DeFronzo et al., 2012**). SGLT1 is also found in the heart, lungs and gastrointestinal (GI) tract, whereas SGLT2 is principally located in the kidney so selective inhibitors of SGLT2 can promote glucose excretion without influencing glucose transport in other organs.

The evolutionary role of SGLT in the kidney has been attributed to the benefits of retaining glucose in times when starvation or food shortages were commonplace. However, when the renal capacity for glucose re-absorption is exceeded in diabetes, glucose spills over into the urine (glycosuria) and causes an osmotic diuresis (polyuria) which, in turn, results in dehydration, thirst and increased drinking (polydipsia). The chronically elevated glucose concentrations in patients with diabetes leads to up-regulation of SGLT2 expression and greater re-absorption of glucose, thus reducing glycosuria at the expense of worsening hyperglycaemia (**DeFronzo et al., 2012**). Because SGLT2 is a co-transporter that reabsorbs sodium ions with glucose, its increased expression also causes salt retention and hypertension.

Table 31.1

GIP, Gastric inhibitory peptide; *GLP-1,* glucagon-like peptide-1.

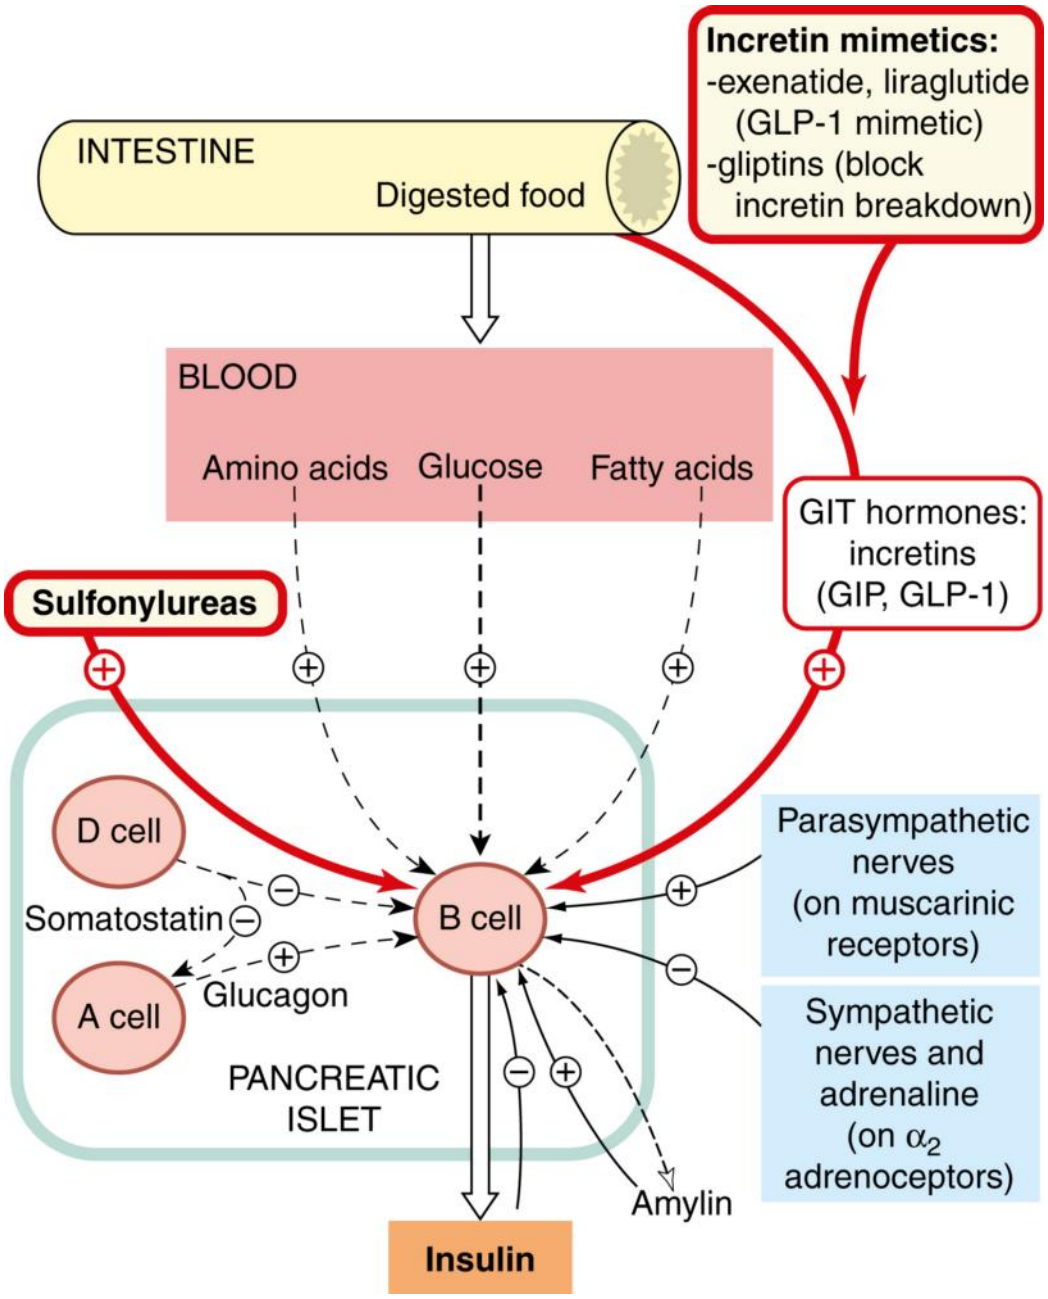

FIG. 31.1 Factors regulating insulin secretion.Blood glucose is the most important factor. Drugs used to stimulate insulin secretion are shown in *red-bordered boxes*. Glucagon potentiates insulin release but opposes some of its peripheral actions and increases blood

glucose. *GIP*, Gastric inhibitory peptide; *GIT*, gastrointestinal tract; *GLP-1,* glucagon-like peptide-1.

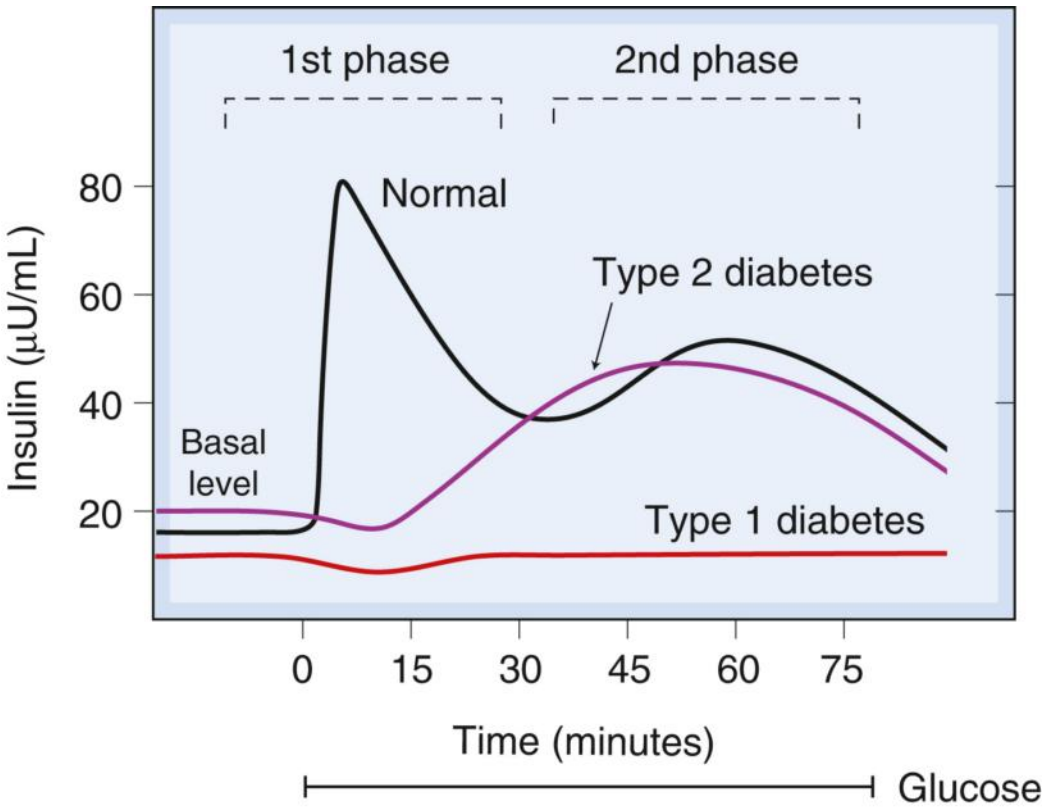

FIG. 31.2 Schematic diagram of the two-phase release of insulin in response to a constant glucose infusion.The first phase is missing in type 2 (non-insulin-dependent) diabetes mellitus, and both are missing in type 1 (insulin-dependent) diabetes mellitus. The first phase is also produced by amino acids, sulfonylureas, glucagon and gastrointestinal tract hormones. Data from Pfeifer, M.A., Halter, J.B., Porte, D. Jr., 1981. Insulin secretion in diabetes mellitus. Am. J. Med. 70, 579–588.

Pancreatic Islet Hormones

The islets of Langerhans, the endocrine part of the pancreas, contain four main types of peptide-secreting cells: β (or B) cells secrete *insulin*, α (or A) cells secrete *glucagon*, δ (or D) cells secrete *somatostatin,* PP cells secrete *pancreatic polypeptide* (PP) plus ε (or E) cells which are present in the developing pancreas and secrete *ghrelin*, a peptide hormone that is involved in food intake and energy homeostasis (see **Ch. 32**).

Table 31.2

Effects of insulin on carbohydrate, fat and protein metabolism

Type of metabolism	Liver cells	Fat cells	Muscle
Carbohydrate metabolism	↓ Gluconeogenesis ↓ Glycogenolysis ↑ Glycolysis ↑ Glycogenesis	↑ Glucose uptake ↑ Glycerol synthesis	↑ Glucose uptake ↑ Glycolysis ↑ Glycogenesis
Fat metabolism	↑ Lipogenesis ↓ Lipolysis	↑ Synthesis of triglycerides ↑ Fatty acid synthesis ↓ Lipolysis	
Protein metabolism	↓ Protein breakdown	–	↑ Amino acid uptake ↑ Protein synthesis

PP is a 36-amino acid peptide closely related to neuropeptide Y (see **Ch. 13**) and peptide YY (see **Ch. 32**). It is released by eating a meal and is implicated in control of food intake (see **Ch. 32**). The core of each islet contains mainly the predominant β cells surrounded by a mantle of α cells interspersed with δ cells or PP cells (see **Fig. 31.1**). In addition to insulin, β cells secrete a peptide known as islet amyloid polypeptide or amylin, which delays gastric emptying and opposes insulin by stimulating glycogen breakdown in striated muscle, and C-peptide (see later). Glucagon opposes

insulin, increasing blood glucose and stimulating protein breakdown in muscle. Somatostatin inhibits secretion of insulin and of glucagon. It is widely distributed outside the pancreas and is also released within the hypothalamus, inhibiting the release of growth hormone from the pituitary gland (see **Ch. 33**).

Insulin

Insulin was the first protein for which the amino acid sequence was determined (by Sanger's group in Cambridge in 1955). It consists of two peptide chains (of 21 and 30 amino acid residues) linked by two disulfide bonds.

Synthesis and Secretion

Like other peptide hormones (see **Ch. 17**), insulin is synthesised as a precursor (preproinsulin) in the rough endoplasmic reticulum. Preproinsulin is transported to the Golgi apparatus, where it undergoes proteolytic cleavage to proinsulin and then to insulin plus a fragment of uncertain function called C-peptide. [1] Insulin and C-peptide are stored in granules in β cells, and are normally co-secreted by exocytosis in equimolar amounts together with smaller and variable amounts of proinsulin.

The main factor controlling the synthesis and secretion of insulin is the blood glucose concentration (see **Fig. 31.1**). β Cells respond both to the absolute glucose concentration and to the rate of change of blood glucose. Other physiological stimuli to insulin release include amino acids (particularly arginine and leucine), fatty acids, the parasympathetic nervous system and *incretins* (especially *GLP-1* and *GIP*, see later). Pharmacologically, sulfonylurea drugs (see later) act by releasing insulin.

There is a steady basal release of insulin and an increase in blood glucose stimulates an additional response. This response has two phases: an initial rapid phase reflecting release of stored hormone, and a slower, delayed phase reflecting continued release of stored hormone and new synthesis (see **Fig. 31.2**). The response is abnormal in diabetes mellitus, as discussed later.

ATP-sensitive potassium channels (K_{ATP}; see **Ch. 4**) determine the resting membrane potential in β cells. Glucose enters β cells via a surface membrane transporter called Glut-2, and its subsequent metabolism via glucokinase (which is the rate-limiting glycolytic enzyme in β cells) links insulin secretion to extracellular glucose. The consequent rise in ATP within β cells blocks K_{ATP} channels, causing membrane depolarisation. Depolarisation opens voltage-dependent calcium channels, leading to Ca^{2+} influx. This triggers insulin secretion in the presence of amplifying messengers, including diacylglycerol, non-esterified arachidonic acid (which facilitates further Ca^{2+} entry) and 12-lipoxygenase products of arachidonic acid (mainly *12*-S-*hydroxyeicosatetraenoic acid* or 12-*S*-HETE; see **Ch. 17**). Phospholipases are commonly activated by Ca^{2+}, but free arachidonic acid is liberated in β cells by an ATP-sensitive Ca^{2+}-insensitive (ASCI) phospholipase A_2. Consequently, in β cells, Ca^{2+} entry and arachidonic acid production are both driven by ATP, linking cellular energy status to insulin secretion.

Insulin release is inhibited by the sympathetic nervous system (see **Fig. 31.1**). Adrenaline (epinephrine) increases blood glucose by inhibiting insulin release (via α_2 adrenoceptors on β-cells in the islets) and by promoting glycogenolysis via β_2 adrenoceptors in striated muscle and liver. Several peptides, including somatostatin,

galanin (an endogenous K_{ATP} activator) and amylin, also inhibit insulin release.

About one-fifth of the insulin stored in the pancreas of the human adult is secreted daily. The plasma insulin concentration after an overnight fast is 20–50 pmol/L. Plasma insulin concentration is reduced in patients with type 1 (insulin-dependent) diabetes mellitus (see later), and markedly increased in patients with *insulinomas* (uncommon functioning tumours of β cells), as is C-peptide, with which it is co-released. [2] It is also raised in obesity and other normoglycaemic insulin-resistant states.

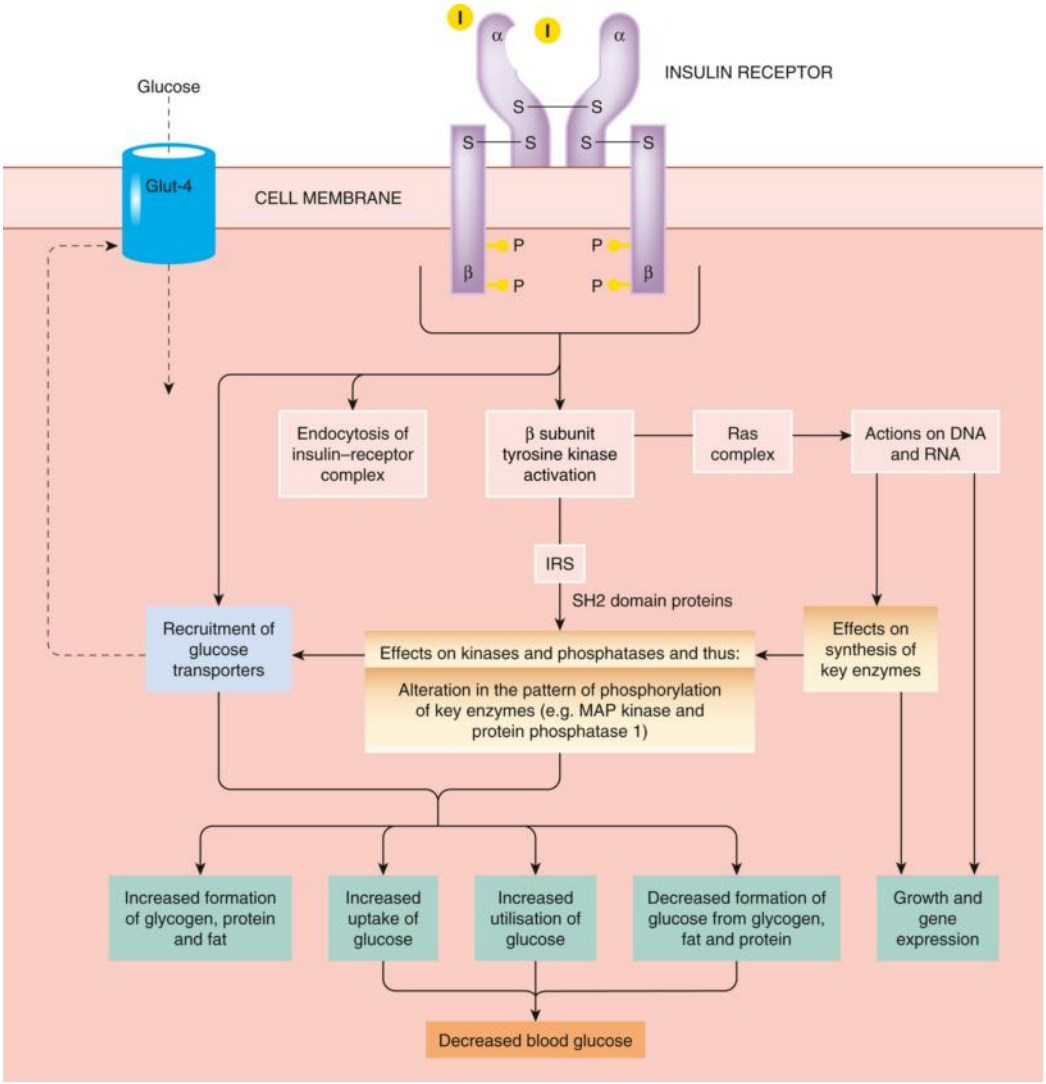

FIG. 31.3 Insulin signalling pathways. *I,* Insulin; *Glut-4,* an insulin-sensitive glucose transporter present in muscle and fat cells; *IRS,* insulin receptor substrate (several forms: 1–4).

Actions

Insulin is the main hormone controlling intermediary metabolism, with actions on liver, fat and muscle (**Table 31.2**). It is an *anabolic hormone*: its overall effect is to conserve fuel by facilitating the

uptake and storage of glucose, amino acids and fats after a meal. Acutely, it reduces blood glucose. Consequently, a fall in plasma insulin increases blood glucose. The biochemical pathways through which insulin exerts its effects are summarised in **Fig. 31.3**, and molecular aspects of its mechanism are discussed later.

Insulin influences glucose metabolism in most tissues, especially the liver, where it inhibits glycogenolysis (glycogen breakdown) and gluconeogenesis (synthesis of glucose from non-carbohydrate sources) while stimulating glycogen synthesis. It also increases glucose utilisation by glycolysis, but the overall effect is to increase hepatic glycogen stores.

In muscle, unlike liver, uptake of glucose is slow and is the rate-limiting step in carbohydrate metabolism. Insulin causes a glucose transporter called Glut-4, which is sequestered in vesicles, to be expressed within minutes on the surface membrane. This facilitates glucose uptake, and stimulates glycogen synthesis and glycolysis.

Insulin increases glucose uptake by Glut-4 in adipose tissue as well as in muscle. One of the main products of glucose metabolism in adipose tissue is glycerol, which is esterified with fatty acids to form triglycerides, thereby affecting fat metabolism (see **Table 31.2**).

Insulin increases synthesis of fatty acid and triglyceride in adipose tissue and in liver. It inhibits lipolysis, partly via dephosphorylation – and hence inactivation – of lipases (see **Table 31.2**). It also inhibits the lipolytic actions of adrenaline, growth hormone and glucagon by opposing their actions on adenylyl cyclase.

Insulin stimulates uptake of amino acids into muscle and increases protein synthesis. It also decreases protein catabolism and inhibits oxidation of amino acids in the liver.

Other metabolic effects of insulin include transport into cells of K^+, Ca^{2+}, nucleosides and inorganic phosphate. [3]

Long-term effects of insulin

In addition to rapid effects on metabolism, exerted via altered activity of enzymes and transport proteins, insulin has long-term actions via altered enzyme synthesis. It is an important anabolic hormone during fetal development. It stimulates cell proliferation (mitogenic action) and is implicated in somatic and visceral growth and development.

Mechanism of action

Insulin binds to a specific receptor on the surface of its target cells. The receptor is a large transmembrane glycoprotein complex belonging to the tyrosine kinase-linked type 3 receptor superfamily (see **Ch. 3**) and consisting of two α and two β subunits (see **Fig. 31.3**).

Occupied receptors aggregate into clusters, which are subsequently internalised in vesicles, resulting in down-regulation. Internalised insulin is degraded in lysosomes, but the receptors are recycled to the plasma membrane.

The signal transduction mechanisms that link receptor binding to the biological effects of insulin are complex. Receptor autophosphorylation – the first step in signal transduction – is a consequence of dimerisation, allowing each receptor to phosphorylate the other, as explained in **Chapter 3**.

Insulin receptor substrate (IRS) proteins undergo rapid tyrosine phosphorylation specifically in response to insulin and insulin-like growth factor-1 but not to other growth factors. The best-characterised substrate is IRS-1, which contains 22 tyrosine residues that are potential phosphorylation sites. It interacts with proteins that contain a so-called SH2 domain (see **Ch. 3**, **Fig. 3.15**), thereby passing on the insulin signal. Knock-out mice lacking IRS-1 are hyporesponsive to insulin (insulin-resistant) but do not become diabetic, because of robust β-cell compensation with increased insulin secretion. By contrast, mice lacking IRS-2 fail to compensate and develop overt diabetes, implicating the IRS-2 gene as a candidate for human type 2 diabetes (IRS proteins are reviewed by **Lavin et al., 2016**). Activation of phosphatidylinositol 3-kinase by the interaction of its SH2 domain with phosphorylated IRS has several important effects, including recruitment of insulin-sensitive glucose transporters (Glut-4) from the Golgi apparatus to the plasma membrane in muscle and fat cells.

The longer-term actions of insulin entail effects on DNA and RNA, mediated partly at least by the Ras signalling complex. Ras is a protein that regulates cell growth and cycles between an active GTP-bound form and an inactive GDP-bound form (see Chs **3** and **57**). Insulin shifts the equilibrium in favour of the active form and initiates a phosphorylation cascade that results in activation of mitogen-activated protein kinase (MAP-kinase), which in turn activates several nuclear transcription factors, leading to the expression of genes that are involved with cell growth and with intermediary metabolism.

Insulin for treatment of diabetes mellitus is considered later in this chapter.

Glucagon

Synthesis and Secretion

Glucagon is a single-chain polypeptide of 21 amino acid residues synthesised mainly in the α cell of the islets, but also in the upper GI tract. It has considerable structural homology with other GI tract hormones, including secretin, vasoactive intestinal peptide and GIP (see **Ch. 30**).

Amino acids (especially L-arginine) stimulate glucagon secretion, as does ingestion of a high-protein meal, but diurnal variation in plasma glucagon concentrations is less than for insulin. Glucagon secretion is stimulated by low and inhibited by high concentrations of glucose and fatty acids in the plasma. Sympathetic nerve activity and circulating adrenaline stimulate glucagon release via β adrenoceptors. Parasympathetic nerve activity also increases secretion, whereas somatostatin, released from δ cells adjacent to the glucagon-secreting α cells in the periphery of the islets, inhibits glucagon release.

Endocrine pancreas and blood glucose

- Islets of Langerhans secrete insulin from β (or B) cells, glucagon from α cells and somatostatin from δ cells.
- Many factors stimulate insulin secretion, but the main one is blood glucose. Incretins, especially GIP and GLP-1 secreted, respectively, by K and L cells in the gut, are also important.

- Insulin is a fuel-storage hormone and also affects cell growth and differentiation. It decreases blood glucose by:
  - increasing glucose uptake into muscle and fat via Glut-4
  - increasing glycogen synthesis
  - decreasing gluconeogenesis
  - decreasing glycogen breakdown.
- Glucagon is a fuel-mobilising hormone, stimulating gluconeogenesis and glycogenolysis, also lipolysis and proteolysis. It increases blood sugar and also increases the force of contraction of the heart (positive inotrope).
- Diabetes mellitus is a chronic metabolic disorder in which there is hyperglycaemia. There is a spectrum of pathologies. Two main phenotypes are:
  - type 1 diabetes, with an absolute deficiency of insulin;
  - type 2 diabetes, with a relative deficiency of insulin associated with reduced sensitivity to its action (insulin resistance).

Actions

Glucagon increases blood glucose and causes breakdown of fat and protein. It acts on specific G protein–coupled receptors to stimulate adenylyl cyclase, and its actions are somewhat similar to β-adrenoceptor–mediated actions of adrenaline. Unlike adrenaline, however, its metabolic effects are more pronounced than its cardiovascular actions. Glucagon is proportionately more active on liver, while the metabolic actions of adrenaline are more pronounced on muscle and fat. Glucagon stimulates glycogen

breakdown and gluconeogenesis, and inhibits glycogen synthesis and glucose oxidation. Its metabolic actions on target tissues are thus the opposite of those of insulin. Glucagon increases the rate and force of contraction of the heart (positive inotropic effect; see **Ch. 20**), although less markedly than adrenaline.

The clinical uses of glucagon are summarised in the clinical box.

Clinical uses of glucagon

- **Glucagon** can be given intramuscularly or subcutaneously as well as intravenously.
- Treatment of *hypoglycaemia* in unconscious patients (who cannot drink); unlike intravenous glucose, it can be administered by non-medical personnel (e.g. spouses or ambulance crew). It is useful if obtaining intravenous access is difficult.
- Treatment of hypotension, *cardiac failure* or *shock* precipitated by acute overdosage of β-adrenoceptor antagonists.

Somatostatin

Somatostatin is secreted by the δ cells of the islets. It is also generated and released in the hypothalamus, where it inhibits the release of growth hormone (see **Ch. 33**). In the islet, it inhibits release of insulin and of glucagon. **Octreotide** is a long-acting analogue of somatostatin. It inhibits release of a number of hormones and is used clinically to relieve symptoms from

mediators (such as VIP and 5-HT) secreted by several uncommon gastroentero-pancreatic endocrine tumours, and for treatment of acromegaly [4] (the endocrine disorder caused by a functioning tumour of cells that secrete growth hormone from the anterior pituitary; see **Ch. 33**).

Amylin (Islet Amyloid Polypeptide)

Amylin is a 37–amino acid residue peptide stored with insulin in secretory granules in β cells and is co-secreted with insulin. The role of amylin in glucose regulations stems from its effect on delaying gastric emptying and promoting satiety (see **Ch. 32**). **Pramlintide**, an amylin analogue with three proline substitutions that reduce its tendency to aggregate into insoluble fibrils, is approved in the United States to treat patients with type 1 diabetes and those with type 2 diabetes who use mealtime insulin but have not achieved satisfactory glucose control. It is injected subcutaneously before each major meal as an adjunct to insulin and reduces insulin requirements. Pramlintide reduces the speed of gastric emptying and decreases the postprandial rise in glucagon. Unwanted effects include hypoglycaemia and nausea – it is contraindicated in patients with loss of gastric motility (gastroparesis), a complication of diabetic autonomic neuropathy.

Incretins

La Barre suggested in the 1930s that crude secretin contained two active principles: ‘excretin’, which stimulates the exocrine pancreas, and ‘incretin’, which stimulates insulin release. He proposed that incretin presented possibilities for the treatment of diabetes.

‘Excretin’ did not catch on (perhaps not helped by an unfortunate association with other bodily functions – at least to an Anglo-Saxon ear), but ‘incretin’ has gone from strength to strength, and some 90 years later several incretin-based drugs are now licensed for clinical use (see later). Incretin action proved to be due to peptide hormones released from the gut, mainly *GIP* and *GLP-1*. These are both members of the glucagon peptide superfamily (see **Ch. 17**). GIP is a 42–amino acid peptide stored in and secreted by enteroendocrine K cells in the duodenum and proximal jejunum. GLP-1 is secreted by L cells which are more widely distributed in the gut, including in the ileum and colon as well as more proximally. Two forms of GLP-1 are secreted after a meal: GLP-1(7-37) and GLP-1(7-36) amide; these are similarly potent. Most of the circulating activity is due to GLP-1(7-36) amide. Release of GIP and GLP-1 by ingested food provides an early stimulus to insulin secretion before absorbed glucose or other products of digestion reach the islet cells in the portal blood (see **Fig. 31.1**). As well as stimulating insulin secretion, both these hormones inhibit pancreatic glucagon secretion and slow the rate of absorption of digested food by reducing gastric emptying. They are also implicated in control of food intake via appetite and satiety (see **Ch. 32**). The actions of GIP and GLP-1 are terminated rapidly by dipeptidyl peptidase-4 (DPP-4). This enzyme is a membrane glycoprotein with rather wide substrate specificity; in clinical practice, the DPP-4 inhibitors are licensed to treat diabetes (see later).

Diabetes Mellitus

Diabetes mellitus is a chronic metabolic disorder characterised by a high blood glucose concentration – persistent hyperglycaemia (fasting plasma glucose >7.0 mmol/L, or plasma glucose >11.1 mmol/L) – caused by insulin deficiency, often combined with insulin resistance. There are a wide spectrum of aetiologies from single gene disorders through autoimmune disease, gestational diabetes, various pancreatic pathologies such as chronic alcoholic pancreatitis and many more. Two main phenotypes diabetes mellitus are:

1. **Type 1 diabetes** (previously known as insulin-dependent diabetes mellitus – IDDM – or juvenile-onset diabetes), in which there is an absolute deficiency of insulin, often caused by auto-immune destruction of the pancreatic b-cells.
2. **Type 2 diabetes** (previously known as non-insulin-dependent diabetes mellitus – NIDDM – or maturity-onset diabetes), in which there is a relative deficiency of insulin associated with reduced sensitivity to its action (insulin resistance).

Hyperglycaemia occurs because of uncontrolled hepatic glucose output and reduced uptake of glucose by skeletal muscle with reduced glycogen synthesis. Insulin deficiency causes muscle wasting through increased breakdown and reduced synthesis of proteins. Diabetic ketoacidosis (DKA) is an acute emergency that is predominantly seen in patients with type 1 diabetes. It develops in the absence of insulin because of accelerated breakdown of fat to acetyl-CoA, which, in the absence of aerobic carbohydrate

metabolism, is converted to acetoacetate and β-hydroxybutyrate (which cause acidosis) and acetone (a ketone).

Various complications develop as a consequence of the metabolic derangements in diabetes, often over several years. Many of these are the result of disease of blood vessels, either large (macrovascular disease) or small (microangiopathy). Dysfunction of vascular endothelium (see **Ch. 21**) is an early and critical event in the development of vascular complications. Oxygen-derived free radicals, protein kinase C and non-enzymic products of glucose and albumin called *advanced glycation end products* (AGEs) have been implicated. Macrovascular disease consists of accelerated atheroma (see **Ch. 22**) and its thrombotic complications (see **Ch. 23**), which are commoner and more severe in patients with diabetes. Microangiopathy is a distinctive feature of diabetes mellitus and particularly affects the retina, kidney and peripheral nerves. Diabetes mellitus is the commonest cause of chronic renal failure, a huge and rapidly increasing problem, and a major burden to society as well as to individual patients. Co-existent hypertension promotes progressive renal damage, and treatment of hypertension slows the progression of diabetic nephropathy and reduces the risk of myocardial infarction. Angiotensin-converting enzyme inhibitors or angiotensin receptor antagonists (see **Ch. 21**) are more effective in preventing diabetic nephropathy than other antihypertensive drugs, perhaps because they prevent fibroproliferative actions of angiotensin II and aldosterone.

Diabetic neuropathy [5] is associated with accumulation of osmotically active metabolites of glucose, produced by the action of aldose reductase, but *aldose reductase inhibitors* have been

disappointing as therapeutic drugs (see **Farmer et al., 2012**, for a review).

Type 1 diabetes can occur at any age, but patients are often, but by no means always, young (children or adolescents) and not obese when they first develop symptoms. There is an inherited predisposition, with a 10- to 15-fold increased incidence in first-degree relatives of an index case, and strong associations with particular histocompatibility antigens (HLA types). Identical twins are less than fully concordant, so environmental factors such as viral infection (e.g. with coxsackie virus or echovirus) are believed to be necessary for genetically predisposed individuals to express the disease. Viral infection may damage pancreatic β cells and expose antigens that initiate a self-perpetuating autoimmune process. The patient becomes overtly diabetic only when more than 90% of the β cells have been destroyed. This natural history provides a tantalising prospect of intervening in the prediabetic stage, and a variety of strategies have been mooted, including immunosuppression, early insulin therapy, antioxidants, nicotinamide and many others; so far these have disappointed, but this remains a very active field.

Type 2 diabetes is accompanied both by insulin resistance (which precedes overt disease) and by impaired insulin secretion, each of which are important in its pathogenesis. Such patients are often obese and usually, although again by no means always, present in adult life, the incidence rising progressively with age as β-cell function declines. Treatment is initially dietary, although oral hypoglycaemic drugs usually become necessary, and most patients ultimately benefit from exogenous insulin. Prospective studies have

demonstrated a relentless deterioration in diabetic control [6] with increasing age and duration of disease.

Insulin secretion (basal, and in response to a meal) in a patient with type 1 or type 2 diabetes is contrasted schematically with that in a healthy control in **Fig. 31.2**.

There are many other less common forms of diabetes mellitus in addition to the two main ones described earlier (for example, syndromes associated with autoantibodies directed against insulin receptors which cause severe insulin resistance, functional α-cell tumours, 'glucagonomas', and many other rarities), and hyperglycaemia can also be a clinically important adverse effect of several drugs, including glucocorticoids (see **Ch. 33**), high doses of thiazide diuretics (see **Ch. 29**) and several of the protease inhibitors used to treat HIV infection (see **Ch. 53**).

Drugs Used in the Treatment of Diabetes

The main groups of drugs used are:

Agents given by injection

- Insulin, in various forms and formulations (used in type 1 and type 2 diabetes)
- Incretin mimetics (e.g. **exenatide, liraglutide, semaglutide**)

Oral agents (used in type 2 diabetes)

- Biguanides (e.g. **metformin**)
- Sulfonylureas (e.g. **tolbutamide, glibenclamide, gliclazide, glipizide**) and related drugs (e.g. **repaglinide, nateglinide**)
- Gliptins (e.g. **sitagliptin**)

- Thiazolidinediones (e.g. **pioglitazone**)

Insulin Treatment

The effects of insulin and its mechanism of action are described earlier. Here we describe pharmacokinetic aspects and adverse effects, both of which are central to its therapeutic use. Insulin for clinical use was once either porcine or bovine but is now almost entirely human (made in expression systems by recombinant DNA technology, see **Ch. 5**). Animal insulins are liable to elicit an immune response; this is less of an issue with recombinant human insulins. Although recombinant insulin is more consistent in quality than insulins extracted from pancreases of freshly slaughtered animals, doses are still quantified in terms of units of activity, with which doctors and patients are familiar, rather than of mass.

Pharmacokinetic aspects and insulin preparations

Insulin is destroyed in the GI tract, and is ordinarily given by injection – usually subcutaneously, but intravenously or occasionally intramuscularly in emergencies. Intraperitoneal insulin can be used in special circumstances in patients with diabetes, through a continuous infusion pump, or through ambulatory peritoneal dialysis for those with end-stage renal failure. Other potential approaches include incorporation of insulin into biodegradable polymer microspheres as a slow-release formulation, and its encapsulation with a lectin in a glucose-permeable membrane. [7] Once absorbed into plasma, insulin has an elimination half-life of approximately 10 min. It is inactivated

enzymically in the liver and kidney, and 10% is excreted in the urine. Renal impairment reduces insulin requirement.

One of the main problems in using insulin is to avoid wide fluctuations in plasma concentration and thus in blood glucose. Different formulations vary in the timing of their peak effect and duration of action. *Soluble insulin* produces a rapid and short-lived effect. Longer-acting preparations are made by precipitating insulin with protamine or zinc, thus forming finely divided amorphous solid or relatively insoluble crystals, which are injected as a suspension from which insulin is slowly absorbed. These preparations include *isophane insulin* and amorphous or crystalline *insulin zinc suspensions*. Mixtures of different forms in fixed proportions are available.

More recently, modifications of insulin molecules have focused on two different areas – one being the production of molecules with a more rapid onset of action to cover mealtimes, and the other being even longer-acting formulations. Development of rapid-acting analogues is based on amino acid substitutions that promote formation of insulin monomers for faster absorption, whilst reducing the aggregation of insulin dimers and hexamers (**Atkin et al., 2015**). Examples of these analogues include insulin aspart, insulin lispro and insulin glulisine, which involve different amino acid switches at positions such as B28 or B29 in the insulin molecule. These analogues act more rapidly (onset of action <15 min and typically reaching peak concentrations within 40–70 min after injection) but for a shorter time than natural insulin, enabling patients to inject themselves immediately before the start of a meal rather than 30 min before eating.

Basal or longer-acting insulin analogues are designed with the opposite intention, namely to provide a constant basal insulin supply and mimic physiological postabsorptive basal insulin secretion. **Insulin glargine**, which is a clear solution, forms a microprecipitate at the physiological pH of subcutaneous tissue, and absorption from the subcutaneous site of injection is prolonged. In contrast, subcutaneous injection of **insulin detemir** causes the molecules to bind together more avidly, thus slowing the absorption into the circulation (**Atkin et al., 2015**). **Insulin degludec** is formed by the addition of a fatty-diacid side chain to human insulin, and the resulting molecules join up to form a depot of long multihexamers after subcutaneous injection. Monomers of insulin degludec slowly dissociate from this depot, thus giving a protracted duration of action >40 h.

Various dosage regimens are used. Some type 1 patients inject a combination of short- and intermediate-acting insulins twice daily, before breakfast and before the evening meal. Improved control of blood glucose can be achieved with the basal-bolus regimen comprising a basal insulin analogue injected once daily (often at night) and multiple daily injections of rapid-acting insulin analogues timed to be given just before meals. Insulin pumps are used in hospital to control blood glucose acutely and are also available in a portable form that delivers continuous subcutaneous infusion for outpatients. The most sophisticated forms of pump regulate the dose by means of a sensor that continuously measures blood glucose, and these programmable systems have become more widely available with significant advances in technology.

Unwanted effects

The main undesirable effect of insulin is hypoglycaemia. This is common and, if very severe, can cause brain damage or sudden cardiac death. In the Diabetes Control and Complications Trial mentioned before, intensive insulin therapy resulted in a three-fold increase in severe hypoglycaemic episodes compared with usual care. The treatment of hypoglycaemia is to take a sweet drink or snack or, if the patient is unconscious, to give intravenous glucose or intramuscular glucagon (see clinical box). Rebound hyperglycaemia ('Somogyi effect') can follow insulin-induced hypoglycaemia, because of the release of counter-regulatory hormones (e.g. adrenaline, glucagon and glucocorticoids). This can cause hyperglycaemia before breakfast following an unrecognised hypoglycaemic attack during sleep in the early hours of the morning. It is essential to appreciate this possibility to avoid the mistake of increasing (rather than reducing) the evening dose of insulin in this situation.

Allergy to human insulin is unusual but can occur. It may take the form of local or systemic reactions. Insulin resistance as a consequence of antibody formation is rare.

Clinical uses of insulin and other hypoglycaemic drugs for injection

- Patients with *type 1 diabetes* require long-term **insulin**:
  - A common regimen is basal-bolus administration using a single long-acting insulin accompanied by short-acting insulin at each mealtime. Insulin pumps have also become an option.

  - In selected patients where diabetes control is less critical, a twice-daily regimen is used; i.e. intermediate-acting preparation (e.g. **isophane insulin**) or a long-acting analogue (e.g. **glargine**) is often combined with soluble insulin or a short-acting analogue (e.g. **lispro**) taken before meals.
- **Soluble insulin** is used (intravenously) in treatment of hyperglycaemic emergencies (e.g. *diabetic ketoacidosis*).
- Approximately one-third of patients with *type 2 diabetes* ultimately require **insulin.**
- Short-term treatment of patients with type 2 diabetes or impaired glucose tolerance during intercurrent events (e.g. *operations*, *infections*, *myocardial infarction*).
- During pregnancy, for *gestational diabetes* not controlled by diet alone. Here, an infusion pump guided by continuous glucose monitoring is a suitable option.
- Emergency treatment of *hyperkalaemia* (see **Ch. 29**): **insulin** is given with glucose to lower extracellular K^+ via redistribution into cells.
- Glucagon-like peptide-1 **(GLP-1) agonist** for type 2 diabetes in addition to oral agents to improve control and lose weight (see **Ch. 32**).

Biguanides

Metformin (present in French lilac, *Galega officinalis*, which was used to treat diabetes in traditional medicine for centuries) is the

only biguanide used clinically to treat type 2 diabetes, for which it is now a drug that is amongst the first choices. [8]

Actions and mechanism

The molecular target or targets through which biguanides act remain unclear, but their biochemical actions are well described, and include:

- reduced hepatic glucose production (gluconeogenesis) which is markedly increased in type 2 diabetes;
- increased glucose uptake and utilisation in skeletal muscle (i.e. reduced insulin resistance);
- reduced carbohydrate absorption from the intestine;
- increased fatty acid oxidation;
- reduced circulating low-density and very low-density lipoprotein (LDL and VLDL, respectively, see **Ch. 22**).

Reduced hepatic gluconeogenesis is especially important. Metformin decreases hepatic glucose production directly or indirectly by inhibiting the mitochondrial respiratory chain complex I (reviewed by **Viollet et al., 2012**). The resulting increase in AMP activates AMP-activated protein kinase (AMPK) which is a master regulator of energy homeostasis in eukaryotes (**Myers et al., 2017**). Activation of AMPK in the duodenum triggers release of GLP-1 which stimulates a gut–brain–liver vagal network that regulates hepatic glucose production (**Duca et al., 2015**). Chronic administration of metformin alters recirculation of bile acids and composition of the gut microbiome in type 2 leading to increased GLP-1 secretion in diabetes patients (**Napolitano et al., 2014**).

Metformin has a half-life of about 3 h and is excreted unchanged in the urine.

Unwanted effects

Metformin, while preventing hyperglycaemia, does *not* cause hypoglycaemia, and the commonest unwanted effects are dose-related GI disturbances (e.g. anorexia, diarrhoea, nausea), which are usually, but not always, transient. Lactic acidosis is a rare but potentially fatal toxic effect, and metformin should not be given routinely to patients with renal or hepatic disease, hypoxic pulmonary disease or shock. Such patients are predisposed to lactic acidosis because of reduced drug elimination or reduced tissue oxygenation. It should be avoided in other situations that predispose to lactic acidosis including alcohol intoxication, and some forms of mitochondrial myopathy that are associated with diabetes. Long-term use may interfere with absorption of vitamin B_{12}.

Clinical use

Metformin is used to treat patients with type 2 diabetes. It does not stimulate appetite (rather the reverse; see earlier!) and is one of the preferred options in the majority of type 2 patients who are obese, provided they have unimpaired renal and hepatic function. It can be combined with other glucose-lowering agents if blood glucose is inadequately controlled. Potential uses outside type 2 diabetes include other syndromes with accompanying insulin resistance including polycystic ovary syndrome, non-alcoholic fatty liver disease, gestational diabetes and some forms of premature puberty.

Glucose transport inhibitors

Several SGLT2 inhibitors are licensed for use in type 2 diabetes. Examples include **canagliflozin, dapagliflozin** and **empagliflozin**.

Mechanism of action

The SGLT2 inhibitors promote glucose excretion into the urine, thereby reducing the concentration of circulating glucose. The resulting glycosuria is associated with an osmotic diuresis and salt excretion (see also Chs **21** and **29**). SGLT2 inhibitors are currently being investigated for numerous other complex effects on the cardiac and renal systems, which may include reduction in oxidative stress and inflammation (described in detail by **Zelniker and Braunwald, 2020**).

Effects

Treatment with SGLT2 inhibitors leads to elevated amounts of glucose in the urine over sustained periods, and an associated increase in urinary volume and sodium ion excretion. Clinical trials have confirmed improvements in fasting and post-prandial glucose concentrations, and significant reduction in glycosylated haemoglobin (**Zelniker and Braunwald, 2020**). The natriuresis, diuresis and the caloric loss (from glucose in the urine) also lead usefully to reduction in systolic blood pressure and body weight. As such, use of SGLT2 inhibitors is now being extended to patients with heart failure, or chronic kidney disease, irrespective of whether they have diabetes or not (**Zelniker and Braunwald, 2020**).

Pharmacokinetic aspects

SGLT2 inhibitors are rapidly absorbed, with time to peak plasma concentrations of less than 2 h. They are highly bound to plasma proteins (>80%).

Unwanted effects

Natriuresis with diuresis can lead to increased urinary volume, hypotension and dehydration, and is accentuated with concomitant use of thiazide diuretics. The elevated glucose concentrations in the urine can lead to a significant increase in the risk of urinary tract and fungal infections such as candidal vaginitis or balanitis with SGLT2 inhibitors (**Zelniker and Braunwald, 2020**). However, there remains considerable debate around the uncertain association between SGLT2 inhibitors and a rare severe necrotising disease of the perineum and external genitalia (Fournier's gangrene) caused by mixed aerobic and anaerobic infection.

Safety concerns include serious adverse events such as lower limb amputations, and increased susceptibility to DKA, including specifically euglycaemic DKA. Here, the glucose-lowering effect of the SGLT2 inhibitors is thought to reduce residual endogenous insulin secretion whilst promoting glucagon production. The resulting decrease in the anti-lipolytic action of insulin leads to greater synthesis of free fatty acids which are subsequently converted to ketones by the liver. Concurrent acute illness, dehydration, decreased food intake or dietary restrictions (e.g. low carbohydrate or ketogenic diet) are important risk factors for DKA with SGLT2 inhibitors. Patients are advised to seek assistance for ketone testing, and to stop taking their SGLT2 inhibitor during acute serious illness, or before surgical procedures.

Clinical use

SGLT2 inhibitors are licensed for use in type 2 diabetes, either alone (when metformin is inappropriate) or in combination with other glucose-lowering therapies. Typically, this would involve SGLT2 use in dual or triple therapy. A potential advantage of SGLT2 inhibition in those with inadequate diabetes control is that the amount of glucose excreted in the urine will be proportionately greater in patients whose plasma glucose concentrations are high.

However, SGLT2 inhibitors are not used for glycaemic control in patients with type 1 disease because of potential harm from DKA.

The SGLT2 inhibitors are considered to have a relatively low risk of hypoglycaemia.

Incretin mimetics and related drugs

Exenatide and lixisenatide are synthetic derivatives of *exendin-4*, a peptide found in the saliva of the Gila monster (a lizard that presumably evolved this as means to disable its prey by rendering them hypoglycaemic). In contrast, other GLP-1 analogues such as liraglutide and semaglutide closely resemble human GLP-1, but with molecular modifications to enable longer duration of action.

GLP-1 agonists lower blood glucose after a meal by increasing insulin secretion, suppressing glucagon secretion and slowing gastric emptying (see earlier). They reduce food intake (by an effect on satiety, see **Ch. 32**) and are associated with modest weight loss. They reduce hepatic fat accumulation. Pancreatitis is a rare but potentially severe adverse effect.

GLP-1 agonists are administered by subcutaneous injection, either once daily (exenatide, **liraglutide**, **lixisenatide**) or once

weekly (extended release exenatide, **albiglutide**, **dulaglutide**). Semaglutide is now available in both injectable and oral formulations.

GLP-1 agonists are used in patients with type 2 diabetes in combination with other drugs (see clinical box on uses of oral hypoglycaemic drugs).

Tirzepatide is a newly developed injectable molecule (see also **Ch. 32**) that has dual GLP-1 and GIP agonist activity. The additional action on GIP is thought to stimulate energy expenditure whilst reducing food intake. Randomised trials have reported significant benefits in terms of diabetes control and weight loss with tirzepatide when compared to insulin or GLP-1 analogues.

Gliptins

Gliptins (e.g. **sitagliptin**, **vildagliptin**, **saxagliptin**, **linagliptin**) are synthetic drugs that competitively inhibit DPP-4, thereby lowering blood glucose by potentiating endogenous incretins (GLP-1 and GIP, see above) which stimulate insulin secretion. They do not cause weight loss or weight gain.

They are absorbed from the gut and administered once (or, in the case of vildagliptin, twice) daily by mouth. They are eliminated partly by renal excretion and are also metabolised by hepatic CYP enzymes. They are usually well tolerated with a range of mild GI adverse effects; liver disease, heart failure (particularly with saxagliptin or alogliptin) and pancreatitis (incidence approximately 0.1%–1%) are less common but potentially serious. Gliptins can be used for type 2 diabetes in addition to other oral hypoglycaemic

drugs, but not together with GLP-1 agonists because of their overlapping mechanisms

Evidence of cardiovascular efficacy or effect on mortality is inconsistent, with some GLP-1 analogues (such as liraglutide, semaglutide, dulaglutide) demonstrating a reduction in major adverse cardiac events (**Gilbert and Pratley, 2020**), whereas neither the gliptins nor exenatide has shown such benefits in large-scale clinical trials.

Sulfonylureas

The sulfonylureas were developed following the chance observation that a sulfonamide derivative (which was being used to treat typhoid) caused hypoglycaemia. Numerous sulfonylureas are available. The first used therapeutically were **tolbutamide** and **chlorpropamide**. Chlorpropamide has a long duration of action and a substantial fraction is excreted in the urine. It is seldom used in clinical practice because of serious adverse effects such as hypoglycaemia, flushing with alcohol and hyponatraemia. **Williams (1994)** comments that 'time honoured but idiosyncratic chlorpropamide should now be laid to rest' – a sentiment with which we concur. Tolbutamide, however, is still available, although far less commonly prescribed nowadays than the so-called second-generation sulfonylureas (e.g. **glibenclamide**, **gliclazide**, **glipizide**; **Table 31.3**) which are more potent. These second-generation drugs all contain the sulfonylurea moiety and act in the same way, but different substitutions result in differences in pharmacokinetics and hence in duration of action (see **Table 31.3**).

Mechanism of action

The principal action of sulfonylureas is on β cells (see **Fig. 31.1**), stimulating insulin secretion and thus reducing plasma glucose. High-affinity binding sites for sulfonylureas are present on the K_{ATP} channels (see **Ch. 4**) in the surface membranes of β cells, and the binding of various sulfonylureas parallels their potency in stimulating insulin release. Block by sulfonylurea drugs of K_{ATP} channel activation causes depolarisation of β cells, Ca^{2+} entry and insulin secretion. (Compare this with the physiological control of insulin secretion, see **Fig. 31.1**.)

Pharmacokinetic aspects

Sulfonylureas are well absorbed after oral administration, and most reach peak plasma concentrations within 2–4 h. The duration of action varies (see **Table 31.3**). All bind strongly to plasma albumin and are implicated in interactions with other drugs (e.g. salicylates and sulfonamides) that compete for these binding sites (see **Ch. 9**). Most sulfonylureas (or their active metabolites) are excreted in the urine, so their action is increased and prolonged in the elderly and in patients with renal disease.

Table 31.3

[a] Relative to tolbutamide.

[b] All are highly protein bound (90%–95%).

[c] Termed *glyburide* in the United States.

Most sulfonylureas cross the placenta and enter breast milk and their use is contraindicated in pregnancy and in breastfeeding.

Unwanted effects

The sulfonylureas are usually well tolerated. Unwanted effects are specified in **Table 31.3**. The commonest adverse effect is hypoglycaemia, which can be severe and prolonged, the highest incidence occurring with long-acting chlorpropamide and glibenclamide and the lowest with tolbutamide. Long-acting sulfonylureas are best avoided in the elderly and in patients with even mild renal impairment because of the risk of hypoglycaemia. Sulfonylureas stimulate appetite and often cause weight gain. This is a major concern in obese patients with diabetes. About 3% of patients experience GI upsets. The sulfonylureas do not appear to confer cardiovascular benefit (**Flory and Lipska, 2019**) and there is continued debate regarding the possibility of a detrimental effect on patients with underlying cardiovascular disease.

Drug interactions

Several drugs augment the hypoglycaemic effect of sulfonylureas. Non-steroidal anti-inflammatory drugs, warfarin, some uricosuric drugs (e.g. **sulfinpyrazone**), alcohol, monoamine oxidase inhibitors, some antibacterial drugs (including sulfonamides, **trimethoprim** and **chloramphenicol**) and some imidazole antifungal drugs have all been reported to produce severe hypoglycaemia when given with a sulfonylurea. The probable basis of most of these interactions is competition for metabolising enzymes, but interference with plasma protein binding or with transport mechanisms facilitating excretion may play some part.

Agents that decrease the action of sulfonylureas on blood glucose include high doses of thiazide diuretics (see Chs **21** and **29**) and

glucocorticoids, all of which can increase circulating glucose concentrations.

Clinical use

Sulfonylureas are used to treat type 2 diabetes in its early stages, but because they require functional β cells, they are not useful in type 1 or late-stage type 2 diabetes. Nowadays, the limitations of sulfonylureas (weight gain, risk of hypoglycaemia, lack of cardiovascular benefit) means that they are seldom used as first-line agents for type 2 diabetes.

Other Drugs that Stimulate Insulin Secretion

Several drugs that act, like the sulfonylureas, by blocking the sulfonylurea receptor on K_{ATP} channels in pancreatic β cells but lack the sulfonylurea moiety have been developed. These include **repaglinide** and **nateglinide** which, although much less potent than most sulfonylureas, have rapid onset and offset kinetics leading to short duration of action and a low risk of hypoglycaemia. [9] These drugs are administered shortly before a meal to reduce the postprandial rise in blood glucose in patients with type 2 diabetes that is inadequately controlled with diet and exercise. They may cause less weight gain than conventional sulfonylureas. Later in the course of the disease, they can be combined with metformin or other oral hypoglycaemic agents. Unlike glibenclamide, these drugs are relatively selective for K_{ATP} channels on β cells versus K_{ATP} channels in vascular smooth muscle.

Thiazolidinediones (glitazones): pioglitazone

The thiazolidinediones (or *glitazones*) were developed following the chance observation that a **clofibrate** analogue, **ciglitazone**, which was being screened for effects on lipids, unexpectedly lowered blood glucose. Ciglitazone caused liver toxicity, and this class of drugs (despite initial commercial success) has been dogged by adverse effects (especially cardiovascular), regulatory withdrawals and controversy. No clinical trials of these agents have demonstrated a beneficial effect on mortality, and they were licensed on the basis of statistically significant effects on haemoglobin A1c (HbA1C) (an integrated marker of longer-term glycaemic control) of uncertain clinical significance. **Pioglitazone** is the only drug of this class that remains in clinical use, its predecessors, rosiglitazone and troglitazone, having faced regulatory action because of increased risk of heart attacks and liver damage, respectively.

Effects

The effect of thiazolidinediones on blood glucose is slow in onset, the maximum effect being achieved only after 1–2 months of treatment. They act by enhancing the effectiveness of endogenous insulin, thereby reducing hepatic glucose output, and increasing glucose uptake into muscle.

They reduce the amount of exogenous insulin needed to maintain a given level of blood glucose by approximately 30%. Reduced blood glucose concentration is accompanied by reduced insulin and free fatty acid concentrations. Weight gain of 1–4 kg is common, usually stabilising in 6–12 months. Some of this is attributable to fluid retention: there is an increase in plasma volume of up to 500 mL, with a concomitant reduction in haemoglobin concentration caused

by haemodilution; there is also an increase in extravascular fluid, and increased deposition of subcutaneous (as opposed to visceral) fat.

Mechanism of action

Thiazolidinediones bind to a nuclear receptor called the *peroxisome proliferator-activated receptor-γ* (PPARγ), which is complexed with retinoid X receptor (RXR; see **Ch. 3**). [10] It remains something of a mystery that glucose homeostasis should be so responsive to drugs that bind to receptors expressed mainly in fat cells; it has been suggested that the explanation may lie in resetting of the glucose–fatty acid (Randle) cycle by the reduction in circulating free fatty acids.

Unwanted effects

Clinical trial data have demonstrated significantly increased risk of a range of adverse events with pioglitazone, including heart failure, bone fracture, oedema and weight gain, and glitazones are now far less frequently used.

Clinical use

Pioglitazone is additive with other oral hypoglycaemic drugs in terms of effect on blood glucose, and a combination tablet with metformin is marketed.

α-Glucosidase inhibitors

Acarbose, an inhibitor of intestinal α-glucosidase, is used in type 2 diabetes inadequately controlled by diet with or without other agents. It delays carbohydrate absorption, reducing the postprandial

increase in blood glucose. The commonest adverse effects are related to its main action and consist of flatulence, loose stools or diarrhoea and abdominal pain and bloating. Like metformin, it may be particularly helpful in obese type 2 patients, and it can be co-administered with metformin.

Treatment of Diabetes Mellitus

Personalised therapy of diabetes is focused on the careful balance of drug treatment aiming for near-normalisation of the HbA1C whilst avoiding hypoglycaemia. Nowadays, numerous clinical guidelines recommend target HbA1Cs which are tailored according to specific individual patient characteristics. Whilst tight control with rigorous monitoring is a cornerstone in younger patients with diabetes (mainly type 1), there are more complex considerations in older, multi-morbid patients with type 2 diabetes who are already on polypharmacy. Studies of intensive control later in the course of the disease have been disappointing, particularly with regards to older patients, where the serious harm from hypoglycaemia may outweigh any benefit from strict glucose-lowering regimens. Realistic goals in patients with type 2 diabetes are usually less ambitious than in younger type 1 patients. Dietary restriction leading to weight loss in overweight and obese patients is the cornerstone (albeit one with a tendency to crumble), combined with increased exercise. Oral agents are used to control symptoms from hyperglycaemia, as well as to limit microvascular complications, and are introduced early. Blood pressure control and statins to prevent atheromatous disease (see **Ch. 22**) are crucial for cardiovascular health. Here, GLP-1 analogues and SGLT2 inhibitors are currently

thought to carry the greatest cardiovascular benefit amongst all the available agents (**Flory and Lipska, 2019**).

Drugs used in diabetes mellitus

Insulin and other injectable drugs

- Human **insulin** is made by recombinant DNA technology. For routine use, it is given subcutaneously (by intravenous infusion in emergencies).
- Different formulations of **insulin** differ in their duration of action:
  - rapid-acting analogues that can be given immediately before a meal, and have shorter half-lives so that post-prandial hypoglycaemia is less likely;
  - short-acting **soluble insulin**: peak action after subcutaneous dose 2–4 h and duration 6–8 h; it is the only formulation that can be given intravenously;
  - intermediate-acting insulin (e.g. **isophane insulin**); and
  - long-acting forms (e.g. **insulin glargine**).
- The main unwanted effect is hypoglycaemia.
- Altering the amino acid sequence (insulin analogues, e.g. **lispro** and **glargine**) can usefully alter **insulin** kinetics.
- **Insulins** are used for all patients with type 1 diabetes and approximately one-third of patients with type 2 diabetes.
- Injectable GLP-1 agonists are used as add-on treatment in certain patients with inadequately controlled type 2 diabetes. Unlike **insulin** they are useful in promoting weight loss.

Oral hypoglycaemic drugs

- These are used in type 2 diabetes.
- Biguanides (e.g. **metformin**):
  - have complex peripheral actions in the presence of residual insulin, increasing glucose uptake in striated muscle and inhibiting hepatic glucose output and intestinal glucose absorption;
  - reduce appetite and encourage weight loss; have low or negligible risk of hypoglycaemia;
  - are amongst the first-line choices in overweight or obese patients.
- SGLT2 inhibitors (e.g. empagliflozin)
  - promote urinary excretion of glucose;
  - have beneficial effects on weight, blood pressure, renal and cardiovascular outcomes;
  - increase the risk of dehydration and urinary tract infections, as well as rare instances of DKA.
- GLP-1 analogues – semaglutide is the only oral formulation available from this class of drugs.
- Gliptins (e.g. **sitagliptin**):
  - potentiate endogenous incretins by blocking DPP-4;
  - are added to other orally active drugs to improve control in patients with type 2 diabetes;
  - are weight-neutral; they are usually well tolerated but pancreatitis is a concern.

- Sulfonylureas and other drugs that stimulate insulin secretion (e.g. **tolbutamide**, **glibenclamide**, **nateglinide**):
  - can cause hypoglycaemia (which stimulates appetite and leads to weight gain);
  - are effective only if β cells are functional;
  - block ATP-sensitive potassium channels in β cells;
  - are well tolerated but promote weight gain and are associated with more cardiovascular disease than is **metformin.**
- Thiazolidinediones have been associated with serious cardiac toxicity. **Pioglitazone** is the only one still widely marketed; it:
  - is a PPARγ (a nuclear receptor) agonist;
  - increases insulin sensitivity and lowers blood glucose in type 2 diabetes;
  - can cause weight gain and oedema;
  - increases osteoporotic fractures.
- α-Glucosidase inhibitor, **acarbose**:
  - reduces carbohydrate absorption;
  - causes flatulence and diarrhoea.

Clinical uses of oral hypoglycaemic drugs

- *Type 2 diabetes mellitus*, to reduce symptoms from hyperglycaemia (e.g. thirst, excessive urination) and to reduce long-term diabetes complications ('tight' control of blood glucose may only have a small effect on cardiovascular

complications in certain settings, depending on the class of drug.)

- **Metformin** is preferred, especially for obese patients unless contraindicated by factors that predispose to lactic acidosis (renal or liver failure, poorly compensated heart failure, hypoxaemia).
- SGLT2 inhibitors improve diabetes control, and are effective in reducing heart failure, hypertension and renal complications.
- GLP-1 agonists (e.g. **exenatide, lixisenatide** or **liraglutide**) are given by injection in obese patients inadequately controlled on one or two hypoglycaemic drugs. These agents are associated with the potential for weight loss or prevention of weight gain in overweight or obese patients. **Semaglutide** can be taken orally or by injection.
- DPP-4 inhibitors (gliptins, e.g. **sitagliptin**) improve control and are well tolerated and weight neutral, but outcome evidence is inconsistent. Pancreatitis and heart failure are possible adverse effects of concern.
- Drugs that act on the sulfonylurea receptor (e.g. **tolbutamide**, **glibenclamide, gliclazide**) are well tolerated but often promote weight gain. They are associated with increased hypoglycaemia and possible cardiovascular risk compared with **metformin.**
- **Pioglitazone** improves control (reduces haemoglobin A_{1C}) but increases weight, causes heart failure and fluid retention and increases risk of fractures.

- **Acarbose** (α-glucosidase inhibitor) reduces carbohydrate absorption; it causes flatulence and diarrhoea.

QUESTIONS

QUESTION 31.1

Glucose is the core source of energy for cellular function. Continuous balancing of glucose availability from dietary and stored sources, with glucose usage in metabolic reactions, is essential for homeostasis.

Which of the following statements about glucose control is correct?

OPTIONS:

A. Somatostatin, released from α cells, inhibits insulin.

B. Pancreatic polypeptide cells (PP cells) release ghrelin.

C. Glucagon, released from α cells, increases blood glucose.

D. Amylin, released from β cells, synergises with insulin.

E. Insulin, released from α cells, lowers blood glucose levels.

QUESTION 31.2

The synthesis and secretion of insulin is tightly regulated and triggered by changes in blood glucose concentration.

Which of the following would not lead to an increase in insulin release?

OPTIONS:

A. Opening of K_{ATP} channels

B. Increased expression of glucokinase

C. Increased calcium influx

D. Increased ATP levels

E. Increased levels of diacylglycerol (DAG)

QUESTION 31.3

Insulin regulates glucose levels through a range of physiological mechanisms.

Which of the following is a physiological effect of insulin?

OPTIONS:

A. Stimulation of glycogenolysis

B. Stimulation of gluconeogenesis

C. Increased lipolysis in adipose tissue

D. Decrease in hepatic glycogen storage

E. Increase in Glut-4 membrane translocation

ANSWERS

ANSWER 31.1

RATIONALE:

A. Somatostatin is released from δ cells and acts to inhibit insulin release.

B. ε cells release ghrelin. PP cells release a similar acting polypeptide implicated in control of food intake.

C.

D. Amylin, secreted with insulin from β cells, facilitates the breakdown of glycogen in striated muscle and inhibits insulin secretion.

E. Insulin released from β cells decreases blood glucose levels by facilitating cellular uptake and storage.

CORRECT ANSWER WITH EXPLANATION:

C. Glucagon is released from α cells to increase blood glucose levels.

Glucagon, released from α cells, opposes insulin, increasing blood glucose and stimulating protein breakdown in muscle.

ANSWER 31.2

RATIONALE:

A.

B. Glucokinase, the rate-limiting glycolytic enzyme in β cells, is responsible for the metabolism of glucose and the triggering of insulin secretion.

C. Depolarisation of the β cells opens voltage-dependent calcium channels, leading to Ca^{2+} influx triggering insulin secretion.

D. ATP blocks K_{ATP} channels, causing membrane depolarisation, triggering calcium entry and insulin release.

E. DAG facilitates Ca^{2+} entry and insulin secretion.

CORRECT ANSWER WITH EXPLANATION:

A. Opening of K_{ATP} channels

ATP from glucose metabolism within β cells blocks K_{ATP} channels, causing membrane depolarisation, opening of voltage-dependent calcium channels leading to insulin secretion.

ANSWER 31.3

RATIONALE:

A. The main function of insulin is to decrease blood glucose levels and as such it inhibits the process of glycogen breakdown to release glucose.

B. The main function of insulin is to decrease blood glucose levels and as such it inhibits the synthesis of glucose from non-carbohydrate sources.

C. Insulin decreases lipolysis by inactivation of lipases and stimulates fatty acid and triglyceride synthesis.

D. Insulin enhances the storage of excess glucose in hepatic glycogen stores.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Increase in Glut-4 membrane translocation

Insulin increases the surface expression of Glut-4 transporters, enabling glucose uptake into cells.

[1] Not to be confused with C-reactive peptide, which is an acute-phase reactant used clinically as a marker of inflammation (Ch. 7).

[2] Insulin for injection does not contain C-peptide, which therefore provides a means of distinguishing endogenous from exogenous insulin. This is used to differentiate insulinoma (an insulin-secreting tumour causing high circulating insulin with high C-peptide) from surreptitious injection of insulin (high insulin with low C-peptide). Deliberate induction of hypoglycaemia by self-injection with insulin is a well-recognised, if unusual, manifestation of psychiatric disorder, especially in health professionals – it has also been used in murder.

[3] The action on $K^+$is exploited in the emergency treatment of hyperkalaemia by intravenous glucose with insulin (see Ch. 29).

[4] Octreotide is used either short term before surgery on the pituitary tumour, or while waiting for radiotherapy of the tumour to take effect, or if other treatments have been ineffective.

[5] Neuropathy ('disease of the nerves') causes dysfunction of peripheral nerve fibres, which can be motor, sensory or autonomic. Diabetic neuropathy often causes numbness in a 'stocking' distribution caused by damage to sensory fibres, and postural hypotension and erectile dysfunction due to autonomic neuropathy.

[6] Diabetic control is not easily estimated by determination of blood glucose, because this is so variable. Instead, glycated haemoglobin (haemoglobin A_{1C}) is measured. This provides an integrated measure of control over the lifespan of the red cell: approximately 120 days. In healthy individuals, 4%–6% (20–42 mmol/mol) of

haemoglobin is glycated; levels above 6.5% (48 mmol/mol) are indicative of diabetes.

[7] This could, in theory, provide variable release of insulin controlled by the prevailing glucose concentration, because glucose and glycated insulin compete for binding sites on the lectin.

[8] Metformin had a very slow start. It was first synthesised in 1922, one of a large series of biguanides with many different pharmacological actions, which proved largely unsuitable for clinical use. Its glucose-lowering effect was noted early on but it was eclipsed by the discovery of insulin. It did not receive FDA approval until 1995.

[9] It is ironic that these newer drugs share many of the properties of tolbutamide, the oldest, least expensive and least fashionable of the sulfonylureas.

[10] Compare with fibrates (to which thiazolidinediones are structurally related), which bind to PPARa (see Ch. 22).

32: Obesity

OVERVIEW

Obesity is a growing health issue around the world and is reaching epidemic proportions in some nations. The problem is not restricted to the inhabitants of the affluent countries, to the adult population or to any one socioeconomic class. Body fat represents stored energy and obesity occurs when the homeostatic mechanisms controlling energy balance become disordered or overwhelmed. In this chapter we first outline the endogenous regulation of appetite and body mass, and then consider the main health implications of obesity and its pathophysiology. We conclude with a discussion of the drugs currently licensed for the treatment of obesity and glance at possible future pharmacological treatments for this condition.

Introduction

Survival requires a continuous provision of energy to maintain homeostasis, even when the supply of food is intermittent. Evolution has furnished a mechanism for storing excess energy latent in foodstuffs in adipose tissue as energy-dense triglycerides, such that these can be easily mobilised when food is scarce. This mechanism, controlled by the so-called *thrifty genes*, was an obvious asset to our hunter–gatherer ancestors, but in many societies a combination of sedentary lifestyle, genetic susceptibility,

cultural influences and unrestricted access to an ample supply of calorie-dense foods has led to a global epidemic of obesity, or 'globesity' as it is sometimes called. Obesity is one component of a cluster of disorders described in other chapters, which often coexist in the same individual, comprising what is now described as 'metabolic syndrome' (formerly 'metabolic X syndrome'), and which constitutes a rapidly growing public health problem.

Definition of Obesity

'Obesity' may be defined as an illness where health (and hence life expectancy) is adversely affected by excess body fat. [1] But at what point does an individual become 'obese'? The generally accepted (WHO) benchmark is the body mass index (BMI). The BMI is expressed as W/h^2, where W = body weight (in kg), h = height (in metres). Although it is not a perfect index (e.g. it does not distinguish between fat and lean mass), the BMI is generally well correlated with other measurements of body fat, and it is widely utilised as a convenient index. While there are problems in defining a 'healthy' weight for a particular population, the WHO classifies adults with a BMI of ≥25 as being overweight and those with a BMI of ≥30 as obese. Childhood obesity is more difficult to assess.

Since the BMI obviously depends on the overall energy balance, another operational definition of obesity would be that it is a multifactorial disorder of energy balance in which calorie retention over the long-term exceeds energy output.

Obesity as a Health Problem

Obesity is a growing and costly global health problem. The WHO in 2016 estimated that worldwide obesity has almost tripled since 1975 and there were more than 1.9 billion overweight adults, approximately one-third of whom – amounting to more than 13% of the world's population – were obese according to the criteria outlined earlier. National obesity levels vary enormously, being less than 4% in Japan and parts of Africa, but a staggering 40% or more in parts of Polynesia. Adult obesity levels in the United States, Europe and the United Kingdom (among others) have increased three-fold since 1980, with figures of 34% being quoted for the United States by WHO (2016) and up to 28% for the United Kingdom. The disease is not confined to adults: some 39 million children or infants under 5 years old are estimated to be overweight or obese. In the United States, the number of overweight children has doubled and the number of overweight adolescents has trebled since 1980, with the overall prevalence of obesity close to 20% (data from the US Centers for Disease Control and Prevention, **https://www.cdc.gov/obesity/data/childhood.html**). Ironically, obesity often coexists with malnutrition in many developing countries. All socioeconomic classes are affected. In the poorest countries, it is the top socioeconomic classes in whom obesity is prevalent, but in the affluent West it is usually the reverse. In England, for example, the rates of obesity-related hospital admission in the most deprived areas are more than two-fold higher than the least deprived areas.

Overall, more people die in the world from being overweight and obese than being underweight, and the financial burden on the healthcare system is huge. An influential report (**McKinsey**

Global Institute, 2014) estimated the global economic burden at US$2.1 trillion in 2014, 2.9% of the global GDP – more than the cost incurred by armed violence, war and terrorism taken altogether.

Obesity often coexists with metabolic and other disorders (particularly hypertension, hypercholesterolaemia and type 2 diabetes), together comprising the *metabolic syndrome*. This carries a high risk of cardiovascular conditions, strokes, certain types of cancers (particularly hormone dependent), respiratory disorders (particularly sleep apnoea) and digestive problems, as well as osteoarthritis. Poor mobility, fear of stigmatisation and social isolation take a further toll on the mental wellbeing of people with obesity. One commentator (**Kopelman, 2000**) has remarked that obesity 'is beginning to replace under-nutrition and infectious diseases as the most significant contributor to ill health'. In England, this is evidenced by the substantial increase in hospitalisations, with up to a million patients in 2019–2020 admitted with a primary or secondary diagnosis of obesity.

Homeostatic Mechanisms Controlling Energy Balance

A common view, and one that is implicitly encouraged by authors of numerous self-help books as well as the enormously lucrative dieting industry, is that obesity is simply the result of bad diet or wilful overeating (hyperphagia). In truth, however, the situation is more complex. On its own, dieting seldom provides a lasting solution: the failure rate is high (probably 90%), and most dieters eventually return to their original starting weight. This suggests the operation of some intrinsic homeostatic system that aims to

maintain some balance between energy intake and energy expenditure. The systems for regulating body weight are, by necessity, intricate and complex in order to cope with the challenges of the substantial day-to-day variation in food intake and physical activity. Here, the homeostatic functions exert their effects through highly sophisticated internal control mechanisms with dynamic interplay between key organs such as the brain, liver, pancreas, gut and adipose tissue.

Energy homeostasis can be affected by genetic predisposition, and subsequently vary throughout life due to the influence of hormonal changes, metabolic stress, inflammation and ageing. When exposed to the same dietary choices, some individuals will become obese whereas others will not. Studies of obesity in monozygotic and dizygotic twins have established a strong genetic influence on the susceptibility to the condition, and studies of rare mutations have led to the discovery and elucidation of the neuroendocrine pathways that match food intake with energy expenditure. These, in turn, have led to the concept that derangements in these control systems are largely responsible for the onset and maintenance of obesity.

The Role of Peripheral Signalling in Body Weight Regulation

Intensive research over several decades has helped us gradually unravel the complex homeostatic interaction among the hypothalamus, brain stem and peripheral signals regarding availability of fuel from adipose tissue and gut. At the beginning of the 20th century it was observed that patients with damage to the hypothalamus tended to gain weight. In the 1940s it was also shown

that discrete lesions in the hypothalamus of rodents caused them to become obese or exhibit unusual feeding behaviour. On the basis of early (1953) observations in rats, Kennedy proposed that a hormone released from adipose tissue acted on the hypothalamus to regulate body fat and food intake. An important conceptual breakthrough came in 1994, when Friedman and his colleagues identified *leptin* [2] as the adipocyte hormone that acts on neural connections, to suppress appetite and reduce adipose tissue.

Leptin mRNA is expressed in adipocytes; its synthesis is increased by glucocorticoids, insulin and oestrogens, and is reduced by β-adrenoceptor agonists. In normal human subjects, the release of leptin is pulsatile and correlated with increasing total fat mass and BMI. Leptin acts predominantly on the hypothalamus to reduce food intake when energy stores are sufficient. The importance of leptin therapy has been emphasised in animal models and rare congenital forms of leptin deficiency (**Fig. 32.1**), but its value as public health intervention is limited by the fact that many obese people actually have leptin resistance rather than a genuine deficiency of leptin.

In addition to its well-recognised action on lowering blood glucose, insulin (see **Ch. 31**) has effects on the brain that are similar to leptin in decreasing food intake. Insulin may also stimulate leptin release although the relationship between these two hormones is complex.

In addition to leptin and insulin, several other mediators, originating mainly from the gastrointestinal (GI) tract as well as in the hypothalamus, play a crucial role in determining food intake, meal size and the feeling of satisfaction produced ('satiety'). [3]

Peptide hormones secreted by cells in the wall of the small intestine in response to the arrival of nutrients in the intestinal lumen (see **Ch. 30**) are important in this connection. **Table 32.1** and **Fig. 32.2** summarise the chief characteristics of these mediators.

The majority of these peptides are released either during, or in anticipation of, eating and most are inhibitory in nature, producing either satiety or satiation. Two exceptions are the gastric hormone, *ghrelin*, which promotes hunger and food intake, and leptin itself, which is controlled by the amount of adipose tissue and is thus more involved with the longer-term energy status of the individual. The main targets for these hormones are receptors on vagal afferent fibres or within the hypothalamus (or elsewhere in the central nervous system [CNS]). Here, they modulate the release of other neurotransmitters that exert a fine regulation over eating behaviour, energy expenditure and body weight. Other actions of these peptide hormones include the release of insulin by the *incretins* (see **Ch. 31**), which include glucagon-like peptide-1 (GLP-1) and gastric inhibitory peptide (GIP).

The small intestine has L-type enteroendocrine cells that release GLP-1 in response to glucose and fat in food and drink. The early action of GLP-1 is to stimulate insulin secretion and inhibit glucagon, thus providing a means of regulating blood glucose concentrations (see **Ch. 31**). However, GLP-1 receptors are found in multiple other sites and their role in tackling obesity appears to be through reduction of appetite, and promotion of satiety centrally at the hypothalamus.

There are a wide range of other gut hormones that have a signalling role in energy homeostasis, but none of them have yet to

be established as therapeutic targets in wider populations. Selected examples from a lengthy list of potentially promising candidates for further research include nesfatin 1, pancreatic peptide tyrosine tyrosine (PYY), oxyntomodulin, ghrelin and obestatin – see **Miller (2019)** for a detailed review.

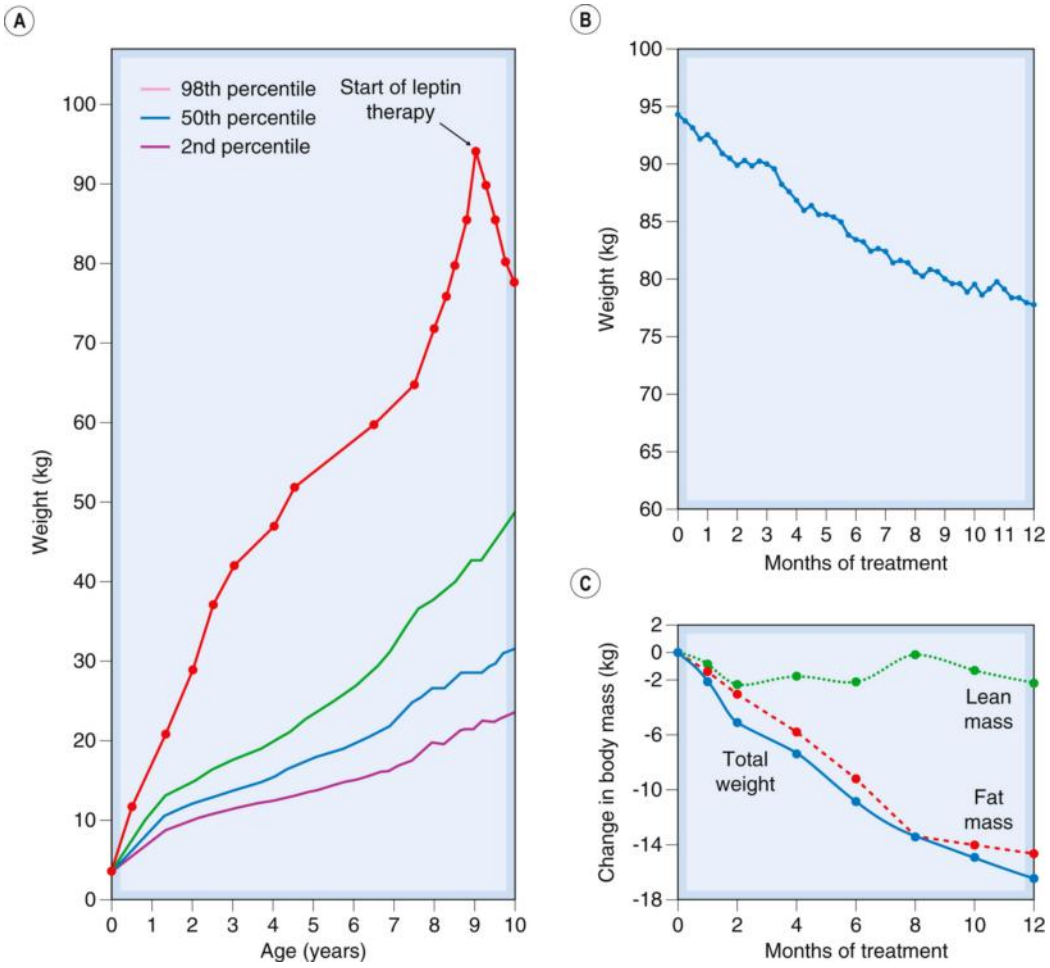

FIG. 32.1 The effect of recombinant leptin on body weight in a 9-year-old severely obese child with endogenous leptin deficiency because of a frame shift mutation in the leptin gene.Although of normal birth weight, the child began gaining weight at 4 months and was constantly demanding food. Prior to treatment, the child weighed 94.4 kg. Weight loss began after 2 weeks' treatment, and her eating pattern returned to normal. She had lost 15.6 kg of body fat after 1 year of treatment. Data and figure adapted from Farooqi, I.S., Jebb, S.A., Langmack,

G., et al., 1999. Effects of recombinant leptin therapy in a child with congenital leptin deficiency. N. Engl. J. Med. 341, 879–884.

Neurological Circuits that Control Body Weight and Eating Behaviour

Control of Food Intake

The manner in which all these hormonal and nutritional signals are processed and integrated with other viscerosensory, gustatory or olfactory information within the CNS is complex. Many sites are involved in different aspects of the process and some 50 hormones and neurotransmitters are implicated. This complex interaction between the CNS and the peripheral metabolic organs (liver, pancreas, gut, adipose tissue) needs to be tightly coordinated so that optimum weight balance is maintained. The account we present here is therefore necessarily an oversimplification: please see **Roh et al. (2016)** and **Miller (2019)** for a more complete picture of how the brain is a key player in the homeostatic regulation of energy balance.

As early lesioning studies predicted, the hypothalamus is the main brain centre that regulates appetite, feeding behaviour and energy status, although other sites in the brain, such as the nucleus accumbens (NAc), the amygdala and, especially, the nucleus tractus solitarius (NTS) in the medulla, are also crucial. Within the hypothalamus, the arcuate nucleus (ARC), situated in the floor of the third ventricle, is a key site. It receives afferent signals originating from the GI tract and contains receptors for leptin and other significant hormones. It also has extensive reciprocal

connections with other parts of the hypothalamus involved in monitoring energy status, in particular the paraventricular nuclei and the ventromedial hypothalamus. **Fig. 32.2** summarises in a simplified fashion some of the interactions that occur in the ARC.

Within the ARC are two groups of functionally distinct neurons that exert opposite effects on appetite. One group, termed *anorexigenic* (appetite-suppressing), secrete pro-opiomelanocortin (POMC)-derived peptides (such as α melanocyte-stimulating hormone [α-MSH]) or cocaine- and amphetamine-regulated transcript (CART [4])–derived peptides. The other group, termed *orexigenic* (appetite-promoting) neurons, secrete neuropeptide Y (NPY) or agouti-related peptide (AgRP). As these groups of neurons have opposing actions, energy homeostasis depends, in the first instance, on the balance between these actions, the final effects of which are transduced by the brain stem motor system and change feeding behaviour.

Table 32.1

CCK, Cholecystokinin; *GI,* gastrointestinal; *GLP-1,* glucagon-like peptide-1; *NPY,* neuropeptide Y; *PYY3–36,* peptide YY.

Neurotransmitters such as GABA, noradrenaline, 5-hydroxytryptamine (5-HT) and dopamine also play a role in the modulation of satiety signals alongside the peptide transmitters. Noradrenaline is co-localised with NPY in some neurons and greatly potentiates its hyperphagic action. Deficit of dopamine impairs feeding behaviour, as do agonists at the 5-HT_{2C} receptor; antagonists at this receptor have the reverse effect. GABA is

released from AgRP neurons and is modulated by nutritional status as well as by hormones such as leptin.

Many neural signals arising from the GI tract are integrated, and relayed on to the hypothalamus, by the NTS in the medulla. Some of these signals, including those of gustatory, olfactory, mechanical and viscerosensory signals, arise from vagal and other spinal afferents originating in the GI tract or liver. Endocrine signals have more complex signalling pathways. For example, cholecystokinin (CCK) is secreted by the duodenum in response to the process of eating and digestion of (especially fatty) foodstuffs. CCK acts locally on CCK_A receptors in the GI tract to stimulate vagal afferents and also acts on CCK_B receptors in the brain to function as a satiety factor.

Inputs from other parts of the CNS also influence feeding behaviour. Of importance to us is the input from the NAc. This centre seems to regulate those aspects of eating that are driven by pleasure or reward – the so-called 'hedonic' aspects of eating (see also **Ch. 50**). The endocannabinoid system (see **Ch. 18**) is important in this response. The hypothalamus contains large amounts of 2-arachidonyl glycerol and anandamide as well as the CB_1 receptor. Administration of endogenous or exogenous (e.g. Δ9-THC) cannabinoids provokes a powerful feeding response. [5] This system in turn may be modulated by 'stress' and other factors in the environment.

Many other hormones such as prolactin, androgens and oestrogens can modulate the activity of the hypothalamic control centres, and the situation is complex. The reader is referred to **Cornejo et al. (2016)** for a summary of this area.

Control of Energy Expenditure

Balancing food intake is the energy expenditure required to maintain metabolism, physical activity and thermogenesis (heat production). The metabolic aspects include, among other things, cardiorespiratory work and the energy required by a multitude of enzymes. Physical activity increases all these, as well as increasing energy consumption by skeletal muscles. Exposure to cold also stimulates thermogenesis, and the reverse is also true. The, often dramatic (20%–40% increase), thermogenic effect of feeding itself may provide a partial protection against developing obesity.

The sympathetic nervous system (sometimes in concert with thyroid hormone) plays a significant part in energy regulation in cardiovascular and skeletal muscle function during physical activity, as well as the thermogenic response of adipose tissue and the response to cold. Adipose tissue is now recognised as an endocrine organ that secretes hormones (e.g. leptin) as well as cytokines in a complex dynamic interplay with skeletal muscle activity to regulate energy stores. Both ‘white’ and (especially) ‘brown’ fat cells (the colour is caused by the high density of mitochondria) play a major role in thermogenesis. Brown fat, which is densely innervated by the sympathetic nervous system, is abundant in rodents and human infants, but far less common in adult humans. There remains substantial uncertainty regarding the exact role of brown fat or the importance of heat-generating mitochondrial uncoupling protein (UCP-1) in human obesity.

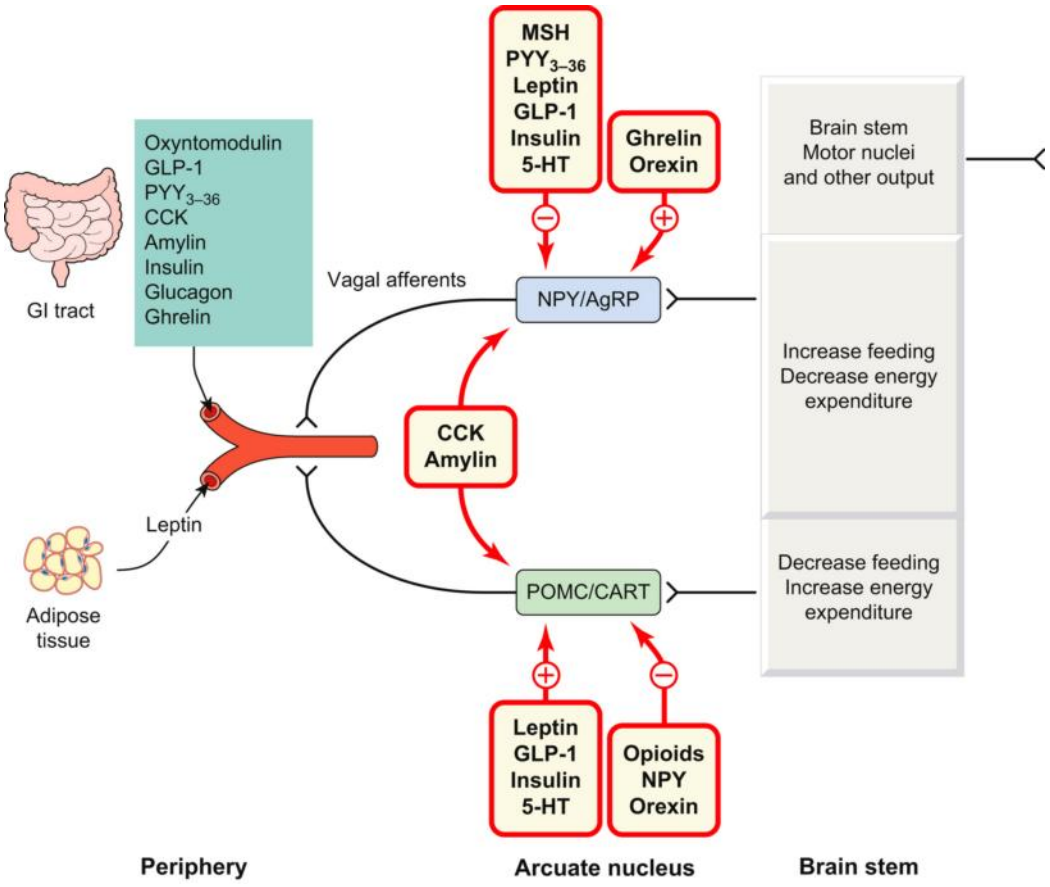

FIG. 32.2 A simplified representation of the role of peripheral hormones and other mediators in the regulation of energy balance and fat stores.The primary level of hypothalamic control is vested in two groups of neurons, with opposing actions, in the arcuate nucleus (ARC). In one group, the peptides neuropeptide Y (NPY) and agouti-related peptide (AgRP) are co-localised; the other contains the polypeptides prepro-opiomelanocortin (POMC) and cocaine- and amphetamine-related transcript (CART), which release α melanocyte-stimulating hormone (MSH). Blood-borne hormones arising

from the gastrointestinal tract or adipose tissue are sensed by receptors on vagal and other afferents and are relayed through the nucleus tractus solitarius to modify the activity of these neuronal circuits. The influence of hormones on each neuronal group is indicated. Some (e.g. leptin) arise from the peripheral blood and influence the ARC neurons directly or indirectly through neuronal signals, while others (e.g. 5-hydroxytryptamine [5-HT], orexin) originate within the central nervous system itself. Activation of the NPY/AgRP group by, for example, a fall in leptin or an increase in ghrelin levels results in increased food intake and decreased energy expenditure. In the POMC/CART group of neurons, increased leptin or other hormone levels triggered by overfeeding produces a predominately inhibitory effect on feeding behaviour. Several other hormones such as cholecystokinin (CCK) and amylin also alter the properties of the ARC neurons although the mechanism is not clear. *GLP-1,* Glucagon-like peptide-1; $PYY_{3–36}$, peptide YY. Modified from Adan, R.A., Vanderschuren, L.J., la Fleur, S.E., 2008. Anti-obesity drugs and neural circuits of feeding. Trends Pharmacol. Sci. 29, 208–217.

Energy balance

Energy balance depends on food intake, energy storage in fat and energy expenditure. In most individuals the process is tightly regulated by a homeostatic system that integrates inputs from a number of internal sensors and external factors. Important components of the system include the following:

- Hormones that signal the status of fat stores (e.g. leptin). Increasing fat storage promotes leptin release from adipocytes.
- Hormones released from the gut during feeding that convey sensations of hunger (e.g. ghrelin), satiety (e.g. CCK) or satiation (e.g. peptide YY [$PYY_{3–36}$]).
- This hormonal information together with neural, gustatory, olfactory and viscerosensory input is integrated in the hypothalamus. The ARC is a key site.
- Two groups of opposing neurons in the ARC sense hormonal and other signals. Those secreting POMC/CART products promote feeding while those secreting NPY/AgRP inhibit feeding. Many other CNS neurotransmitters (e.g. endocannabinoids) are involved.

The net output from this process is relayed to other sites in the brain stem motor nuclei that control feeding behaviour.

The Pathophysiology of Human Obesity

In most adults, body fat and body weight remain more or less constant over many years, even decades, in the face of very large variations in food intake and energy expenditure amounting to about a million calories per year. The steady-state body weight and BMI of an individual, as explained, depend upon the integration of multiple interacting regulatory pathways. How, then, does obesity occur? Why is it so difficult for the obese to lose weight and maintain the lower weight?

The main determinant is manifestly a disturbance of the complex homeostatic mechanisms that control energy balance, and genetic factors that underlie this disturbance. Other factors, such as the environment, food availability and lack of physical activity, also contribute. Additionally, of course, there are overlaying social, cultural and psychological aspects. The pathophysiology of obesity most likely involves disturbance(s) in any or all of the multitude of other factors involved in energy balance, thus making it difficult to achieve long-term success with drug therapy directed at single targets. We discuss here the physiological and genetic mechanisms; the role of social, cultural and psychological aspects we will leave (with a profound sigh of relief) to the psychosociologists!

Food Intake and Obesity

As **Spiegelman and Flier (1996)** point out, 'one need not be a rocket scientist to notice that increased food intake tends to be associated with obesity'. A typical obese subject will usually gain 20 kg over a decade or so. This means that there has been a daily excess of energy input over energy requirement of 30–40 kcal initially (i.e.

1.5%–2%), increasing gradually to maintain the increased body weight.

The type of food eaten, as well as the quantity, can disturb energy homeostasis. Fat is an energy-dense foodstuff, and it may be that the satiety mechanisms regulating appetite, which react rapidly to carbohydrate and protein, react too slowly to stop an individual consuming excess fat.

However, when obese individuals reduce their calorie intake as part of a diet regime, they shift into negative energy balance. When they lose weight, the resting metabolic rate decreases, and there is a concomitant reduction in energy expenditure. Thus an individual who was previously obese and is now of normal weight generally needs fewer calories to maintain that weight than an individual who has never been obese. The decrease in energy expenditure appears to be largely caused by an alteration in the conversion efficiency of chemical energy to mechanical work in the skeletal muscles. This adaptation to the caloric reduction contributes to the difficulty of maintaining weight loss by diet.

Physical Exercise and Obesity

It used to be said that the only exercise effective in combating obesity was pushing one's chair back from the table. It is now recognised that physical activity – i.e. increased energy expenditure – has a much more positive role in reducing fat storage and adjusting energy balance in the obese, particularly if associated with modification of the diet. A serendipitous natural population study provides an example. Many years ago, a tribe of Pima Indians split into two groups. One group in Mexico continued to live simply at

subsistence level, eating frugally and spending most of the week in hard physical labour. They are generally lean and have a low incidence of type 2 diabetes. The other group settled in the United States – an environment with easy access to calorie-rich food and less need for hard physical work. They are, on average, 57 lb (26 kg) heavier than the Mexican group and have a high incidence of early-onset type 2 diabetes.

Genetic Factors and Obesity

Rapid advances in genetic epidemiology have driven research towards large genome-wide association studies of obesity rather than limited or narrow observations of twins, nuclear families and adoption cohorts. It is now thought that genetic components underpin about 40%–50% of the susceptibility or predisposition to obesity in general populations. However, there are subgroups of people with severe obesity where the relative genetic contribution ('heritability') is much higher and exceeds 60%–80%. At least 15 separate genes (mainly related to the leptin-melanocortin pathway) have been implicated in monogenic or single-gene defects that contribute to obesity and can be passed on in traditional Mendelian pattern. Nevertheless, about two-thirds of the heritability surrounding BMI can be attributed to common DNA variants, of which there are potentially thousands. As more and more variants come to our attention, it becomes likely that each additional new variant may on its own only exert a modest effect on BMI, and the sum of their influence is more than the parts.

Overall, most cases of obesity will turn out to be polygenic in nature, involving a complex interaction between multiple sets of

genetic sites. Single-gene defects that exert a substantial individual effect are thought to be the main underlying factor in less than 10% of people with obesity. Even then, a large population study (UK Biobank) of the melanocortin pathway has found that the accompanying polygenic contribution can significantly ameliorate the effects of the single-gene defect, thus creating substantial heterogeneity in the BMI of people carrying an MC_4 variant (see **Chami et al., 2020**). The potential influence of thousands of DNA variants on susceptibility to obesity, when taken in tandem with complex epigenetic, environmental and behavioural factors, makes it very difficult to develop safe and effective long-term pharmacological agents for prevention and treatment of obesity (see **Bouchard, 2021**, for an excellent discussion on the genetics of obesity).

Obesity

- Obesity is a multifactorial disorder of energy balance, in which long-term calorie intake exceeds energy output.
- A subject with a body mass index (BMI) (W/h^2) of 20–25 kg/m^2 is considered as having a healthy body weight, one with a BMI of 25–30 kg/m^2 as overweight, and one with a BMI >30 kg/m^2 as obese.
- Obesity is a growing problem in most rich nations; the incidence – at present approximately >30% in the United States and >20% in Europe – is increasing.
- A BMI >30 kg/m^2 significantly increases the risk of type 2 diabetes, hypercholesterolaemia, hypertension, ischaemic

heart disease, gallstones and some cancers.

- The causes of obesity include:
  - dietary, exercise, social, financial and cultural factors;
  - genetic susceptibility;
  - deficiencies in the synthesis or action of leptin or other gut hormone signals;
  - defects in the hypothalamic neuronal systems responding to any of these signals;
  - defects in the systems controlling energy expenditure (e.g. reduced sympathetic activity), decreased metabolic expenditure of energy or decreased thermogenesis caused by a reduction in β_3 adrenoceptor-mediated tone and/or dysfunction of the proteins that uncouple oxidative phosphorylation.

Pharmacological Approaches to the Problem of Obesity

The first weapons in the fight against obesity are diet and exercise. Unfortunately, these often fail or show only short-term efficacy, leaving surgical techniques (such as gastric stapling or bypass) or drug therapy as a viable alternative. *Bariatric* (weight loss) surgery is much more effective than currently licensed drugs, and is believed to work chiefly, not by mechanically limiting gastric capacity, but by its effects on gut hormone responses to feeding, acting, for example, to produce earlier satiety. This may be construed as indirect evidence for the utility of pharmacological measures designed to interrupt these messengers.

The attempt to control body weight with drugs has had a long and, regrettably, a largely undistinguished [8] history. Many types of 'anorectic' (appetite suppressant) agents have been tested in the past, including the uncoupling agent **dinitrophenol** (DNP), **amphetamine** and derivatives such as **dexfenfluramine** and **fenfluramine**. All have been withdrawn from clinical use because of serious adverse effects. DNP, an industrial chemical, is advertised online for slimmers and bodybuilders as a weight loss and 'fat-burning agent', and has caused deaths among those who use it for this purpose. It blocks mitochondrial ATP production, diverting energy metabolism to generate heat instead of ATP and increasing the overall metabolic rate, which can cause life-threatening hyperthermia. [9]

Centrally Acting Appetite Suppressants

There have been many attempts to use centrally acting drugs to control appetite and this is an area which is still being actively exploited by drug hunters. Regulatory authorities in the United States and Europe have licensed the mixture of the opioid-receptor antagonist **naltrexone** and the noradrenaline–dopamine uptake–reuptake inhibitor, **bupropion** (see **Ch. 50**). This combination was associated with modest weight loss but there are ongoing concerns about neuropsychiatric (drowsiness, impaired mood and driving) and cardiovascular (e.g. hypertension) adverse effects. Intriguingly, a large cardiovascular trial of this product was abandoned by the academic team when potentially favourable data in the early interim phase were leaked by the pharmaceutical company. Subsequent

analysis of the larger trial dataset failed to confirm these favourable findings, and a further cardiovascular trial is ongoing.

Qsymia, a mixture of an old appetite suppressant drug, **phentermine**, and an anticonvulsant, **topiramate**, was approved in the United States in 2012 despite some reservations about cardiovascular and neuropsychiatric adverse effects such as depression, anxiety and altered cognition (culminating in a negative licensing decision in Europe). The drug stimulates the synaptic release of serotonin as well as noradrenaline and dopamine (and increases GABA action).

Sibutramine (now withdrawn in most countries because of clinical trial evidence demonstrating increased cardiovascular risk) inhibits the reuptake of 5-HT and noradrenaline at the hypothalamic sites that regulate food intake. [10] Its main effects are to reduce food intake and cause dose-dependent weight loss (**Fig. 32.3**). It enhanced satiety and was reported to produce a reduction in waist circumference, a decrease in plasma triglycerides and very-low-density lipoproteins, but an increase in high-density lipoproteins. Like many similar drug regimes, sibutramine was much more effective when combined with lifestyle modification.

Other serotoninergic drugs have been tested with disappointing long-term findings. **Lorcaserin**, a 5-HT_{2C} receptor agonist, was approved in the United States in 2012 for use as an appetite suppressant in certain patients. It acts by increasing POMC levels in the hypothalamus. In clinical trials, it enhanced weight loss through dieting, but patients regained weight after stopping the drug. It also improved blood sugar control but this did not translate into subsequent cardiovascular benefits. **Lorcaserin** was withdrawn in

2020 due to a small increased risk of cancer when compared to placebo.

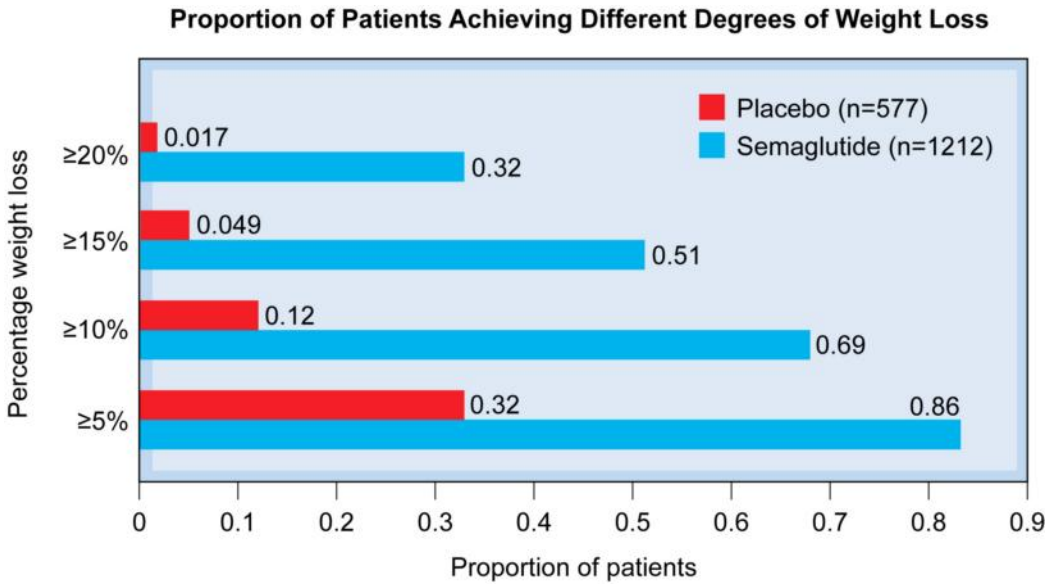

FIG. 32.3 The effect of treatment with a glucagon-like peptide-1 agonist, semaglutide 2.4 mg injected once weekly, with monthly counselling on diet and exercise.The Y axis shows percentage weight loss after 68 weeks follow-up. The X axis shows the proportions of patients achieving a particular amount of weight loss. Whilst semaglutide is clearly more effective than placebo, there remains a sizeable proportion (3 in 10) who do not achieve 10% reduction in weight with semaglutide. Data from Wilding, J. P. H., Batterham, R. L., Calanna, S., et al. 2021. Once-weekly semaglutide in adults with overweight or obesity. N. Engl. J. Med. 384, 989–1002.

The cannabinoid pathway was the target of the CB_1 receptor antagonist **rimonabant** which was originally developed to promote smoking cessation (see **Ch. 18**). This drug was introduced as an

appetite suppressant following some encouraging clinical trials but was eventually withdrawn in the United States in 2008 because of adverse effects on mood seen in some patients. A similar fate overtook another promising CB_1 antagonist, **taranabant**.

Orlistat

The only drug currently (2021) available without prescription in the United Kingdom for the treatment of obesity is the lipase inhibitor **orlistat**, used with concomitant dietary and other therapy (e.g. exercise).

In the intestine, orlistat reacts with serine residues at the active sites of gastric and pancreatic lipases, irreversibly inhibiting these enzymes and thereby preventing the breakdown of dietary fat to fatty acids and glycerol. It therefore decreases absorption (and correspondingly causes faecal excretion) of some 30% of dietary fat. Given in conjunction with a low-calorie diet in obese individuals, it produces a modest but consistent loss of weight compared with placebo-treated control subjects. In a meta-analysis of 11 long-term placebo-controlled trials encompassing more than 6000 patients, orlistat was found to produce a 2.9% greater reduction in body weight than in the control group, and 12% more patients lost 10% or more of their body weight compared with the controls (**Padwal et al., 2003**).

Orlistat is also reported to be effective in patients suffering from type 2 diabetes and other complications of obesity. It reduces leptin levels and blood pressure, protects against weight loss–induced changes in biliary secretion, delays gastric emptying and gastric secretion and improves several important metabolic parameters

without interfering with the release or action of thyroid or other important hormones (**Curran and Scott, 2004**). It does not induce changes in energy expenditure.

Pharmacokinetic Aspects and Unwanted Effects

Virtually all (97%) of orlistat is excreted in the faeces (83% unchanged), with only negligible amounts of the drug or its metabolites being absorbed.

Abdominal cramps, flatus with discharge and faecal incontinence can occur, as can intestinal borborygmi (rumbling) and oily spotting. Surprisingly, in view of the possibility of these antisocial effects occurring, the drug is well tolerated. Supplementary therapy with fat-soluble vitamins may be needed. The absorption of contraceptive pills and **ciclosporin** (see **Ch. 25**) may be decreased. The former is not usually clinically significant but the latter is potentially more serious. Given its good safety record, orlistat is available in the UK as an over-the-counter medicine for weight loss.

GLP-1 Receptor Agonists

Clinical trials have demonstrated the efficacy of GLP-1 receptor agonists (**liraglutide**, **semaglutide**) in lowering body weight (mainly through loss of visceral fat) in conjunction with diet and exercise (**Fig. 32.3**). Specific formulations of **liraglutide** (daily subcutaneous injection) and **semaglutide** (licensed as a once weekly subcutaneous injection; there is a daily oral formulation in clinical trials) are available. Higher doses of these drugs are required for treatment of obesity than the typical dose ranges used for glucose lowering in type II diabetes mellitus (see **Ch. 31**). GI

upset (nausea, vomiting, altered bowel habit) is a recognised adverse effect that stems from GLP-1 and its action on the gut.

Recent developments include studies of agonists at two or more targets which may include GIP and glucagon receptors. **Tirzepatide** is an example of a dual GIP and GLP-1 receptor agonist with greater clinical trial efficacy in controlling blood glucose as well as promoting weight loss compared to **semaglutide** in type II diabetes. Here, it is thought that GIP reduces food intake whilst increasing energy expenditure, thus potentially acting in tandem with GLP-1 agonism to have greater effects on body weight. Oxyntomodulin has structural similarities to proglucagon, and it has functional activity as a dual glucagon receptor and GLP-1 receptor agonist to similarly suppress appetite whilst enhancing energy use. The short half-life and high renal clearance of oxyntomodulin make it unsuitable for long-term use, but related molecules are currently being trialled.

Clinical uses of anti-obesity drugs

- The main treatment of obesity is a suitable sustainable diet and increased exercise.
- **Orlistat**, which causes fat malabsorption, is used together with dietary restriction in obese individuals, and also in overweight patients who have additional cardiovascular risk factors (e.g. diabetes mellitus, hypertension).
  - Orlistat therapy should be stopped after 12 weeks if the patient has not been able to lose at least 5% of their body weight from the time of drug initiation.

- **Liraglutide** and **semaglutide** are GLP-1 inhibitors that are effective in promoting weight loss as part of a diet and exercise programme; there is some evidence that **semaglutide** may be marginally more effective than **liraglutide.**
- Many centrally acting appetite suppressants (e.g. **fenfluramine**, **sibutramine**) have been withdrawn because of addiction, or other serious cardiovascular adverse effects.
- GI ('bariatric') surgery for obesity is a highly invasive procedure with potential complications but is effective for long-term management of severe obesity.

New Approaches to Obesity Therapy

As might be imagined, the quest for further effective anti-obesity agents is the subject of prodigious efforts by the pharmaceutical industry. However, this road is littered with examples of highly promising candidates that did not progress to fruition after further study (see **Williams et al., 2020**, for a comprehensive review)

Rare cases of leptin deficiency in patients have been successfully treated by long-term treatment with the hormone (**metreleptin**, a recombinant human leptin analogue), but this is unlikely to be of more than limited use in the future. Other strategies aim to alter the CNS levels of neurotransmitters such as NPY or melanocortins, which transduce hormonal signals regulating appetite. The tractability of the MC_4 receptor itself as a drug target, coupled with the observation that defects in MC_4 signalling are prevalent in obesity, has attracted much interest from the pharmaceutical

industry. However, the polygenic nature of obesity means that **setmelanotide**, a melanocortin agonist, is only approved in the United States for rare genetic obesity disorders related to mutations in the MC_4 pathway. **Setmelanotide** can reduce body weight and hunger in certain target groups but has to be administered as a daily subcutaneous injection.

A host of other peptides have been studied, including amylin, oxyntomodulin and leptin analogues and NPY antagonists. Even vaccination against ghrelin or somatostatin has been mooted as a therapeutic strategy but none of these candidates have shown sustained benefit on their own. The complex multifactorial nature of obesity, coupled with substantial individual variation in response to single agents, has shifted the research focus towards combination therapy covering two or more targets (see **Finer, 2021**, and **Williams et al., 2020**).

All in all, it is depressing that despite all the ground-breaking work on the neuroendocrine control of feeding and body weight, so few really novel drugs with acceptable benefit:harm profiles have found their way on to the market. The lack of sustained success with pharmacological therapies has led to the emergence of bariatric surgery as a more promising long-term option for reducing complications such as hypertension and diabetes mellitus in patients with severe obesity.

QUESTIONS

QUESTION 32.1

Body weight is regulated by the release of a complex array of peripheral peptide mediators.

Release of which of the following mediators would not induce satiety?

OPTIONS:

A. Leptin

B. Insulin

C. Ghrelin

D. Glucagon-like peptide-1 (GLP-1)

E. Amylin

QUESTION 32.2

There is a complex interaction between the neurological circuits in the central nervous system (CNS) and the peripheral metabolic organs that needs to be tightly coordinated so that optimum weight balance is maintained.

Effects of which of the following CNS transmitters would decrease food intake?

OPTIONS:

A. Noradrenaline

B. Neuropeptide Y (NPY)

C. Dopamine

D. 2-arachidonyl glycerol (2AG)

E. Cholecystokinin (CCK)

QUESTION 32.3

Orlistat is an effective weight loss treatment and is currently the only drug available without prescription in the United Kingdom for the treatment of obesity.

The effectiveness of orlistat can be attributed to all of the following mechanisms except ...

OPTIONS:

A. Increasing energy expenditure

B. Reducing leptin secretion

C. Preventing the breakdown of dietary fat to fatty acids and glycerol

D. Delaying gastric emptying

E. Maintaining biliary secretion

ANSWERS

ANSWER 32.1

RATIONALE:

A. Leptin is an adipocyte hormone that acts on neural connections, to suppress appetite and reduce adipose tissue.

B. Insulin has effects on the brain that are similar to leptin in decreasing food intake. Insulin may also stimulate leptin release although the relationship between these two hormones is complex.

C.

D. GLP-1 stimulates insulin secretion and inhibits glucagon and acts on receptors to mediate a reduction of appetite, and

promotion of satiety centrally at the hypothalamus.

E. Amylin released from the pancreas decreases food intake.

CORRECT ANSWER WITH EXPLANATION:

C.Ghrelin

Ghrelin promotes hunger and food intake, via receptors on vagal afferent fibres or within the hypothalamus where they modulate the release of other neurotransmitters that exert a fine regulation over eating behaviour.

ANSWER 32.2

RATIONALE:

A. Noradrenaline is co-localised with NPY in some neurons and greatly potentiates its hyperphagic action.

B. NPY is released from *orexigenic* (appetite-promoting) neurons in the arcuate nucleus.

C. Dopamine is predicted to stimulate food intake as a deficit of dopamine impairs feeding behaviour.

D. Cannabinoids acting on CB_1 receptors provoke a powerful feeding response.

E.

CORRECT ANSWER WITH EXPLANATION:

E. CCK

CCK is secreted by the duodenum in response to the process of eating and digestion of (especially fatty) foodstuffs and acts on CCK_B receptors in the brain to function as a satiety factor.

ANSWER 32.3

RATIONALE:

A.

B. It can be used in patients with type II diabetes and other complications of obesity, reducing leptin levels and blood pressure.

C. In the intestine, orlistat irreversibly inhibits gastric and pancreatic lipases preventing the breakdown of dietary fat to fatty acids and glycerol. It therefore decreases absorption (and correspondingly causes faecal excretion) of some 30% of dietary fat.

D. It delays gastric emptying and gastric secretion and improves several important metabolic parameters.

E. It protects against weight loss-induced changes in biliary secretion.

CORRECT ANSWER WITH EXPLANATION:

A. Increasing energy expenditure

Orlistat has no effect on energy expenditure.

---

[1] 'Persons who are naturally very fat are apt to die earlier than those who are slender' observed Hippocrates.

[2] The word is derived from the Greek *leptos*, meaning thin.

[3] The terminology can be confusing. 'Hunger' obviously refers to the desire to eat; 'satiation' is the feeling that you have eaten enough in the course of a meal. 'Satiety' refers to the feeling after a meal that you don't yet need another.

[4] So called because the administration of cocaine or amphetamine stimulates the transcription of this gene. Its expression in the hypothalamus is related to nutritional status implicating it in the

control of appetite. Its receptor is unknown but it probably modulates the action of NPY and leptin.

5 This effect is responsible for the 'munchies', a common side effect of smoking cannabis.

8 As the showman Bynum said: 'There's a sucker born every minute … and one born to take him' … thyroxine (to increase metabolic rate, see Ch. 34), swallowing parasites (intestinal worms compete for ingested food), amphetamines (see Ch. 59), drugs that cause malabsorption, hence leaking fat per rectum (see later in this chapter) … really!

9 DNP is reported to have been given to Russian soldiers in the Second World War, to keep them warm.

10 Many antidepressant drugs act by the same mechanism (see Ch. 48), and also cause weight loss by reducing appetite. However, sibutramine does not have antidepressant properties. Furthermore, depressed patients are often obese, and antidepressant drugs are used to treat both conditions (see Appolinario et al., 2004).

33: The pituitary and the adrenal cortex

OVERVIEW

The pituitary gland and the adrenal cortex release hormones that regulate salt and water balance, energy expenditure, growth, sexual behaviour and development, immune function and many other vital mechanisms. The commander-in-chief of this impressive hormonal campaign is the hypothalamus and the functioning unit is known as the *hypothalamo–pituitary–adrenal (HPA) axis*. In the first part of this chapter we review the control of pituitary function by hypothalamic hormones, and the physiological roles and clinical utilities of both anterior and posterior pituitary hormones. The second part of the chapter focuses on adrenal hormones and, in particular, the anti-inflammatory effect of glucocorticoids. This should be read in conjunction with the relevant sections of **Chapters 3** and 25.

The Pituitary Gland

The pituitary gland comprises three histologically distinct structures which arise from two separate embryological precursors (**Fig. 33.1**). The *anterior pituitary* and the *intermediate lobe* are derived from the endoderm of the buccal cavity, while the *posterior pituitary* is derived from neural ectoderm. The anterior and

posterior lobes receive independent neuronal input from the hypothalamus, with which they have an intimate functional relationship.

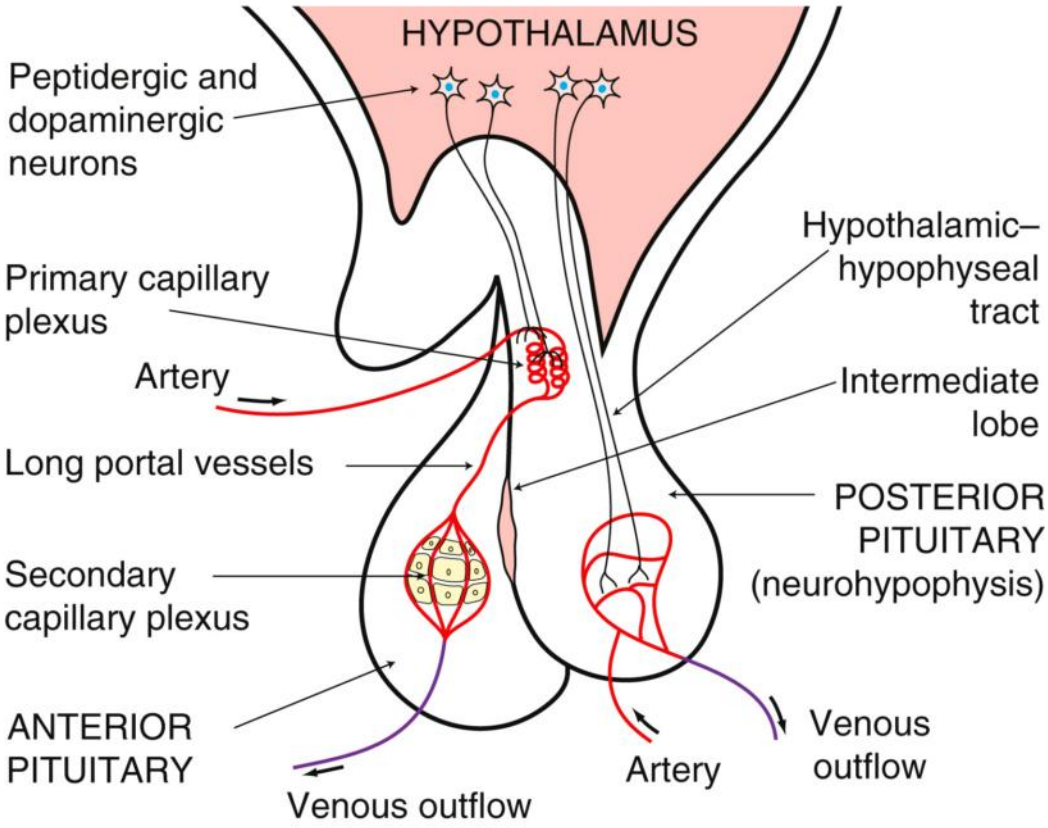

FIG. 33.1 Schematic diagram of vascular and neuronal relationships between the hypothalamus, the posterior pituitary and the anterior pituitary. The main portal vessels to the anterior pituitary lie in the pituitary stalk and arise from the primary plexus in the hypothalamus, but some (the short portal vessels) arise from the vascular bed in the posterior pituitary (not shown).

The Anterior Pituitary Gland

The anterior pituitary gland (*adenohypophysis*) secretes a number of hormones crucial for normal physiological function. Within this tissue are specialised cells such as *corticotrophs*, *lactotrophs* (*mammotrophs*), *somatotrophs*, *thyrotrophs* and *gonadotrophs*, which secrete hormones that regulate different endocrine organs throughout the body (**Table 33.1**). Interspersed among these are other cell types, including *folliculostellate cells*, which exert a nurturing and regulatory influence on the hormone-secreting endocrine cells, providing them with both structural and chemical support within the hypothalamus.

Secretion from the anterior pituitary is largely regulated by the release from the hypothalamus of, what are generally known as, 'releasing factors' – in effect, local hormones – that reach the pituitary through the bloodstream. [1] The blood supply to the hypothalamus divides to form a meshwork of capillaries, the *primary plexus*, which drains into the *hypophyseal portal vessels*. These pass through the pituitary stalk to feed a *secondary plexus* of capillaries in the anterior pituitary. Peptidergic neurons in the hypothalamus secrete a variety of releasing or inhibitory hormones directly into the capillaries of the primary capillary plexus (see **Table 33.1** and **Fig. 33.1**). Most of these regulate the secretion of hormones from the anterior lobe, although the *melanocyte-stimulating hormones* (MSHs) are secreted mainly from the intermediate lobe.

The release of stimulatory hormones is regulated by negative feedback pathways between the hormones of the hypothalamus, the anterior pituitary and the peripheral endocrine glands. Hormones

secreted from the peripheral glands exert regulatory actions on both the hypothalamus and the anterior pituitary, constituting the *long negative feedback* pathways. Anterior pituitary hormones acting directly on the hypothalamus comprise the *short negative feedback* pathway. This feedback mechanism is particularly pronounced in the HPA axis and underlies the pharmacological basis of some drug actions, which take advantage of such pronounced negative feedback loops.

The peptidergic neurons in the hypothalamus are themselves influenced by other centres within the central nervous system (CNS) and mediated through neural pathways that release dopamine, noradrenaline, 5-hydroxytryptamine and the opioid peptides (which are particularly abundant in the hypothalamus). Hypothalamic control of the anterior pituitary is also exerted through the *tuberohypophyseal dopaminergic pathway* (see **Ch. 39**), the neurons of which lie in close apposition to the primary capillary plexus. Dopamine secreted directly from dopaminergic neurons into the hypophyseal portal circulation reaches the anterior pituitary via the bloodstream, inhibiting the secretion of prolactin (see **Ch. 35**).

Table 33.1

ACTH, Adrenocorticotrophic hormone; *CRF,* corticotrophin-releasing factor; *FSH,* follicle stimulating hormone; *GH,* growth hormone; *GHRF,* growth hormone-releasing factor; *GnRH,* gonadotrophin (or luteinising hormone)-releasing hormone; *LH,* luteinising hormone; *MSH,* melanocyte-stimulating hormone; *PRF,* prolactin-releasing factor; *TRH,* thyrotrophin-releasing hormone; *TSH,* thyroid-stimulating hormone.

[a] These hormones are often spelled without the 'h' (e.g. corticotropin, thyrotropin, etc.) in contemporary texts. We have retained the original nomenclature in this edition.

Hypothalamic Hormones

The secretion of anterior pituitary hormones is primarily regulated by the peptide 'releasing factors' that originate from the hypothalamus. The most significant are described in more detail later. **Somatostatin** and **gonadotrophin-releasing hormone** are used therapeutically, the others have mainly diagnostic utilities or are useful research tools. Some of these peptides also function as neurotransmitters or neuromodulators elsewhere in the CNS (see **Ch. 39**).

Somatostatin

Somatostatin is a peptide of 14 amino acid residues, and as its name suggests ('statin'), it is inhibitory by nature. It inhibits the release of growth hormone and thyroid-stimulating hormone (TSH, thyrotrophin) from the anterior pituitary (**Fig. 33.2**), and insulin

and glucagon from the pancreas. It also decreases the release of most gastrointestinal (GI) hormones and reduces gastric acid and pancreatic secretion.

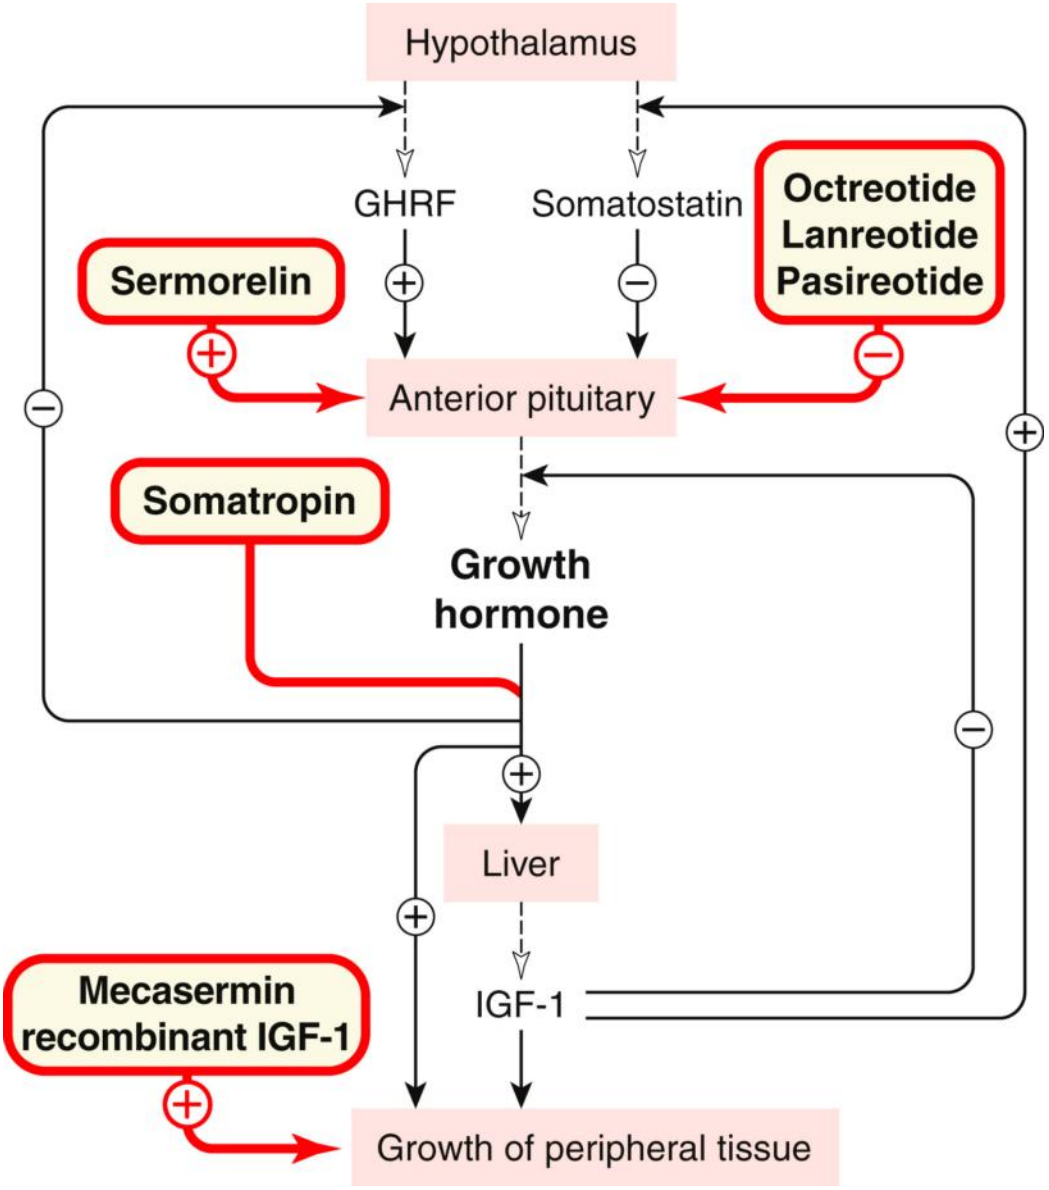

FIG. 33.2 Control of growth hormone secretion and its actions.Drugs are shown in *red-bordered boxes*. *GHRF,* Growth hormone-releasing factor; *IGF-1,* insulin-like growth factor-1.

Octreotide is a long-acting analogue of **somatostatin**. It is used for the treatment of *carcinoid* and other hormone-secreting tumours (see **Ch. 16**). It also has a place in the therapy of

acromegaly (a condition in which there is oversecretion of growth hormone in an adult). It also constricts splanchnic blood vessels and is used to treat bleeding *oesophageal varices*. **Octreotide** is generally given subcutaneously. The peak action is at 2 h, and the suppressant effect lasts for up to 8 h.

Unwanted effects include pain at the injection site and GI disturbances. Gallstones and postprandial hyperglycaemia have also been reported and acute hepatitis or pancreatitis has occurred in a few cases.

Lanreotide and **pasireotide** have similar effects. **Lanreotide** is also used in the treatment of thyroid tumours, while **pasireotide**, which is a particularly potent analogue, is used in the treatment of *Cushing's syndrome* when surgery is inappropriate or has been ineffective.

Gonadotrophin-Releasing Hormone

Gonadotrophin- (or luteinising hormone [LH]-) releasing hormone (GnRH, previously known as LHRH) is a decapeptide that releases both *follicle-stimulating hormone* and *luteinising hormone* from gonadotrophs. **Gonadorelin** [2] and its analogues (**buserelin**, **goserelin**, **leuprorelin**, **nafarelin** and **triptorelin**) are used mainly in the treatment of infertility and some hormone-dependent tumours (see **Ch. 35**).

Growth Hormone-Releasing Factor (Somatorelin)

Growth hormone-releasing factor (GHRF) is a peptide with 44 amino acid residues. The main action of GHRF is summarised in **Fig. 33.2**.

An analogue, **sermorelin** (discontinued in some countries), has been used as a diagnostic test for growth hormone secretion. Given intravenously, subcutaneously or intranasally, it causes secretion of growth hormone within minutes and peak concentrations in 1 h. The action is selective for the somatotrophs in the anterior pituitary, and no other pituitary hormones are affected. Unwanted effects are rare.

Thyrotrophin-Releasing Hormone

Thyrotrophin-releasing hormone (TRH) from the hypothalamus releases TSH from the thyrotrophs.

Protirelin (now discontinued in the United Kingdom) is a synthetic TRH that has been used for the diagnosis of thyroid disorders (see **Ch. 34**). Given intravenously in normal subjects, it causes an increase in plasma TSH concentration, whereas in patients with hyperthyroidism there is a blunted response because the raised blood thyroxine concentration has a negative feedback effect on the anterior pituitary. The opposite occurs with hypothyroidism, where there is an intrinsic defect in the thyroid itself.

Corticotrophin-Releasing Factor

Corticotrophin-releasing factor (CRF) is a peptide that releases **adrenocorticotrophic hormone** (ACTH, corticotrophin) and β-endorphin from corticotrophs in the anterior pituitary gland. CRF acts synergistically with *antidiuretic hormone* (ADH; arginine-vasopressin, see **Ch. 29**), and both its action and release are inhibited by glucocorticoids (see **Fig. 33.4**, later). Synthetic preparations have been used to test the ability of the pituitary to

secrete ACTH, and to assess whether ACTH deficiency is caused by a pituitary or a hypothalamic defect. It has also been used to evaluate hypothalamic pituitary function after therapy for Cushing's syndrome (see **Fig. 33.7**, later).

Anterior Pituitary Hormones

The main hormones of the anterior pituitary are listed in **Table 33.1**. The gonadotrophins are dealt with in **Chapter 35** and TSH in **Chapter 34**. The actions of the remainder are summarised here.

Growth Hormone (Somatotrophin)

Growth hormone is secreted by the somatotroph cells and is the most abundant pituitary hormone. Secretion is high in the newborn, decreasing at 4 years of age to an intermediate level, which is then maintained until after puberty, after which there is a further decline. Recombinant human growth hormone (hGH), **somatropin**, is available for treating growth defects and other developmental problems.

Regulation of secretion

Secretion of growth hormone is regulated by the action of hypothalamic GHRF and modulated by somatostatin, as described earlier and outlined in **Fig. 33.2**. A different peptide releaser of growth hormone ('ghrelin') is released from the stomach and pancreas and is implicated in the control of appetite and of body weight (see **Ch. 32**). One of the mediators of growth hormone action, insulin-like growth factor (IGF)-1, which is released from the liver, has an inhibitory effect on growth hormone secretion by stimulating somatostatin release from the hypothalamus.

As with other anterior pituitary secretions, growth hormone release is pulsatile, and its plasma concentration may fluctuate 10- to 100-fold. These surges occur repeatedly during the day and night and reflect the dynamics of hypothalamic control. Deep sleep is a potent stimulus to growth hormone secretion, particularly in children.

Actions

The main effect of growth hormone (and its analogues) is to stimulate normal growth. To do so, it acts in conjunction with other hormones secreted from the thyroid, the gonads and the adrenal cortex. It stimulates hepatic production of the IGFs – also termed *somatomedins* – which mediate most of its anabolic actions. IGF-1 (the principal mediator) mediates many of these anabolic effects, stimulating the uptake of amino acids and increasing protein synthesis by skeletal muscle (and therefore muscle bulk) as well as by the cartilage at the epiphyses of long bones (thus influencing bone growth). Receptors for IGF-1 exist on many other cell types, including liver cells and fat cells.

Disorders of production and clinical use

Deficiency of growth hormone (or failure of its action) results in *pituitary dwarfism*. In this condition, which may result from lack of GHRF or a lack of IGF generation or action, the normal proportions of the body are maintained even though overall stature is reduced. Growth hormone is used therapeutically in these patients (often children) as well as those suffering from the short stature caused by chronic renal insufficiency or associated with the chromosomal

disorder known as *Turner's syndrome* (a condition in which females are missing an X-chromosome).

Humans are insensitive to growth hormone of other species, so hGH must be used clinically. Human cadavers were the original source, but this led to the spread of *Creutzfeldt–Jakob disease*, a prion-mediated neurodegenerative disorder (see **Ch. 40**). hGH is now prepared by recombinant DNA technology (**somatropin**), which avoids this risk. Satisfactory linear growth can be achieved by giving **somatropin** subcutaneously, six to seven times per week, and therapy is most successful when started early.

hGH is also used illicitly by athletes (see **Ch. 59**) to increase muscle mass. The large doses used have serious side effects, causing abnormal bone growth and cardiomegaly. It has also been tested as a means of combating the bodily changes in senescence; clinical trials have shown increases in body mass, but no functional improvement. Human recombinant IGF-1 (**mecasermin**) is also available for the treatment of growth failure in children who lack adequate amounts of this hormone.

An excessive production of growth hormone in children results in *gigantism*. An excessive production in adults, which is usually the result of a benign pituitary tumour, results in *acromegaly*, in which there is enlargement mainly of the jaw and of the hands and feet. The dopamine agonist **bromocriptine** and octreotide may mitigate the condition. Another useful agent is **pegvisomant**, a modified analogue of growth hormone prepared by recombinant technology that is a highly selective antagonist of growth hormone actions. **Pegvisomant** is used where surgical treatment or **somatostatin** analogue therapy is negated or ineffective.

Prolactin

Prolactin is secreted from the anterior pituitary gland by lactotroph (mammotroph) cells. These are abundant in the gland and increase in number during pregnancy, probably under the influence of oestrogen.

Regulation of secretion

Prolactin secretion is under tonic inhibitory control by dopamine (acting on D_2 receptors on the lactotrophs) released from the hypothalamus (**Fig. 33.3** and see **Table 33.1**). The main stimulus for release is suckling but also auditory input from infant crying noise; in rats, both the smell and the sounds of hungry pups are also effective triggers. Neural reflexes from the breast may stimulate the secretion from the hypothalamus of prolactin-releasing factor(s), possible candidates for which include TRH and **oxytocin**. Oestrogens increase both prolactin secretion and the proliferation of lactotrophs through the release, from a subset of lactotrophs, of the neuropeptide *galanin*. Dopamine antagonists (used mainly as antipsychotic drugs; see **Ch. 47**) are potent stimulants of prolactin release, whereas agonists such as **bromocriptine** (see Chs **39** and **47**) suppress prolactin release. **Bromocriptine** is also used in Parkinson's disease (see **Ch. 40**).

Actions

The prolactin receptor is a single transmembrane domain receptor of the kinase-linked type (see **Ch. 3**) related to the cytokine receptors. Several different isoforms and splice variants are known. These are found not only in the mammary gland but are widely

distributed throughout the body, including the brain, ovary, heart, lungs and immune system. The main function of prolactin in women is the control of milk production. At parturition the prolactin concentration rises and lactation is initiated. Maintenance of lactation depends on suckling (see earlier), which causes a 10- to 100-fold increase in blood prolactin levels within 30 min.

Together with other hormones, prolactin is responsible for the proliferation and differentiation of mammary tissue during pregnancy. It also inhibits gonadotrophin release and/or the response of the ovaries to these trophic hormones. This is one of the reasons why ovulation does not usually occur during breastfeeding.

According to one rather appealing hypothesis, the high postpartum concentration of prolactin reflects its biological function as a 'parental' hormone. Certainly, broodiness and nest-building activity can be induced in birds, mice and rabbits by prolactin injections. Prolactin also exerts other, apparently unrelated, actions, including stimulating mitogenesis in lymphocytes. There is some evidence that it may play a part in regulating immune responses.

Modification of prolactin secretion

Prolactin itself is not used clinically. **Bromocriptine**, a dopamine receptor agonist, is used to decrease excessive prolactin secretion (*hyperprolactinaemia*). It is well absorbed orally, and peak concentrations occur after 2 h. Unwanted reactions include nausea and vomiting. Dizziness, constipation and postural hypotension may also occur. **Cabergoline** and **quinagolide** are similar.

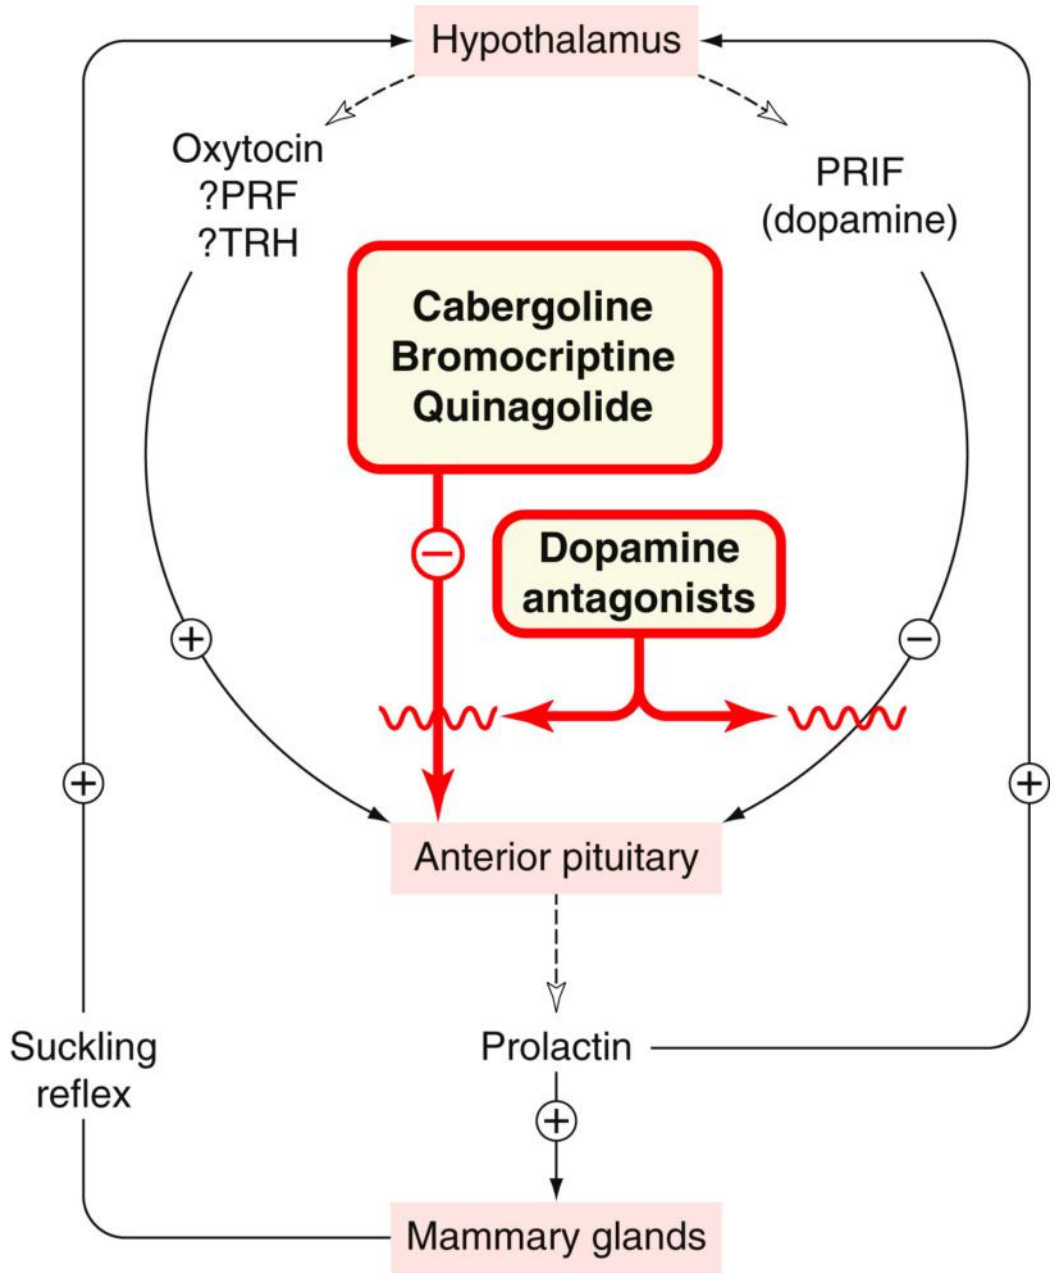

FIG. 33.3 Control of prolactin secretion.Drugs are shown in *red-bordered boxes*. *PRF,* Prolactin-releasing factor(s); *PRIF,* prolactin release-inhibiting factor(s); *TRH,* thyrotrophin-releasing hormone.

Clinical uses of bromocriptine

- To prevent lactation.
- To treat galactorrhoea (i.e. non-puerperal lactation in either sex), owing to excessive prolactin secretion (hyperprolactinaemia).
- To treat prolactin-secreting pituitary tumours (prolactinomas).
- In the treatment of Parkinson's disease (see **Ch. 40**) and of acromegaly.

Adrenocorticotrophic Hormone

ACTH (corticotrophin) is the anterior pituitary secretion that controls the synthesis and release of the glucocorticoids of the adrenal cortex (see **Table 33.1**). It is a 39-residue peptide derived from the precursor pro-opiomelanocortin (POMC) by sequential proteolytic processing. It acts on the MC_2 member of the family of melanocortin receptors (see later). Failure of ACTH action because of defects in its receptor or intracellular signalling pathways can lead to severe glucocorticoid deficiency (**Chan et al., 2008**). Details of the regulation of ACTH secretion are shown in **Fig. 33.4**.

This hormone occupies (together with cortisone) an important place in the history of inflammation therapy because of the work of Hench and his colleagues in the 1940s, who first observed that both substances had anti-inflammatory effects in patients with rheumatoid disease. The effect of ACTH was thought to be secondary to stimulation of the adrenal cortex but, interestingly, the

hormone also has anti-inflammatory actions in its own right, through activation of macrophage (melanocortin) MC_3 receptors (**Getting et al., 2002**).

FIG. 33.4 Regulation of synthesis and secretion of adrenal corticosteroids.The long negative feedback loop is more physiologically significant than the short loop *(dashed lines)*. Adrenocorticotrophic hormone (ACTH, corticotrophin) has only a minimal effect on mineralocorticoid production. Drugs are shown in *red-bordered boxes*. *ADH,* Antidiuretic hormone (vasopressin); *CRF,* corticotrophin-releasing factor.

ACTH itself is not often used in therapy today, because its action is less predictable than that of the corticosteroids and it may provoke antibody formation. **Tetracosactide** (**tetracosactrin**), a synthetic polypeptide that consists of the first 24 N-terminal residues of human ACTH, suffers from some of the same drawbacks but is now widely used for assessing the competency of the adrenal cortex. The drug is given intramuscularly or intravenously, and the concentration of hydrocortisone in the plasma is measured by radioimmunoassay.

Actions

Acting through MC_2 receptors, **tetracosactide** and ACTH have two actions on the adrenal cortex:

- Stimulation of the synthesis and release of glucocorticoids. This action occurs within minutes of injection, and the ensuing biological actions are predominately those of the released steroids.

- A trophic action on adrenal cortical cells, and regulation of the levels of key mitochondrial steroidogenic enzymes. The loss of this effect accounts for the adrenal atrophy that results from chronic glucocorticoid administration, which suppresses ACTH secretion.

Melanocyte-Stimulating Hormone (Msh)

α-, β- and γ-MSH are peptide hormones with structural similarity to ACTH and are derived from the same precursor. Together, these peptides are referred to as *melanocortins*, because their first recognised action was to stimulate the production of melanin by specialised skin cells called *melanocytes*. As such, they play an important part in determining hair colouration, skin colour, [3] pigmentation patterns and reaction to (and protection from) ultraviolet light.

MSH acts on melanocortin receptors, of which five (MC_{1-5}) have been cloned. These are G protein–coupled receptors (GPCRs) that activate cAMP synthesis. Melanin formation is controlled by the MC_1 receptor. Excessive α-MSH production can provoke abnormal proliferation of melanocytes and may predispose those individuals to melanoma.

Melanocortins exhibit numerous other biological effects. For example, α-MSH inhibits the release of interleukin (IL)-1β and tumour necrosis factor (TNF)-α reduces neutrophil infiltration and exhibits anti-inflammatory and antipyretic activity. Levels of α-MSH are increased in the synovial fluid of patients with rheumatoid arthritis. These immunomodulatory effects are transduced by MC_1 and MC_3 receptors. Agonists at these receptors with potential anti-

inflammatory activity are being sought. Central injection of α-MSH also causes changes in animal behaviour, such as increased grooming and sexual activity as well as reduced feeding through actions on MC_4 receptors, and agonists of MC_4 are under investigation as potential treatments for obesity and for erectile impotence.

Intracerebroventricular or intravenous injection of γ-MSH increases blood pressure, heart rate and cerebral blood flow. These effects are also likely to be mediated by the MC_4 receptor.

Two naturally occurring ligands for melanocortin receptors (*agouti-signalling protein* and *agouti-related peptide*, together called the *agouti*) have been discovered in human tissues. These are proteins that competitively antagonise the effect of MSH at melanocortin receptors.

The anterior pituitary gland and hypothalamus

- The anterior pituitary gland secretes hormones that regulate:
  - the release of *glucocorticoids* from the adrenal cortex
  - the release of *thyroid hormones*
  - the release of sex hormones: *ovulation* in the female and *spermatogenesis* in the male
  - *growth*
  - *mammary gland* structure and function
- Each anterior pituitary hormone is itself regulated by a specific hypothalamic releasing factor. Feedback mechanisms

govern the release of these factors. Clinically useful drugs of this type include:

- *GHRF* (**sermorelin**) and analogues of growth hormone (**somatrophin**)
- *thyrotrophin-releasing factor* (**protirelin**) and TSH (thyrotrophin; used to test thyroid function)
- **octreotide** and **lanreotide**, analogues of ***somatostatin*** , which inhibit growth hormone release
- *CRF*, used in diagnosis
- *gonadotrophin-releasing factor,* ***gonadorelin*** *and analogues*. Used to treat infertility and some carcinomas

Adrenocorticotrophic hormone and the adrenal steroids

- ACTH (**tetracosactrin**, **tetracosactide**) stimulates synthesis and release of glucocorticoids (e.g. **hydrocortisone**), as well as some androgens, from the adrenal cortex.
- CRF from the hypothalamus regulates ACTH release and is regulated in turn by neural factors and negative feedback effects of plasma glucocorticoids.
- Mineralocorticoid (e.g. aldosterone) release from the adrenal cortex is controlled by the renin–angiotensin system.

Posterior Pituitary Gland

The posterior pituitary gland (neurohypophysis) consists largely of the terminals of nerve cells originating from the *supraoptic* and *paraventricular nuclei* of the hypothalamus. Their axons form the *hypothalamic–hypophyseal tract*, and the fibres terminate in dilated nerve endings in close association with capillaries in the posterior pituitary gland (see **Fig. 33.1**). Peptides, synthesised in the hypothalamic nuclei, pass down these axons into the posterior pituitary, where they are stored and eventually secreted into the bloodstream.

The two main hormones of the posterior pituitary are **oxytocin** (which contracts the smooth muscle of the uterus; for details see **Ch. 35**) and **vasopressin** (ADH; see Chs **21** and **29**). They are highly homologous cyclic nonapeptides. Several analogues have been synthesised that vary in their antidiuretic, vasopressor and oxytocic (uterine stimulant) properties.

Vasopressin

Regulation of secretion and physiological role

Vasopressin released from the posterior pituitary has a crucial role in the control of the water content of the body through its action on the cells of the distal part of the nephron and the collecting tubules in the kidney (see **Ch. 29**). The hypothalamic nuclei that control fluid balance lie close to the nuclei that synthesise and secrete vasopressin.

One of the main stimuli for vasopressin release is an increase in plasma osmolarity (which produces a sensation of thirst). A decrease in circulating blood volume (*hypovolaemia*) is another, and here the stimuli arise from stretch receptors in the

cardiovascular system or from angiotensin release. *Diabetes insipidus* is a condition in which large volumes of dilute urine are produced because vasopressin secretion is reduced or absent, or because of a reduced sensitivity of the kidney to the hormone.

Vasopressin receptors

There are three classes of receptor: V_{1A}, V_{1B} and V_2. All are GPCRs. V_2 receptors stimulate adenylyl cyclase, which mediates the main physiological actions of vasopressin in the kidney, whereas the V_{1A} and V_{1B} receptors are coupled to the phospholipase C/inositol trisphosphate system.

The receptor for oxytocin (OT receptor) is also a GPCR, which primarily signals through phospholipase C stimulation but has a secondary action on adenylyl cyclase. Vasopressin is a partial agonist at OT, but its effects are limited by the distribution of the receptor, which, as might be inferred from its classic action on the pregnant uterus, is high in the myometrium, endometrium, mammary gland and ovary. The central actions of oxytocin (and vasopressin) have also attracted the attention of sociobiologists as they are important in 'pair bonding' and the other psychosocial interactions. [4]

Actions

Renal actions

Vasopressin binds to kidney V_2 receptors in the basolateral membrane of the cells of the distal tubule and collecting ducts of the nephron. Its main effect in the collecting duct is to increase the rate of insertion of water channels (*aquaporins*) into the luminal

membrane, thus increasing the permeability of the membrane to water (see **Ch. 29**). It also activates urea transporters and transiently increases Na^+ absorption, particularly in the distal tubule.

Several drugs affect the action of vasopressin. Non-steroidal anti-inflammatory drugs and **carbamazepine** increase, and **lithium**, **colchicine** and **vinca alkaloids** decrease, vasopressin effects. The effects of the last two agents are secondary to their action on the microtubules required for translocation of water channels. The V_2 receptor antagonists **tolvaptan and demeclocycline** (actually a tetracycline antibiotic) counteract the action of vasopressin in renal tubules and can be used to treat patients with water retention combined with urinary salt loss (and thus *hyponatraemia*) caused by excessive secretion of the hormone. This *syndrome of inappropriate ADH secretion* ('SIADH') is associated with lung or other malignancies or head injury. Specific V_2 receptor antagonists are also being investigated in the treatment of heart failure (see **Ch. 22**).

Other non-renal actions

Vasopressin causes contraction of smooth muscle, particularly in the cardiovascular system, by acting on V_{1A} receptors (see **Ch. 22**). The affinity of vasopressin for these receptors is lower than that for V_2 receptors, and smooth muscle effects are seen only with doses larger than those affecting the kidney. Vasopressin also stimulates blood platelet aggregation and mobilisation of coagulation factors. When released into the pituitary portal circulation, it promotes the release of ACTH from the anterior pituitary by an action on V_{1B}

receptors (see **Fig. 33.4**). In the CNS, vasopressin, like oxytocin, is believed to have a role in modulating emotional and social behaviour.

Pharmacokinetic aspects

Vasopressin, and various peptidergic analogues, are used clinically either for the treatment of diabetes insipidus or as vasoconstrictors. Several analogues have been developed to (a) increase their duration of action and (b) shift the relative potency between the V_1 and V_2 receptors.

The main substances used are:

- ***vasopressin*** *itself:* short duration of action, weak selectivity for V_2 receptors, given by subcutaneous or intramuscular injection, or by intravenous infusion;
- ***desmopressin:*** increased duration of action, V_2-selective and thereby with fewer pressor effects, can be given by several routes including nasal spray;
- ***terlipressin:*** increased duration of action, low but protracted vasopressor action (and minimal antidiuretic properties), used to reduce bleeding (e.g. from oesophageal varices) and maintain blood pressure;
- ***felypressin:*** a short-acting vasoconstrictor that is injected with local anaesthetics such as prilocaine to prolong their action (see **Ch. 44**).

Vasopressin itself is rapidly eliminated, with a plasma half-life less than 10 min and a short duration of action. Tissue peptidases metabolise the hormone and 33% is removed by the kidney.

Desmopressin is less subject to degradation by peptidases, and its plasma half-life is 75 min.

Unwanted effects

There are few unwanted effects, and these are mainly cardiovascular in nature: intravenous vasopressin may cause spasm of the coronary arteries with resultant angina, but this risk can be minimised if the antidiuretic peptides are administered intranasally.

The posterior pituitary gland

- The posterior pituitary gland secretes:
  - oxytocin (see **Ch. 35**)
  - antidiuretic hormone (**ADH, vasopressin**), which acts on V_2 receptors in the distal kidney tubule to increase water reabsorption and, in higher concentrations, on V_{1A} receptors to cause vasoconstriction. It also stimulates ACTH secretion.
- Substances available for clinical use are **vasopressin** and the analogues **desmopressin**, **felypressin** and **terlipressin.**

Clinical uses of antidiuretic hormone (ADH, vasopressin) and analogues

- Diabetes insipidus: **felypressin**, **desmopressin.**
- Initial treatment of bleeding oesophageal varices: **vasopressin**, **terlipressin**, **felypressin.** (**Octreotide** – a

somatostatin analogue – is also used, but direct injection of sclerosant via an endoscope is the main treatment.)

- Prophylaxis against bleeding in haemophilia (e.g. before tooth extraction): **vasopressin**, **desmopressin** (by increasing the concentration of factor VIII).
- **Felypressin** is used as a vasoconstrictor with local anaesthetics (see **Ch. 44**).
- **Desmopressin** is used for persistent nocturnal enuresis in older children and adults.

The Adrenal Cortex

The adrenal glands consist of two parts: the inner *medulla*, which secretes catecholamines (see **Ch. 15**), and the outer *cortex*, which secretes adrenal steroids. The cortex comprises three concentric zones: the *zona glomerulosa* (the outermost layer), which elaborates mineralocorticoids; the *zona fasciculata*, which elaborates glucocorticoids; and the innermost *zona reticularis*, which produces androgen precursors. The principal adrenal steroids are those with glucocorticoid and mineralocorticoid activities. [5] Androgen secretion (see **Ch. 35**) by the cortex is not considered further in this chapter.

The mineralocorticoids regulate water and electrolyte balance, and the main endogenous hormone is *aldosterone*. The glucocorticoids have widespread actions on carbohydrate and protein metabolism, as well as potent regulatory effects on host defence mechanisms (see Chs 7 and **25**). The adrenal gland secretes a mixture of glucocorticoids; in humans the main hormone is

hydrocortisone (also, confusingly, known as *cortisol*), and in rodents it is *corticosterone*. The mineralocorticoid and glucocorticoid actions are not completely separated in naturally occurring steroids and some glucocorticoids have quite substantial effects on water and electrolyte balance. In fact, both hydrocortisone and aldosterone are equiactive on mineralocorticoid receptors but, in mineralocorticoid-sensitive tissues such as the kidney, the action of *11β-hydroxysteroid dehydrogenase Type 2* converts hydrocortisone to the inactive metabolite cortisone, [6] thereby preventing the tissue from responding to hydrocortisone. Interestingly, there is increasing evidence that some glucocorticoid synthesis can take place locally at extra-adrenal sites such as thymus and skin (see **Talaber et al., 2015**; **Hannen et al., 2017**) providing a fresh perspective on the local control of inflammatory processes.

With the exception of *replacement therapy*, glucocorticoids are most commonly employed for their anti-inflammatory and immunosuppressive properties (see **Ch. 25**). In this therapeutic context, their metabolic and other actions are seen as unwanted side effects. Synthetic steroids have been developed that exhibit a partial separation of the glucocorticoid from the mineralocorticoid actions (**Table 33.2**), but it has not yet been possible completely to separate the anti-inflammatory from the other actions of the glucocorticoids.

The adrenal gland is essential to life, and animals deprived of these glands are able to survive only under rigorously controlled conditions. In humans, a deficiency in corticosteroid production, termed *Addison's disease*, is characterised by muscular weakness,

low blood pressure, depression, anorexia, loss of weight and hypoglycaemia. Addison's disease may have an autoimmune aetiology, or it may be secondary to destruction of the gland by chronic inflammatory conditions such as tuberculosis.

When corticosteroids are produced in excess, the clinical picture depends on which molecular species predominates. Excessive *glucocorticoid activity* results in *Cushing's syndrome*, the manifestations of which are outlined in **Fig. 33.7**. This can be caused by hypersecretion from the adrenal glands or by prolonged therapeutic use of glucocorticoids. An excessive production of *mineralocorticoids* results in retention of Na^+ and loss of K^+. This may be caused by hyperactivity or tumours of the adrenals (*primary hyperaldosteronism*, or *Conn's syndrome*, an uncommon but important cause of hypertension; see **Ch. 22**), or by excessive activation of the renin–angiotensin system such as occurs in some forms of kidney disease, cirrhosis of the liver or congestive cardiac failure (*secondary hyperaldosteronism*).

Glucocorticoids

Synthesis and release

Glucocorticoids are not stored in the adrenal gland but are synthesised under the influence of circulating ACTH secreted from the anterior pituitary gland (see **Fig. 33.4**) and released in a pulsatile fashion into the blood. While glucocorticoids are continuously released, there is a well-defined circadian rhythm in the secretion in healthy humans, with the net blood concentration being highest early in the morning, gradually diminishing throughout the day and reaching a low point in the evening or night.

ACTH secretion itself (also pulsatile in nature) is regulated by CRF released from the hypothalamus, and by vasopressin released from the posterior pituitary gland. The release of both ACTH and CRF, in turn, is reflexly inhibited by the ensuing rising concentrations of glucocorticoids in the blood.

Table 33.2

ACTH, Adrenocorticotrophic hormone; *GR,* glucocorticoid receptor.

[a] Duration of action (half-lives in hours): short, 8–12; intermediate, 12–36; long, 36–72. Some drugs are inactive until converted to active compounds in vivo and therefore have negligible affinity for the glucocorticoid receptor.

Data for relative affinity obtained from Baxter, J.D., Rousseau, G.G. (Eds.), 1979. Glucocorticoid Hormone Action. Monographs on Endocrinology. Springer-Verlag, Berlin.

Opioid peptides also exercise a tonic inhibitory control on the secretion of CRF, and psychological factors, excessive heat or cold, injury or infections can also affect the release of both vasopressin and CRF. This is the principal mechanism whereby the HPA axis is activated in response to perceived threats in the external environment.

The biosynthetic precursor of glucocorticoids is cholesterol (**Fig. 33.5**). The initial conversion of cholesterol to *pregnenolone* is the rate-limiting step and is regulated by ACTH. Some biosynthetic reactions can be inhibited by drugs, and these have a utility in treating Cushing's disease or adrenocortical carcinoma.

Metyrapone prevents the β-hydroxylation at C11, and thus the formation of hydrocortisone and corticosterone. Synthesis is blocked at the 11-deoxycorticosteroid stage, leaving intermediates that have no effects on the hypothalamus and pituitary, so there is a marked increase in ACTH in the blood. **Metyrapone** can therefore be used to test ACTH production and may also be used to treat patients with Cushing's syndrome. **Trilostane** (previously used to treat Cushing's syndrome and primary hyperaldosteronism but now largely restricted to veterinary indications) blocks an earlier enzyme in the pathway – the *3β-dehydrogenase*. **Aminoglutethimide** inhibits the initial step in the biosynthetic pathway and has the same overall effect as metyrapone.

Trilostane and **aminoglutethimide** are not currently used in the United Kingdom but **ketoconazole**, an antifungal agent (see **Ch. 54**), also inhibits steroidogenesis and may be of value in the specialised treatment of Cushing's syndrome (**Fig. 33.7**). **Mitotane** suppresses glucocorticoid synthesis by a direct (and unknown) mechanism on the adrenal gland. It is chiefly used to treat advanced or inoperable adrenocortical carcinomas.

Mechanism of glucocorticoid action

The glucocorticoid effects relevant to this discussion are initiated by interaction of the drugs with specific intracellular glucocorticoid receptors (GRs) [7] belonging to the nuclear receptor superfamily (although there may be other binding proteins or sites; see **Norman et al., 2004**). This superfamily also includes the receptors for mineralocorticoids, the sex steroids, thyroid hormones, vitamin D_3 and retinoic acid (see **Ch. 3**). The actual

mechanism of transcriptional control is complex, with at least four mechanisms operating within the nucleus. These are summarised diagrammatically in **Fig. 33.6**.

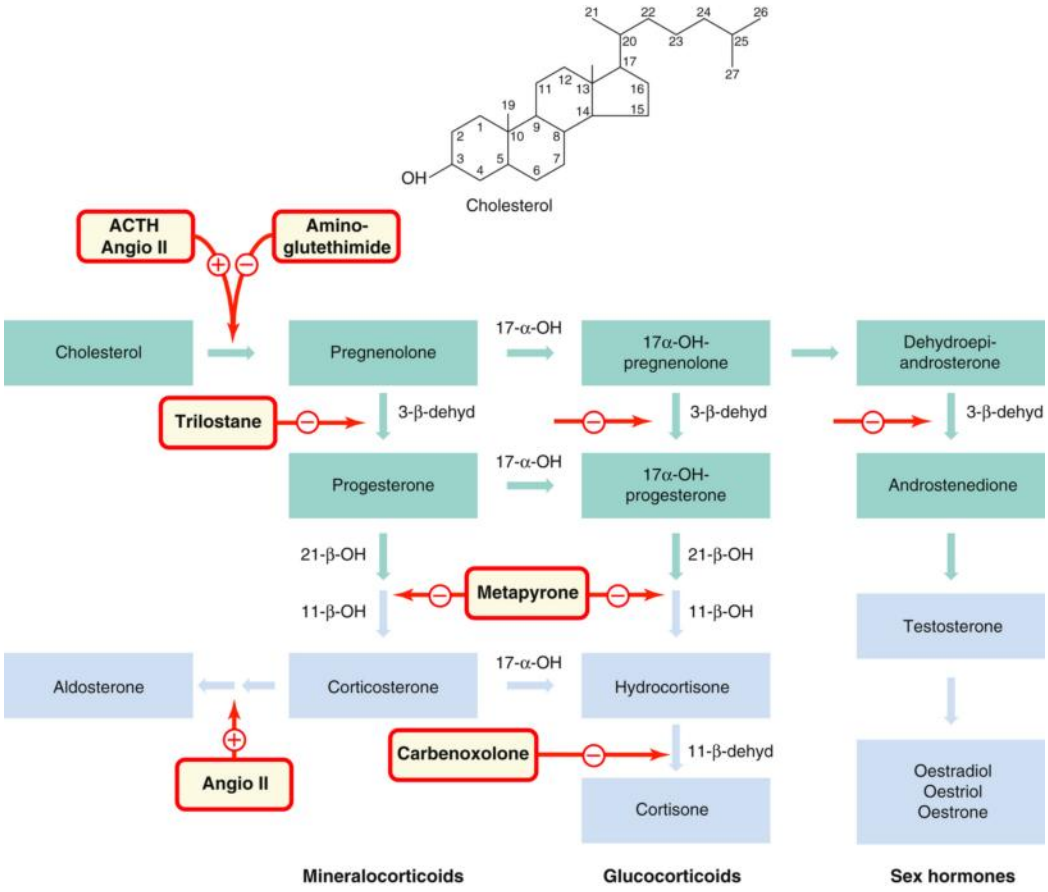

FIG. 33.5 Biosynthesis of corticosteroids, mineralocorticoids and sex hormones.All steroid hormones are synthesised from cholesterol. The biosynthetic pathway involves successive steps of hydroxylation and dehydrogenation and these are targets for drugs. Intermediates are shown in *green boxes*; interconversions occur between the pathways. *Blue boxes* indicate circulating hormones. Drugs are shown in *red-bordered boxes* adjacent to their sites of action. Glucocorticoids are produced by cells of the zona fasciculata, and their synthesis is stimulated by adrenocorticotrophic hormone (ACTH);

aldosterone is produced by cells of the zona glomerulosa, and its synthesis is stimulated by angiotensin II (angio II). Metyrapone inhibits glucocorticoid synthesis; aminoglutethimide and trilostane block synthesis of all three types of adrenal steroid (see text for details). Carbenoxolone inhibits the interconversion of hydrocortisone and cortisone in the kidney. Not shown is mitotane, which suppresses adrenal hormone synthesis through an unknown mechanism. Enzymes: *17-α-OH,* 17-α-hydroxylase; *3-β-dehyd,* 3-β-dehydrogenase; *21-β-OH,* 21-β-hydroxylase; *11-β-OH,* 11-β-hydroxylase; *11-β-dehyd,* 11-β-hydroxysteroid dehydrogenase.

When the nuclear actions of GRs were first discovered, it was thought that this mechanism could account for all the actions of the hormones, but a surprising discovery overturned this idea. **Reichardt et al. (1998)**, using transgenic mice in which the GR was unable to dimerise (and therefore unable to function in the nucleus), found that glucocorticoids were still able to exert a great many biological actions. This suggested that in addition to controlling gene expression within the nucleus, the liganded receptor itself could initiate important signal transduction events while still in the cytosolic compartment (there may even be a subpopulation of receptors that reside there permanently). One such effect seems to be interaction of the receptor with the regulatory complex, NF-κB (see **Fig. 33.6** and **Ch. 3**) and other

important interactions may involve protein kinases/phosphatase signalling systems. Some of these cytosolic actions are very rapid. For example, the liganded GR-induced phosphorylation by protein kinase C (PKC) and subsequent release of the protein *Annexin A1*, which has potent inhibitory effects on leukocyte trafficking and other anti-inflammatory actions, occurs in minutes and cannot be accounted for by changes in protein synthesis; and there are many other examples of non-transcriptional activities of glucocorticoids (see **Buttgereit and Scheffold, 2002**; **Panettieri et al., 2019**).

In recent years, our understanding of the glucocorticoid field has been further enriched by the discovery of numerous isoforms and splice variants of GR, some of which are expressed in a tissue-specific manner (see **Oakley and Cidlowski, 2013**). This opens up a real possibility of highly selective glucocorticoid drugs in the future.

Mechanism of action of the glucocorticoids

- Glucocorticoids bind intracellular receptors that then dimerise, migrate to the nucleus and interact with DNA to modify gene transcription, inducing synthesis of some proteins and inhibiting synthesis of others.
- Many acute glucocorticoid actions are mediated by signalling systems triggered by the liganded receptor in the cytosol. Some are very rapid.
- There may be different populations of receptors including membrane-bound receptors which may also transduce rapid actions.

- Tissue and splice variants of the GR are found to be distributed in a tissue-specific fashion.

Actions

General metabolic and systemic effects

The main metabolic effects are on carbohydrate and protein metabolism. The glucocorticoids cause both a decrease in the uptake and utilisation of glucose and an increase in gluconeogenesis, resulting in a tendency to hyperglycaemia (see **Ch. 31**). There is a concomitant increase in glycogen storage, which may be a result of insulin secretion in response to the increase in blood sugar. Overall, there is decreased protein synthesis and increased protein breakdown, particularly in muscle, and this can lead to tissue wasting. Catecholamines and some other hormones cause lipase activation through a cAMP-dependent protein kinase, the synthesis of which requires the 'permissive' presence of glucocorticoids, and several other examples of this type of hormone action have been observed. Large doses of glucocorticoids given over a long period result in the redistribution of body fat characteristic of Cushing's syndrome (**Fig. 33.7**).

Glucocorticoids tend to produce a negative calcium balance by decreasing Ca^{2+} absorption in the GI tract and increasing its excretion by the kidney. Together with increased breakdown of bone matrix protein this may cause osteoporosis. In higher, non-physiological concentrations, the glucocorticoids have some mineralocorticoid actions, causing Na^{+} retention and K^{+} loss –

possibly by swamping the protective 11β-hydroxysteroid dehydrogenase and acting off-target at mineralocorticoid receptors.

Negative feedback effects on the anterior pituitary and hypothalamus

Both endogenous and exogenous glucocorticoids have a negative feedback effect on the secretion of CRF and ACTH (see **Fig. 33.4**), thus inhibiting the secretion of endogenous glucocorticoids and potentially causing atrophy of the adrenal cortex. If therapy is prolonged, it may take many months to return to normal function once the drugs are withdrawn.

Anti-inflammatory and immunosuppressive effects

Endogenous glucocorticoids maintain a low-level anti-inflammatory tone and are secreted in increased amounts in response to inflammatory stimuli. Consequently, adrenalectomised animals and humans with adrenal insufficiency show a heightened response to even mild insults, injuries or stresses. On this basis, it has been suggested that a failure of appropriate glucocorticoid secretion in response to injury or infection may underlie certain chronic inflammatory human pathologies.

Exogenous glucocorticoids are the anti-inflammatory drugs *par excellence*, and when given therapeutically, suppress the operation of both the innate and adaptive immune system. They reverse virtually all types of inflammatory reaction, whether caused by invading pathogens, by chemical or physical stimuli, or by inappropriately deployed immune responses such as are seen in hypersensitivity or autoimmune disease. When used prophylactically to suppress graft rejection, glucocorticoids are more

efficient in suppressing the initiation and generation of the immune response than they are in preventing the operation of an established response where clonal proliferation has already occurred. Exogenous glucocorticoids are often co-administered with chemotherapeutics in cancer (see **Ch. 57**). This co-administration often enhanced the effectiveness of the anti-cancer agents, through a not very well understood mechanism. Of late, exogenous glucocorticoids are also administered to patients with severe **COVID-19** to reduce inflammation and sclerosis, improve lung function, and boost overall survival.

Given that glucocorticoids modify the expression of so many genes (approximately 1% of the total genome is affected), and that the extent and direction of regulation varies between tissues and even at different times during disease, you will not be surprised to learn that their anti-inflammatory effects are complex.

Actions on *inflammatory* cells include:

- decreased egress of neutrophils from blood vessels and reduced activation of neutrophils, macrophages and mast cells secondary to decreased transcription of the genes for cell adhesion factors and cytokines;
- decreased overall activation of T-helper (Th) cells, reduced clonal proliferation of T cells and a 'switch' from the Th1 to the Th2 immune response (see **Ch. 7**);
- decreased fibroblast function, less production of collagen and glycosaminoglycans and, under some circumstances, reduced healing and repair.

Actions on the mediators of inflammatory and immune responses (**Ch. 17**) include:

- decreased production of prostanoids through reduced expression of cyclo-oxygenase II and suppression of substrate arachidonic acid release;
- decreased generation of many cytokines, including IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, TNF-α, cell adhesion factors and granulocyte–macrophage colony-stimulating factor. These are largely secondary to inhibition of gene transcription;

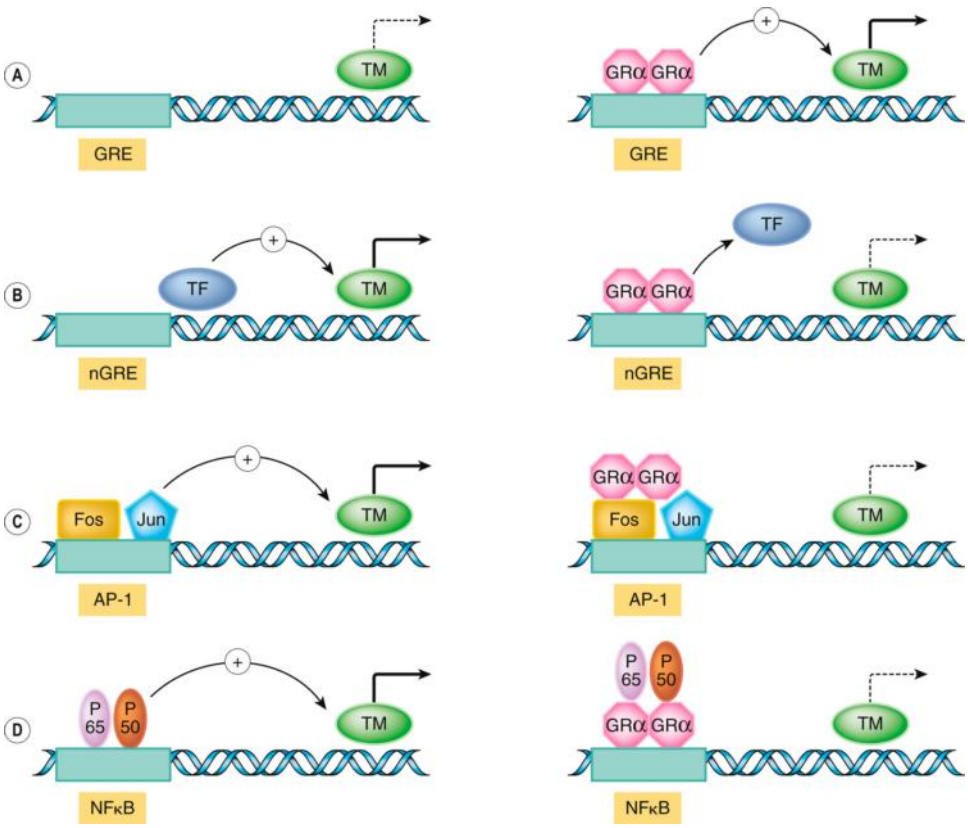

FIG. 33.6 Molecular mechanism of action of glucocorticoids.The schematic figure shows four possible ways by which the liganded glucocorticoid receptor can control gene expression following translocation into the nucleus. (A) Basic transactivation mechanism. Here, the transcriptional machinery (TM) is presumed to be operating at a low level. The liganded glucocorticoid receptor (GR) dimer binds to one or more 'positive' glucocorticoid response elements (GREs) within the promoter sequence *(shaded zone)* and upregulates transcription. (B) Basic transrepression

mechanism. The TM is constitutively driven by transcription factors (TFs). In binding to the 'negative' GRE (nGRE), the receptor complex displaces these factors and expression falls. (C) Fos/Jun mechanism. Transcription is driven at a high level by Fos/Jun transcription factors binding to their AP-1 regulatory site. This effect is reduced in the presence of the GR. (D) Nuclear factor (NF)-κβ mechanism. The TFs P65 and P50 bind to the NF-κβ site, promoting gene expression. This is prevented by the presence of the GR, which binds the TFs, preventing their action (this may occur in the cytoplasm also). (For further details of the structure of the glucocorticoid receptor, see **Ch. 3**.) Redrawn from Oakley, R.H., Cidlowski, J.A., 2001. The glucocorticoid receptor: expression, function and regulation of glucocorticoid responsiveness. In: Goulding, N.J., Flower, R.J. (Eds.), Milestones in Drug Therapy: Glucocorticoids. Birkhäuser Verlag, Basel.

- reduction in the concentration of complement components in the plasma;
- decreased generation of nitric oxide by the inducible nitric oxide synthase 2 (NOS2) isoform;

- decreased release of histamine and other mediators from basophils and mast cells;
- decreased immunoglobulin G (IgG) production;
- increased synthesis of anti-inflammatory factors such as IL-10, IL-1-soluble receptor and Annexin 1.

Endogenous anti-inflammatory glucocorticoids circulate constantly in the blood and are increased during inflammatory episodes – or even by the anticipation of a stressful event. It is suggested (see **Munck et al., 1984**) that the anti-inflammatory and immunosuppressive actions of endogenous glucocorticoids play a crucial counter-regulatory role, in that they prevent excessive activation of inflammation and other powerful defence reactions that might, if unchecked, threaten homeostasis. Certainly, this view is borne out by experimental work. While these drugs are of great value in treating conditions characterised by hypersensitivity and unwanted inflammation, they carry the hazard that they are able to suppress the same defence reactions that protect us from infection and other insults.

Unwanted effects

Low-dose glucocorticoid replacement therapy is usually without problems, but serious unwanted effects occur with large doses or prolonged administration of glucocorticoids. The major effects are as follows:

- *Suppression of the response to infection or injury*: opportunistic infection can be potentially very serious unless quickly treated with antimicrobial agents along with

an increase in the dose of steroid. Oral thrush (candidiasis, a fungal infection; see **Ch. 54**) frequently occurs when glucocorticoids are taken by inhalation, because of suppression of local anti-infective mechanisms. Wound healing is impaired, and peptic ulceration may also occur.

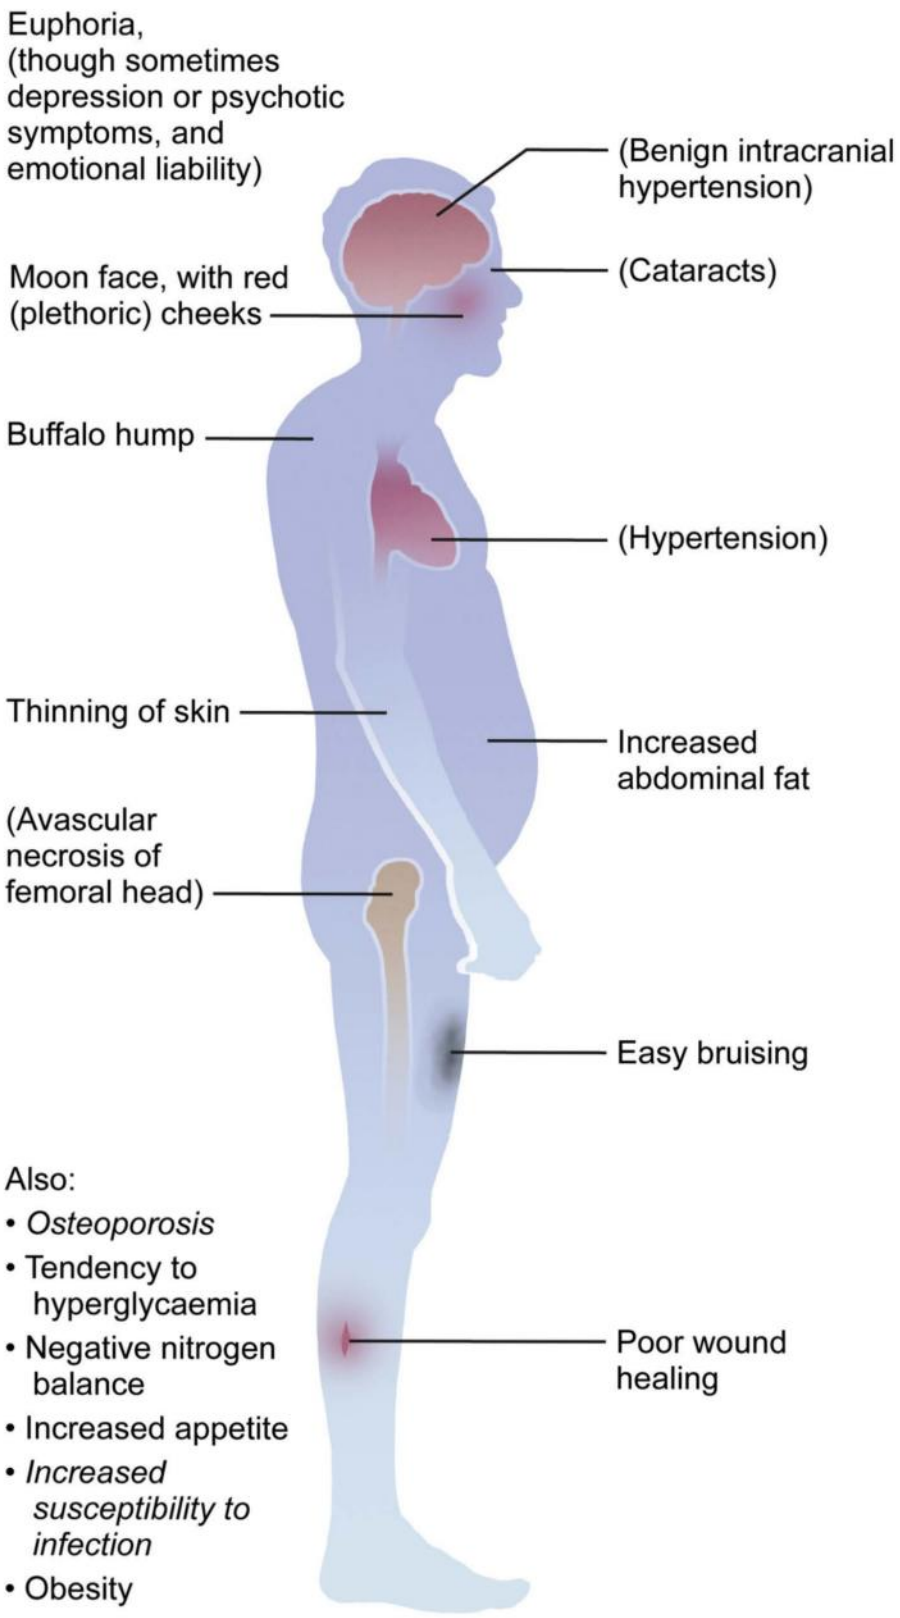
- *Cushing's syndrome* (see **Fig. 33.7**).
- *Osteoporosis*, with the attendant hazard of fractures, is one of the main limitations to long-term glucocorticoid therapy. These drugs influence bone density both by regulation of calcium and phosphate metabolism and through effects on collagen turnover. They reduce osteoblast function (which deposits bone matrix) and increase the activity of osteoclasts (which digest bone matrix). An effect on the blood supply to bone can result in avascular necrosis of the head of the femur (see **Ch. 36**).
- *Hyperglycaemia* produced by exogenous glucocorticoids may develop into frank (pre-) diabetes.
- *Muscle wasting* and proximal muscle weakness.
- In children, *inhibition of growth* [8] if treatment is continued for more than 6 months.
- *CNS effects:* euphoria and psychosis with short-term administration, depression with chronic treatment.
- *Other effects:* glaucoma (in genetically predisposed persons), raised intracranial pressure and an increased incidence of cataracts.

Sudden withdrawal of the drugs after prolonged therapy may result in acute adrenal insufficiency because of suppression of the patient's capacity to synthesise corticosteroids. [9] Careful procedures

for phased withdrawal should be followed. Recovery of full adrenal function usually takes about 8 weeks, although it can take 18 months or more after prolonged high-dose treatment.

Pharmacokinetic aspects

There are many glucocorticoid drugs in therapeutic use. Although **cortisol** (**hydrocortisone**), the endogenous hormone, is often used, synthetic derivatives are even more common. These have different physicochemical properties as well as varying potencies and have been optimised for administration by oral, systemic or intra-articular routes or for topical application such as by aerosol directly into the respiratory tract or nose or as eye drops. They may be formulated as creams or ointments for application to the skin (see **Ch. 26**) or as foam enemas for the GI tract (see **Ch. 30**). Topical administration diminishes the likelihood of systemic toxic effects unless large quantities are used. When prolonged use of systemic glucocorticoids is necessary, therapy on alternate days may decrease suppression of the HPA axis and other unwanted effects.



Euphoria,
(though sometimes
depression or psychotic
symptoms, and
emotional liability)
(Benign intracranial
hypertension)
Moon face, with red
(plethoric) cheeks
(Cataracts)
Buffalo hump
(Hypertension)
Thinning of skin
Increased
abdominal fat
(Avascular
necrosis of
femoral head)
Easy bruising
Also:
• Osteoporosis
• Tendency to
hyperglycaemia
• Negative nitrogen
balance
• Increased appetite
• Increased
susceptibility to
infection
• Obesity
Poor wound
healing

FIG. 33.7 Cushing's syndrome.This is caused by excessive exposure to endogenous glucocorticoids, by disease (e.g. an adrenocorticotrophic hormone-secreting tumour) or by prolonged administration of glucocorticoid drugs (*iatrogenic Cushing's syndrome*). *Italicised* effects are particularly common. Less frequent effects, related to dose and duration of therapy, are shown in *parentheses*. Redrawn from Baxter, J.D., Rousseau, G.G. (Eds.), 1979. Glucocorticoid Hormone Action. Monographs on Endocrinology. Springer-Verlag, Berlin.

Endogenous glucocorticoids are transported in the plasma bound to *corticosteroid-binding globulin* (CBG) and to albumin. About 77% of plasma **hydrocortisone** is bound to CBG, but many synthetic glucocorticoids are not bound at all. Albumin has a lower affinity for hydrocortisone but binds both natural and synthetic steroids. Both CBG-bound and albumin-bound steroids are biologically inactive. Hydrocortisone has a plasma half-life of 90 min, although many of its biological effects have a latency of 2–8 h.

As small lipophilic molecules, glucocorticoids probably enter their target cells by simple diffusion. Biological inactivation, which occurs in liver cells and elsewhere, is initiated by reduction of the C4–C5 double bond. Cortisone and **prednisone** are inactive until converted in vivo by the 11β-dehydrogenase type 1 to **hydrocortisone** and **prednisolone**, respectively.

The clinical uses of systemic glucocorticoids are summarised in the clinical box. **Dexamethasone** has a special use: it is used to test HPA axis function. In the **dexamethasone** suppression test a relatively low dose of the drug is given, usually at night. This would be expected to suppress the hypothalamus and pituitary, resulting in a reduced ACTH secretion and hydrocortisone output in the plasma about 9 h later. Failure of suppression implies hypersecretion of ACTH or of glucocorticoids (Cushing's syndrome).

Actions of glucocorticoids

Common drugs used systemically include **hydrocortisone**, **prednisolone** and **dexamethasone**.

Metabolic actions

- *Carbohydrates:* decreased uptake and utilisation of glucose accompanied by increased gluconeogenesis; this causes a tendency to hyperglycaemia.
- *Proteins:* increased catabolism, reduced anabolism.
- *Lipids:* a permissive effect on lipolytic hormones and a redistribution of fat, as observed in Cushing's syndrome.

Regulatory actions

- *Hypothalamus and anterior pituitary gland:* a negative feedback action resulting in reduced release of ACTH and therefore endogenous glucocorticoids.
- *Cardiovascular system:* reduced vasodilatation, decreased fluid exudation.

- *Musculoskeletal:* decreased osteoblast and increased osteoclast activity.
- *Inflammation and immunity:*
  - in acute inflammation: decreased influx and activity of leukocytes;
  - in chronic inflammation: decreased activity of mononuclear cells, decreased angiogenesis, less fibrosis;
  - in lymphoid tissues: decreased clonal expansion of T and B cells, and decreased action of cytokine-secreting T cells. Switch from Th1 to Th2 response;
  - decreased production and action of many pro-inflammatory cytokines, including interleukins, TNF-α and granulocyte–macrophage colony-stimulating factor;
  - reduced generation of eicosanoids;
  - decreased generation of IgG;
  - decrease in complement components in the blood;
  - increased release of *anti-inflammatory* factors such as IL-10, IL-1Ra and Annexin 1.
- Overall effects: reduction in the activity of the innate and acquired immune systems, but also diminution in the protective aspects of the inflammatory response and sometimes decreased healing.

Pharmacokinetics and unwanted actions of the glucocorticoids

- Administration can be oral, topical or parenteral. Most naturally occurring glucocorticoids are transported in the blood by CBG or albumen and enter cells by diffusion. They are metabolised in the liver.
- Unwanted effects are seen mainly after prolonged systemic use as anti-inflammatory or immunosuppressive agents but not usually following replacement therapy. The most important of these are:
  - suppression of response to infection
  - suppression of endogenous glucocorticoid synthesis
  - metabolic actions (see earlier)
  - osteoporosis
  - iatrogenic Cushing's syndrome (see **Fig. 33.7**)

Clinical uses of glucocorticoids

- Replacement therapy for patients with adrenal failure (*Addison's disease*).
- Anti-inflammatory/immunosuppressive therapy (see also **Ch. 25**):
  - in *asthma* (see **Ch. 28**);
  - topically in various inflammatory conditions of skin, eye, ear or nose (e.g. *eczema, allergic conjunctivitis* or *rhinitis*; see **Ch. 27**);
  - *hypersensitivity states* (e.g. severe allergic reactions);
  - in miscellaneous diseases with autoimmune and inflammatory components (e.g. *rheumatoid arthritis* and

other ‘connective tissue’ diseases, *inflammatory bowel diseases*, some forms of *haemolytic anaemia*, *idiopathic thrombocytopenic purpura*);
  - to prevent graft-versus-host disease following organ or bone marrow transplantation;
  - to reduce lung inflammation and damage in intensive care COVID-19 patients.
- In neoplastic disease (see **Ch. 57**):
  - in combination with cytotoxic drugs in treatment of specific malignancies (e.g. *Hodgkin’s disease*, *acute lymphocytic leukaemia*);
  - to reduce cerebral oedema in patients with metastatic or primary *brain tumours* (**dexamethasone**).

Mineralocorticoids

The main endogenous mineralocorticoid is aldosterone. Its chief action is to increase Na^+ reabsorption by the distal tubules in the kidney, with a concomitant increase in excretion of K^+ and H^+ (see **Ch. 29**). An excessive secretion of mineralocorticoids, as in *Conn’s syndrome*, causes marked Na^+ and water retention, with increased extracellular fluid volume and sometimes hypokalaemia, alkalosis and hypertension. Decreased mineralocorticoid secretion, as in some patients with Addison’s disease, causes Na^+ loss and a marked decrease in extracellular fluid volume. There is a concomitant decrease in the excretion of K^+, resulting in hyperkalaemia.

Regulation of aldosterone synthesis and release

The regulation of the synthesis and release of aldosterone depends mainly on the electrolyte composition of the plasma and on the activity of the angiotensin II system (see **Fig. 33.4** and Chs **22** and **29**). Low plasma Na^+ or high plasma K^+ concentrations directly stimulate aldosterone release from the zona glomerulosa cells of the adrenal. Depletion of Na^+ also activates the renin–angiotensin system (see **Ch. 22**, **Fig. 22.4**). One of the effects of angiotensin II is to increase the synthesis and release of aldosterone (see **Ch. 29**, **Fig. 29.5**).

Mechanism of action

Like other steroid hormones, aldosterone acts through specific intracellular receptors of the nuclear receptor family. Unlike the GR, which is present in most cells, the *mineralocorticoid receptor* (also called the *corticosteroid receptor type I*) is restricted to a few tissues, such as the kidney and the transporting epithelia of the colon and bladder. Cells containing mineralocorticoid receptors also contain the 11β-hydroxysteroid dehydrogenase type 2 enzyme, which converts hydrocortisone (cortisol) into inactive cortisone, but does not inactivate aldosterone. This ensures that the cells are appropriately affected only by the mineralocorticoid hormone itself. Interestingly, this enzyme is inhibited by **carbenoxolone,** a compound derived from liquorice (and previously used to treat gastric ulcers; see **Ch. 30**). If this inhibition is marked, cortisol accumulates and acts on the mineralocorticoid receptor, producing an off-target effect similar to Conn's syndrome (*primary hyperaldosteronism*) except that the circulating aldosterone concentration is not raised.

As with the glucocorticoids, the interaction of aldosterone with its receptor initiates transcription and translation of specific proteins, resulting in an increase in the number of sodium channels on the apical membrane of the renal tubular cell, and subsequently an increase in the number of Na^+-K^+-ATPase molecules in the basolateral membrane (see **Fig. 29.5**), causing increased K^+ excretion (see **Ch. 29**). In addition to the genomic effects, there is evidence for a rapid *non-genomic* effect of aldosterone on Na^+ influx, through an action on the Na^+-H^+ exchanger at the apical membrane.

Clinical use of mineralocorticoids and antagonists

The main clinical use of mineralocorticoids is replacement therapy of patients with Addison's disease. The most commonly used drug is **fludrocortisone** (see **Table 33.2** and **Fig. 33.4**), which can be taken orally to supplement the necessary glucocorticoid replacement. **Spironolactone** is a competitive antagonist of aldosterone, and it also prevents the mineralocorticoid effects of other adrenal steroids on the renal tubule (see **Ch. 29**). Side effects include gynaecomastia and impotence, due to **spironolactone's** ability to also partially block androgen and progesterone receptor function. It is used to treat primary or secondary hyperaldosteronism and, in conjunction with other drugs, for the treatment of resistant hypertension and of heart failure (see **Ch. 22**) and oedema (see **Ch. 29**). **Eplerenone** has a similar indication and mechanism of action, although fewer side effects as it has lower affinity for the sex hormone receptors (see **Ch. 22**).

Mineralocorticoids

Fludrocortisone is given orally to produce a mineralocorticoid effect. This drug:

- increases Na^+ reabsorption in distal tubules and increases K^+ and H^+ efflux into the tubules;
- acts on intracellular receptors that modulate DNA transcription, causing synthesis of Na^+ channel and other proteins that mediate the effect of the drug;
- may be used together with a glucocorticoid in replacement therapy regimes.

New Directions in Glucocorticoid Therapy

Recent advances in the treatment of severely ill COVID-19 patients showed glucocorticoid treatment to be an effective therapy to minimise mortality rates particularly among mechanically ventilated patients but also those receiving supplemental oxygen only. The RECOVERY randomised clinical trial showed marked improvements among patients treated with systemic glucocorticoids (**Horby et al., 2021**), reducing lung damage and overall patient survival. It is intuitive that the first pharmacological improvements shown in COVID-19 patients would be through glucocorticoids. Indeed, glucocorticoids are highly effective in controlling inflammation, but their utility is constrained by their potentially harmful side effects. The ideal solution would be a glucocorticoid

possessing the anti-inflammatory but not the unwanted metabolic or other effects.

Following the discovery of cortisol, the pharmaceutical industry pursued this ambitious goal by testing straightforward structural analogues of cortisol. While this yielded many new active and interesting compounds (several of which are in clinical use today), none achieved a true 'separation' of the glucocorticoid actions. Recently, there have been fresh attempts to accomplish this. The development of structural analogues at novel sites on the steroid template (e.g. **Uings et al., 2013**) has met with more success, and structural details of the receptor revealed by X-ray crystallography has enabled the design of non-steroidal receptor ligands (see, for example, **Biggadike et al., 2009**; **He et al., 2014**). Another approach has been to add other functional groups on to the steroid molecule, which alters the conformation of the liganded receptor. **Fiorucci et al. (2002)** attached a nitric oxide donating group to prednisolone, finding augmented efficacy and reduced unwanted effects. The compound is reported to be useful in the treatment of inflammatory bowel disease (see **Schacke et al., 2007**). The design of 'soft' glucocorticoids which are rapidly metabolised to inactive species, thereby limiting their capacity for producing side effects, is also being investigated (see **Dobricic et al., 2017**).

Many investigators in this area have been influenced by the 'dissociated steroids' or 'transrepression hypothesis': this is the notion, based upon some experimental observations, that the anti-inflammatory effects of glucocorticoids are generally caused by the *down*-regulation (*transrepression*) of genes such as those coding for cytokines, whilst the unwanted effects are usually caused by *up*-

regulation (*transactivation*) of metabolic and other genes (e.g. tyrosine amino transferase and phosphoenol pyruvate carboxykinase). Because transactivation and transrepression utilise different molecular pathways (see **Fig. 33.6**) which depend upon different conformational states of the GR, researchers have sought **S**elective **G**lucocorticoid **R**eceptor **A**gonists (SEGRAs) that promote one set of actions without the other. The application of this idea has been reviewed by **Schacke et al. (2007)** and the development of compounds for treating skin and ocular conditions has been reported (**Schacke et al., 2009**; **Spinelli et al., 2014**). However, some anti-inflammatory effects of glucocorticoids do not fit neatly into this scheme (**Vandevyver et al., 2013**); its shortcomings have been reviewed by **Clark and Belvisi (2012)**.

Another approach focuses upon the histone deacetylase enzymes that facilitate the transcriptional regulation of genes following nuclear receptor binding to hormone response elements (**Hayashi et al., 2004**). There may be a specific isoform of this enzyme that deals with gene up-regulation, and if this could be inhibited, it would lessen the possibility of those unwanted effects. **Barnes (2011)** has reviewed this approach, particularly as it relates to the therapy of asthma. A more general review of the whole area, with particular relevance to the treatment of rheumatic diseases, has been provided by **Strehl et al. (2011)**. Other molecular tactics that show promise include the use of GILZ (**G**lucocorticoid-Induced **L**eucine **Z**ipper protein) as a therapeutic agent (**Beaulieu and Morand, 2011**) or exploitation of the cytosolic, non-genomic actions of these drugs (**Jiang et al., 2014**)

The quest for the glucocorticoid magic bullet continues.

QUESTIONS

QUESTION 33.1

The hypothalamo–pituitary–adrenal (HPA) axis plays an important role in regulating and maintaining homeostasis through the regulated release of hormones.

Which of the following hormones is released from the hypothalamus to act on the anterior pituitary?

OPTIONS:

A. Somatostatin

B. Somatotrophin

C. Somatropin

D. Sermorelin

E. Somatomedin

QUESTION 33.2

Vasopressin is a key hormone released from the posterior pituitary gland that plays a crucial role in the regulation of water content in the body.

Which of the following statements about the physiological and pharmacological effects of vasopressin is correct?

OPTIONS:

A. Vasopressin acts on V1A receptors in the kidney to promote water reabsorption.

B. Vasopressin is a useful adjunct during dental surgery for patients with haemophilia.

C. Vasopressin analogues are used therapeutically for their vasodilator effects to prolong the effects of local anaesthetics.

D. Vasopressin antagonists would be useful in the treatment of diabetes insipidus.

E. Vasopressin causes relaxation of uterine smooth muscle.

QUESTION 33.3

The adrenal steroids, comprising the mineralocorticoids, glucocorticoids and androgens, are the hormonal mediators of the

HPA axis.

Which of the following statements concerning the regulation and function of the adrenal hormones is correct?

OPTIONS:

A. Aldosterone release is triggered by high plasma Na^+ concentration.

B. Dexamethasone is used to detect an insufficiency in glucocorticoid production.

C. Some of the anti-inflammatory effects of glucocorticoids may be mediated by protein kinase A (PKA)–mediated transcription of annexin-A1.

D. Hydrocortisone is inactivated to cortisone in the kidney by 11-β-hydroxylase.

E. Aldosterone increases K^+ efflux in kidney tubules.

QUESTION 33.4

In humans, hydrocortisone is the main glucocorticoid secreted from the adrenal cortex and has widespread actions on carbohydrate and protein metabolism and host defence.

Which of the following is an indirect effect of glucocorticoid actions?

OPTIONS:

A. Osteoporosis

B. Redistribution of body fat

C. Increased glycogen storage

D. Increased gluconeogenesis

E. Tissue wasting

ANSWERS

ANSWER 33.1

RATIONALE:

A.

B. Somatotrophin or growth hormone is secreted from the anterior pituitary.

C. Somatropin is recombinant human growth factor used for growth defects.

D. Sermorelin is an analogue of growth hormone-releasing factor and has been used diagnostically to test for growth hormone release.

E. Somatomedins are insulin-like growth factors synthesised in the liver.

CORRECT ANSWER WITH EXPLANATION:

A. Somatostatin

Somatostatin is released from the hypothalamus and inhibits the release of growth hormone and thyroid-stimulating hormone from the anterior pituitary.

ANSWER 33.2

RATIONALE:

A. Vasopressin acting on V2 receptors increases the expression of aquaporins and hence water reabsorption in the renal collecting ducts.

B.

C. Felypressin (an analogue of vasopressin) is a short-acting vasoconstrictor that is injected with local anaesthetics such as prilocaine to prolong their action.

D. Vasopressin receptor agonists would be useful in the treatment of diabetes insipidus, which results in excessive urine production.

E. Vasopressin causes contraction of vascular smooth muscle. Oxytocin, also released from the posterior pituitary, contracts uterine smooth muscle.

CORRECT ANSWER WITH EXPLANATION:

B. Vasopressin is a useful adjunct during dental surgery for patients with haemophilia.

It stimulates blood clotting through platelet aggregation and mobilisation of clotting factors.

ANSWER 33.3

RATIONALE:

A. Low Na^+ plasma concentration stimulates aldosterone release to increase Na^+ reabsorption.

B. The dexamethasone suppression test is used to detect hypersecretion of adrenocorticotrophic hormone or glucocorticoids.

C. Glucocorticoid induces the protein kinase C (PKC)–mediated phosphorylation and release of the potent anti-inflammatory mediator annexin-A1.

D. Hydrocortisone is metabolised in the kidney by 11-β-hydroxysteroid dehydrogenase.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Aldosterone increases K^+ efflux in kidney tubules.

This occurs by an increase in the expression of the Na^+/K^+ ATPase transporters on the basolateral membrane to facilitate Na^+ reabsorption.

ANSWER 33.4

RATIONALE:

A. Glucocorticoids tend to produce a negative calcium balance by decreasing Ca^{2+} absorption in the GI tract and increasing its excretion by the kidney. Together with increased breakdown of bone matrix protein this may cause osteoporosis.

B. Glucocorticoids synergise with catecholamines and some other hormones to cause lipase activation through a cAMP-dependent protein kinase.

C.

D. The glucocorticoids cause both a decrease in the uptake and utilisation of glucose and an increase in gluconeogenesis.

E. Glucocorticoids decrease protein synthesis and increase protein breakdown, particularly in muscle, and this can lead to tissue wasting.

CORRECT ANSWER WITH EXPLANATION:

C. Increased glycogen storage

The increase in glycogen storage may be an indirect result of insulin secretion in response to the increase in blood sugar.

---

[1] The term ‘factor’ was originally coined at a time when neither their structure nor their function was known. These are blood-borne

messengers, and are indeed clearly hormones but the nomenclature, although irrational, lingers on. This process is common in biological nomenclature.

[2] In this context, the suffix '-relin' denotes peptides that stimulate hormone release.

[3] The Out-of-Africa model of skin colouration suggests that genetic drift in Europeans led to functional variation in MC_1 melanocortin receptor (MC_1R) as reduced UV levels resulted in less selective pressure on the MC_1R sequence.

[4] Oxytocin is released during childbirth, lactation and orgasm and has been shown to promote trust and other prosocial behaviour. This has earned it the nickname of the 'love hormone' (or, even more nauseatingly, the 'cuddle hormone') in the popular press and internet discussion groups.

[5] So named because early experimenters noticed that separate fractions of adrenal gland extracts caused changes in either blood glucose or salt and water retention.

[6] Oddly, it was cortisone that Hench originally demonstrated to have potent anti-inflammatory activity in his classic studies of 1949. The reason for this apparent anomaly is the presence in some tissues of the enzyme *11ß-hydroxysteroid dehydrogenase Type 1* which can reduce cortisone to cortisol (i.e. hydrocortisone), thus restoring its biological activity.

[7] Reader beware! The glucocorticoid receptor is also referred to as the *Type II corticosteroid receptor*, the Type I corticosteroid

receptor being what we more usually call the mineralocorticoid receptor (MR).

[9] Patients on long-term glucocorticoid therapy are advised to carry a card stating, ‘I am a patient on STEROID TREATMENT which must not be stopped abruptly’.

34: The thyroid

OVERVIEW

Diseases of the thyroid gland are common, and in this chapter we deal with drug therapy used to mitigate these disorders. We set the scene by briefly outlining the structure, regulation and physiology of the thyroid, and highlight the most common abnormalities of thyroid function. We then consider the drugs that can be used to replace thyroid hormones when these are deficient or cease to function adequately, or which decrease thyroid function when this is excessive.

Synthesis, Storage and Secretion of Thyroid Hormones

The thyroid gland secretes three main hormones, which control general metabolic activities in the body: in this chapter we shall focus on two of these hormones, *thyroxine* (T_4) and *tri-iodothyronine* (T_3). The third hormone secreted by this gland is *calcitonin,* which is involved in the control of plasma [Ca^{2+}]. It is used to treat osteoporosis and other metabolic bone diseases. It is dealt with in **Ch. 36**. The term *thyroid hormones* will be used here solely to refer to T_4 and T_3.

Both T_3 and T_4 circulate in the blood tightly bound (>99%) to plasma proteins, mainly *thyroxine binding globulin* (TBG). The

majority (~85%) of the secreted thyroid hormone is T_4. This is converted into the (three- to five-fold) more active species, T_3, in a tissue-specific manner. Both hormones are critically important for normal growth and development and for controlling energy metabolism.

The functional unit of the thyroid is the follicle or acinus. Each follicle consists of a single layer of epithelial cells surrounding a cavity, the *follicle lumen*, which is filled with a thick colloid containing *thyroglobulin*. Thyroglobulin is a large glycoprotein, each molecule of which contains about 115 tyrosine residues. It is synthesised, glycosylated and then secreted into the lumen of the follicle, where iodination of the tyrosine residues occurs. Surrounding the follicles is a dense capillary network and the blood flow through the gland is very high in comparison with other tissues. The main steps in the synthesis, storage and secretion of thyroid hormone (**Fig. 34.1**) are:

- uptake of plasma iodide by the follicle cells;
- oxidation of iodide and iodination of tyrosine residues of thyroglobulin;
- secretion of thyroid hormone.

Uptake of Plasma Iodide by the Follicle Cells

Iodide uptake must occur against a concentration gradient (normally about 25:1) so it is an energy-dependent process. Iodide is captured from the blood and moved to the lumen by two transporters: the Na^+/I^- symporter (NIS), located at the basolateral surface of the thyrocytes (the energy being provided by Na^+/K^+-atpase), and *pendrin* [1] (PDS), an I^-/Cl^- porter in the apical

membranes (**Nilsson, 2001**). Uptake is very rapid: labelled iodide (^{125}I) is found in the lumen within 40 s of intravenous injection. Numerous mutations have been discovered in the NIS and PDS genes and these contribute to thyroid disease in some patients.

Oxidation of Iodide and Iodination of Tyrosine Residues

The oxidation of iodide and its incorporation into thyroglobulin (termed the *organification* of iodide) are catalysed by *thyroperoxidase*, an enzyme situated at the inner surface of the cell at the interface with the colloid. The reaction requires the presence of hydrogen peroxide (H_2O_2) as an oxidising agent. Iodination occurs after the tyrosine has been incorporated into thyroglobulin. The reaction is shown in **Fig. 34.2**.

Tyrosine residues are iodinated first at position 3 on the ring, forming monoiodotyrosine (MIT) and then, in some molecules, at position 5 as well, forming di-iodotyrosine (DIT). While still incorporated into thyroglobulin, these molecules are then coupled in pairs, either MIT with DIT to form T_3 or two DIT molecules to form T_4 (Figs **34.2** and **34.3**). The mechanism for coupling is believed to involve a peroxidase system similar to the iodination reaction. About one-fifth of the tyrosine residues in thyroglobulin are iodinated in this way.

The iodinated thyroglobulin of the thyroid forms a large store of thyroid hormone within the gland, with a relatively slow turnover. This is in contrast to some other endocrine secretions (e.g. the hormones of the adrenal cortex), which are not stored but synthesised and released as required.

Secretion of Thyroid Hormone

The thyroglobulin molecule is taken up into the follicle cell by endocytosis. The endocytotic vesicles then fuse with lysosomes, and proteolytic enzymes act on thyroglobulin, releasing T_4 and T_3 to be secreted into the plasma. The surplus MIT and DIT, which are released at the same time, are scavenged by the cell and the iodide is removed enzymatically and reused.

Regulation of Thyroid Function

Thyrotropin-releasing hormone (TRH), released from the hypothalamus in response to various stimuli, releases *thyroid-stimulating hormone* (TSH; thyrotrophin) from the anterior pituitary (**Fig. 34.4**), as does the synthetic tripeptide **protirelin** (pyroglutamyl-histidyl-proline amide), which is used in this way for diagnostic purposes. TSH acts on receptors on the membrane of thyroid follicle cells through a mechanism that involves cAMP and phosphatidylinositol 3-kinase. It has a trophic action on thyroid cells and controls all aspects of thyroid hormone synthesis, mainly by stimulating transcription of the iodide transporter genes, thereby increasing the uptake of iodide by follicle cells. This, in turn, controls all aspects of thyroid hormone synthesis including:

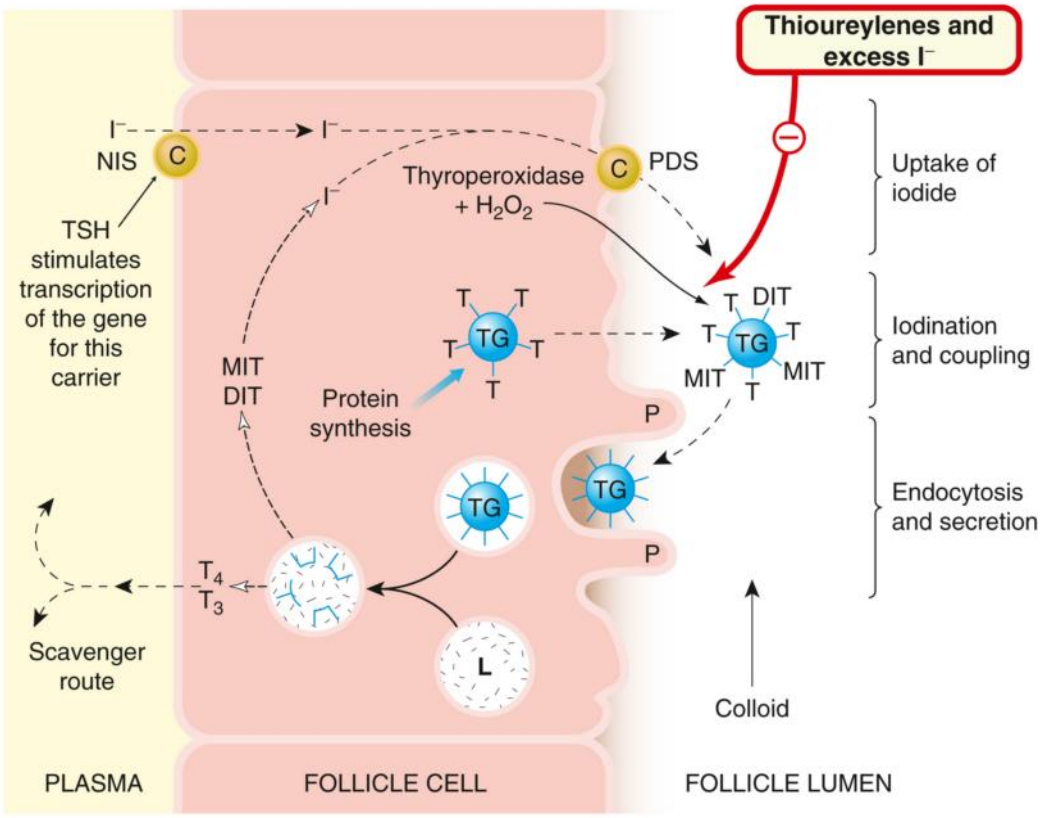

FIG. 34.1 Diagram of thyroid hormone synthesis and secretion, with the sites of action of some drugs used in the treatment of thyroid disorders.Iodide in the blood is transported by the carriers NIS and PDS through the follicular cell and into the colloid-rich lumen, where it is incorporated into tyrosines in thyroglobulin under the influence of the thyroperoxidase enzyme and monoiodotyrosine units are produced and coupled to produce the hormones (see text for details). Thyroid-stimulating hormone (thyrotropin; TSH) stimulates the endocytosis of thyroglobulin and the hormones are subsequently cleaved from the globulin by

lysosomal enzymes and exported into the blood. *DIT,* Di-iodotyrosine; *L,* lysosome; *MIT,* monoiodotyrosine; *P,* pseudopod; *T,* tyrosine; T_3, tri-iodothyronine; T_4, thyroxine; *TG,* thyroglobulin.

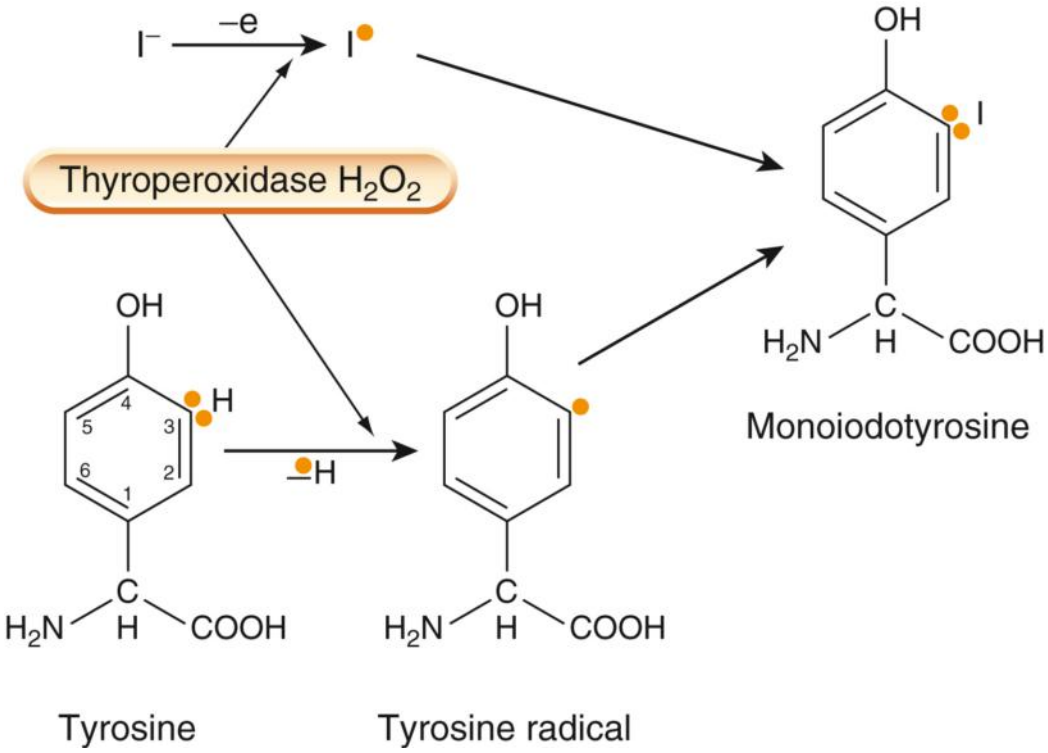

FIG. 34.2 Iodination of tyrosyl residues by the thyroperoxidase–H_2O_2 complex.This probably involves two sites on the enzyme, one of which removes an electron from iodide to give the free radical I•; another removes an electron from tyrosine to give the tyrosyl radical *(orange dot)*. Monoiodotyrosine results from the addition of the two radicals.

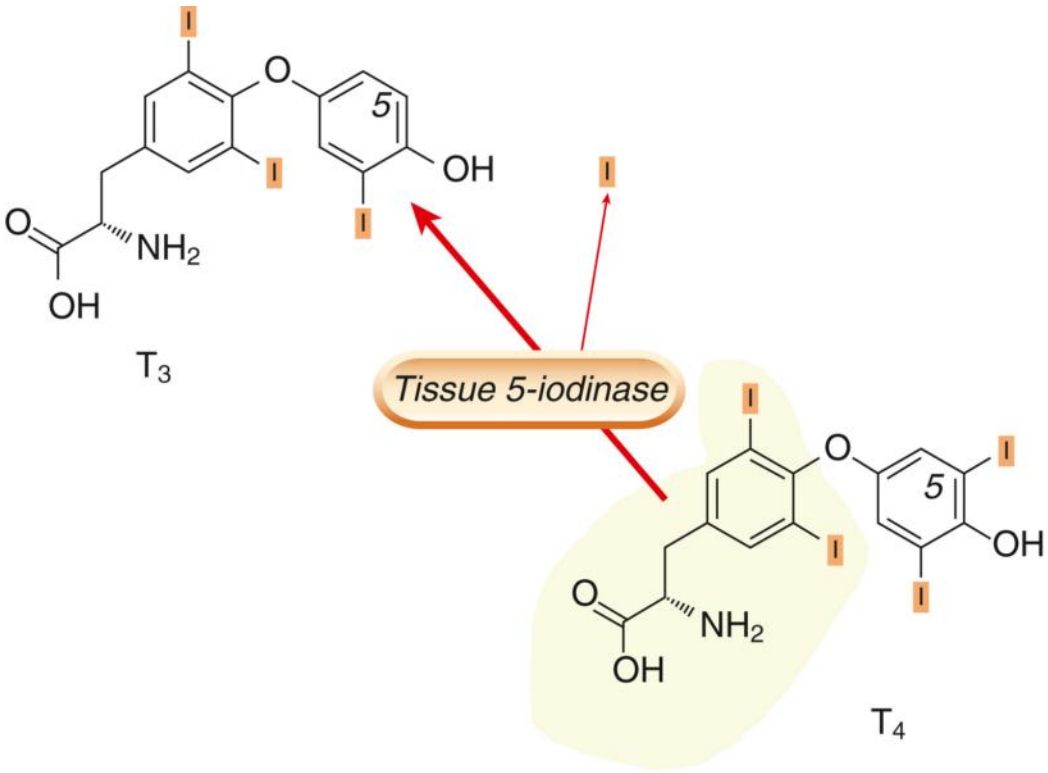

FIG. 34.3 The structures of thyroxine T_3 and T_4.The positions of the iodine residues are indicated in *orange*. T_4 is converted, in a tissue-specific manner, to the more active species T_3 by mono de-iodination at position 5 of the ring. The basic tyrosine unit is shaded in *yellow*.

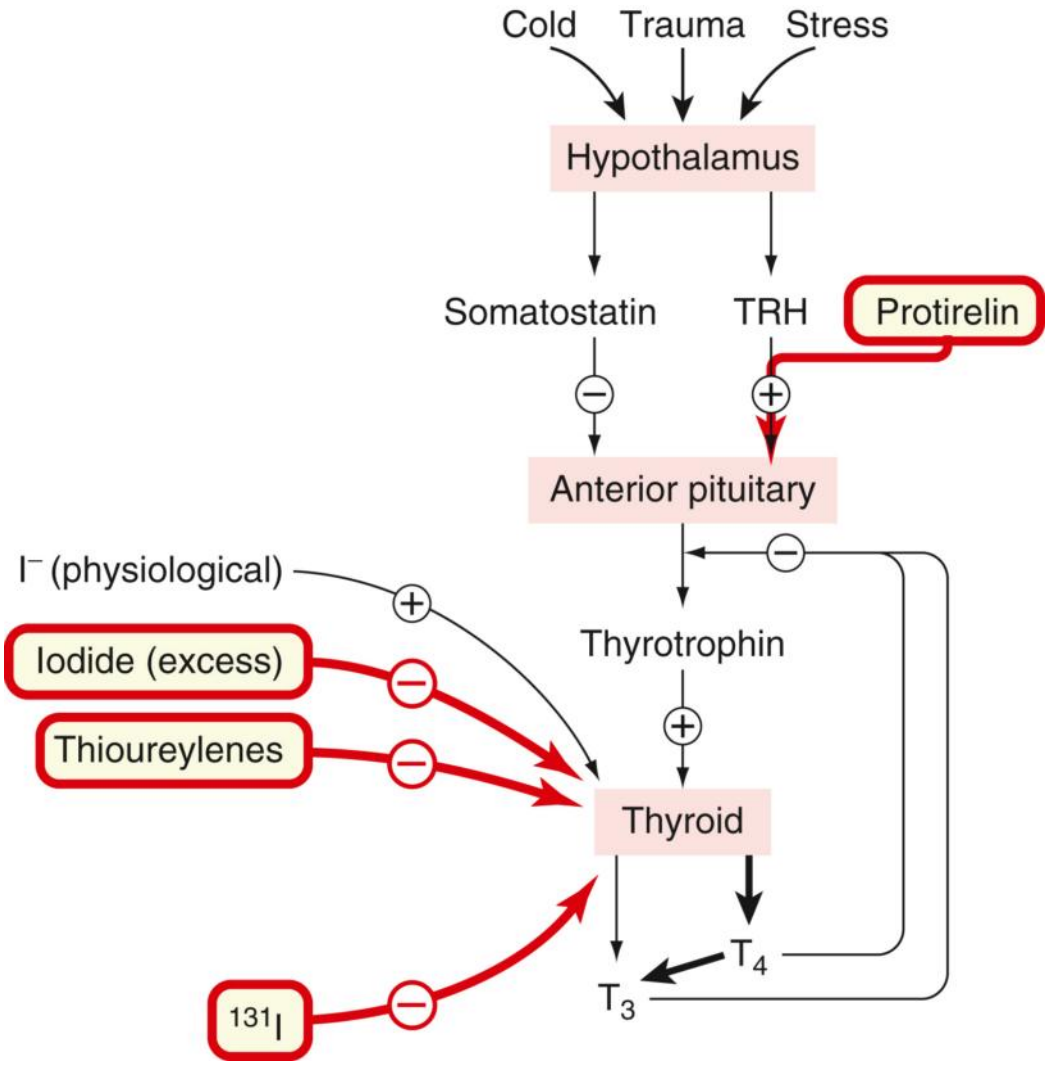

FIG. 34.4 Regulation of thyroid hormone secretion.Iodide (I^-) is essential for thyroid hormone synthesis, but excess of endogenous or exogenous iodide (30 times the daily requirement of iodine) may be used to inhibit the increased thyroid hormone production of thyrotoxicosis. Protirelin, as well as recombinant human thyrotropin-releasing hormone (TRH), is sometimes used to stimulate the system for diagnostic purposes. Larger amounts of iodine

(as the ^{131}I isotope) are used for ablation of thyroid tissue (see text for details). T_3, Tri-iodothyronine; T_4, thyroxine.

- the synthesis and secretion of thyroglobulin;
- the generation of H_2O_2 and the iodination of tyrosine;
- the endocytosis and proteolysis of thyroglobulin;
- the actual secretion of T_3 and T_4;
- the blood flow through the gland.

The production of TSH is also regulated by a negative feedback effect of thyroid hormones on the anterior pituitary gland and the hypothalamus; T_3 is more active than T_4 in this respect. The peptide **somatostatin** also reduces basal TSH release. The control of the secretion of TSH thus depends on a balance between the actions of T_3/T_4 and TRH (and probably also **somatostatin**) on the pituitary and most likely also at the hypothalamus. However, the relationship between T_3/T_4 concentration and TSH secretion is not linear. Small changes in thyroid hormones can produce very large changes in TSH secretion whilst large changes in TSH produce only small alterations in T_3/T_4. It is important to recognise this, as measurement of TSH is a key diagnostic tool when assessing thyroid function in patients.

The other main factor influencing thyroid function is the plasma iodide concentration. About 100 nmol of T_4 is synthesised daily, necessitating uptake by the gland of approximately 500 nmol of iodide each day (equivalent to about 70 μg of iodine). A reduced iodine intake, with reduced plasma iodide concentration, will result

in a decrease of hormone production and an increase in TSH secretion. An increased plasma iodide has the opposite effect, although this may be modified by other factors. The overall feedback mechanism responds to changes of iodide slowly over fairly long periods of days or weeks, because there is a large reserve capacity for the binding and uptake of iodide in the thyroid. The size and vascularity of the thyroid are reduced by an increase in plasma iodide and this is exploited therapeutically in preparing hyperthyroid patients for surgery to the gland. Diets deficient in iodine eventually result in a continuous excessive compensatory secretion of TSH, and eventually in an increase in vascularity and (sometimes gross) hypertrophy of the gland. [2]

Actions of the Thyroid Hormones

The physiological actions of the thyroid hormones fall into two main categories: those affecting metabolism and those affecting growth and development. Both T_3 and T_4 are extensively plasma bound and only the free concentrations of the hormones are active.

Effects on Metabolism

The thyroid hormones produce a general increase in the metabolism of carbohydrates, fats and proteins, and regulate these processes in most tissues, T_3 being three to five times more active than T_4 in this respect (**Fig. 34.5**). Although the thyroid hormones directly control the activity of some of the enzymes of carbohydrate metabolism, most effects are brought about in conjunction with other hormones, such as insulin, glucagon, the glucocorticoids and the catecholamines. There is an increase in oxygen consumption and

heat production, which is manifested as an increase in the measured basal metabolic rate. This reflects the action of these hormones on tissues such as heart, kidney, liver and muscle, although not on others, such as the gonads, brain or spleen. This calorigenic action is important as part of the response to a cold environment. Administration of thyroid hormone results in augmented cardiac rate and output, and increased tendency to dysrhythmias such as atrial fibrillation.

Effects on Growth and Development

The thyroid hormones have a critical effect on growth, partly by a direct action on cells, but also indirectly by influencing growth hormone production and potentiating its effects on its target tissues. The hormones are important for a normal response to *parathormone* (see **Ch. 36**) and calcitonin as well as for skeletal development; they are also essential for normal growth and maturation of the central nervous system.

Mechanism of Action

While there is some evidence for non-genomic actions (see **Bassett et al., 2003**), thyroid hormones act mainly through a specific nuclear receptor, TR (see **Ch. 3**). Two distinct genes, TRα and TRβ, code for several receptor isoforms that have distinct functions. T_4 may be regarded as a prohormone, because when it enters the cell, it is converted to T_3, which then binds with high affinity to TR. This interaction is likely to take place in the nucleus, where TR isoforms generally act as a constitutive repressor of target genes. When T_3 is bound, these receptors change conformation, the co-repressor

complex is released and a co-activator complex is recruited, which then activates transcription, resulting in generation of mRNA and protein synthesis. Some rare cases of thyroid hormone resistance linked to TRβ mutations have been reported (**Lai et al., 2015**) which can be associated with deaf mutism and colour blindness in the most severely deficient forms.

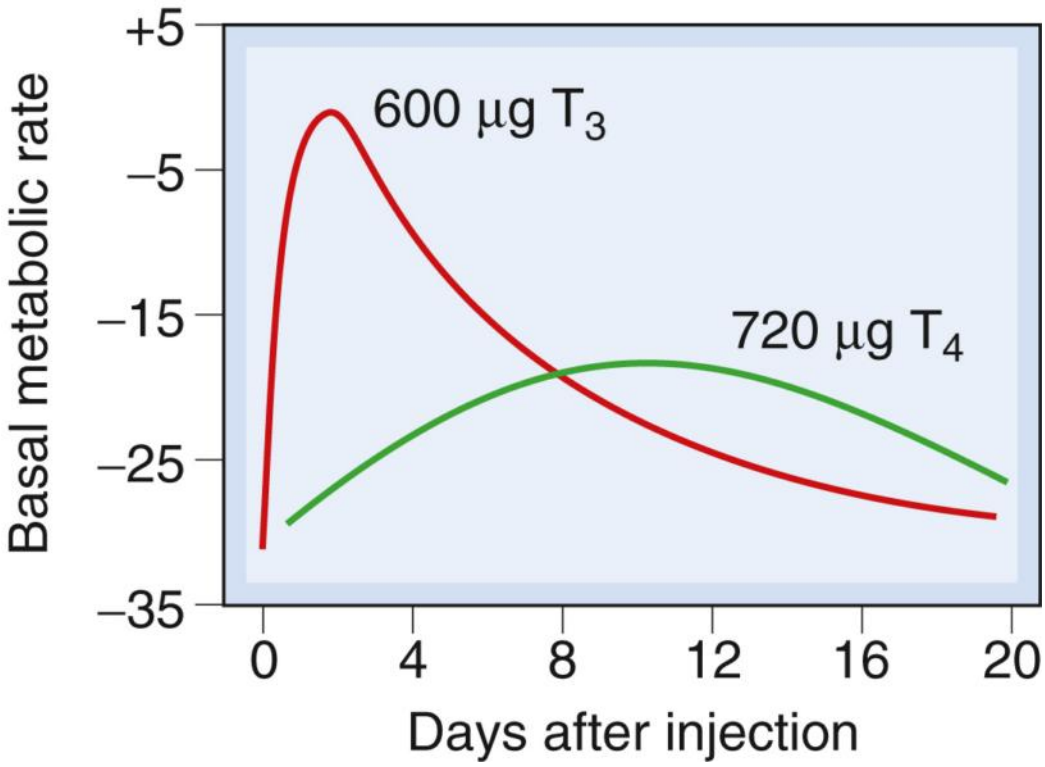

FIG. 34.5 The effect of equimolar doses of triiodothyronine *(T_3)* and thyroxine *(T_4)* on basal metabolic rate (BMR) in a hypothyroid subject.Note that this figure is meant only to illustrate overall differences in effect; thyroxine is not given clinically in a single bolus dose as here, but in regular daily doses so that the effect builds up to a plateau. The apparent differences in potency really represent differences in kinetics of T3 (*red line*) and T4 (*green line*), reflecting the prohormone role of T_4. Modified from Blackburn, C.M., McConahey, W.M., Keating, F.R., Jr., Albert, A., 1954. Calorigenic effects of single intravenous doses of L-triiodothyronine

and L-thyroxine in myxedematous persons. J. Clin. Invest. 33, 819–824.

Transport and Metabolism of Thyroid Hormones

Plasma concentrations of these hormones can be measured by radioimmunoassay and are approximately 1×10^{-7} mol/L (T_4) and 2×10^{-9} mol/L (T_3). Both are eventually metabolised in their target tissues by deiodination, deamination, decarboxylation and conjugation with glucuronic and sulfuric acids. The liver is a major site of metabolism, and the free and conjugated forms are excreted partly in the bile and partly in the urine. The half-life of T_3 is a few hours, whereas that of T_4 varies between 3–4 days in hyperthyroidism and 9–10 days in hypothyroidism. [3] Abnormalities in the metabolism of these hormones may occur naturally or be induced by drugs or heavy metals, and this may give rise to a variety of (uncommon) clinical conditions such as the 'low T_3 syndrome'.

Abnormalities of Thyroid Function

Thyroid disorders are among the most common endocrine diseases in all age groups, including children. Subclinical thyroid disease is prevalent in the middle-aged and elderly. Thyroid disorders are accompanied by many extra-thyroidal symptoms, particularly in the heart, gastrointestinal system and skin. One (rare) cause of organ dysfunction is thyroid cancer. Many other thyroid disorders have an autoimmune basis – in fact, autoimmune thyroid disease is the commonest autoimmune disease. The reason for this is not clear,

although it may be linked to a breakdown in immune tolerance to the TSH receptor, although other factors cannot be ruled out (**Lee et al., 2015**). It may be linked to other autoimmune conditions such as rheumatoid arthritis.

There are two main types of autoimmune thyroid disorder, *Graves' disease* [4] and *Hashimoto's disease*. Both are associated with the production of thyroid autoantibodies and immune damage to the gland itself. [5] Oddly perhaps, they result in different clinical pictures, with Graves' disease leading to thyrotoxicosis while Hashimoto's thyroiditis leads to hypoactive thyroid. Regardless of causation, thyroid dysfunction is often associated with typical gross enlargement of the gland, known as *goitre*. Like other autoimmune diseases, such thyroid disorders are more common in women than men and occur with increased frequency during pregnancy (**Cignini et al., 2012**).

Hyperthyroidism (Thyrotoxicosis)

In thyrotoxicosis there is excessive secretion and activity of the thyroid hormones, resulting in a high metabolic rate, an increase in skin temperature and sweating and heat intolerance. Nervousness, tremor, tachycardia and increased appetite associated with loss of weight occur. There are several types of hyperthyroidism, but only two are common: *exophthalmic* or *diffuse toxic goitre* (Graves' disease) and *toxic nodular goitre*.

Diffuse toxic goitre is an organ-specific autoimmune disease caused by autoantibodies to the TSH receptor which, when active, increase T_4 secretion. Constitutively active mutations of the TRH receptor may also be involved. As is indicated by the name, patients

with exophthalmic goitre have protrusion of the eyeballs. The pathogenesis of this condition is not fully understood, but it is thought to be caused by the presence of TSH receptor–like proteins in orbital tissues. There is also an enhanced sensitivity to catecholamines. Toxic nodular goitre is caused by a benign tumour and may develop in patients with long-standing simple goitre. This condition does not usually have concomitant exophthalmos. The antidysrhythmic drug **amiodarone** (see **Ch. 21**) is rich in iodine and can cause either hyperthyroidism or hypothyroidism. Some iodine-containing radiocontrast agents, such as **iopanoic acid** and its congeners, used as imaging agents to visualise the gall bladder, may also interfere with thyroid function. The chronic use of psychotropic agents may precipitate a variety of thyroid abnormalities (**Bou Khalil and Richa, 2011**).

Simple, Non-Toxic Goitre

A dietary deficiency of iodine, if prolonged, causes a rise in plasma TRH and eventually an increase in the size of the gland. This condition is known as simple or non-toxic goitre. Another cause is ingestion of *goitrogens* (e.g. from cassava root). The enlarged thyroid usually manages to produce normal amounts of thyroid hormone, although if the iodine deficiency is very severe, hypothyroidism may supervene.

Hypothyroidism

A decreased activity of the thyroid results in hypothyroidism, and in severe cases *myxoedema*. Once again, this disease is usually immunological in origin, and the manifestations include low

metabolic rate, slow speech, deep hoarse voice, lethargy, bradycardia, sensitivity to cold and mental impairment. Patients also develop a characteristic thickening of the skin (caused by the subcutaneous deposition of glycosaminoglycans), which gives myxoedema its name. In Hashimoto's thyroiditis, there is an immune reaction against thyroglobulin or some other component of thyroid tissue, which can lead to both hypothyroidism and myxoedema. Genetic factors play an important role. Destruction of glandular tissue whilst treating thyroid tumours with radioiodine is another cause of hypothyroidism. Some drugs (e.g. cholecystographic agents or anti-epileptic drugs) as well as environmental 'endocrine disruptors' [6] may interfere with the normal production of thyroid hormones.

Thyroid deficiency during development, affecting 1 in 3000–4000 births, causes congenital hypothyroidism (known as *Congenital iodine deficiency syndrome*), characterised by gross restriction of growth and intellectual disability. [7]

Drugs Used in Diseases of the Thyroid

Hyperthyroidism

Hyperthyroidism may be treated pharmacologically or surgically. In general, surgery is now used only when there are mechanical problems resulting from compression of the trachea by the thyroid. Under such circumstances it is usual to remove only part of the organ. Although the condition of hyperthyroidism can be controlled with antithyroid drugs, these drugs do not alter the underlying autoimmune mechanisms or improve the exophthalmos associated with Graves' disease.

Radioiodine

Radioiodine is a first-line treatment for hyperthyroidism (particularly in the United States). The isotope used is ^{131}I (usually as the sodium salt), and the dose generally is 5–15 mCi. Given orally, it is taken up and processed by the thyroid in the same way as the stable form of iodide, eventually becoming incorporated into thyroglobulin. The isotope emits both β and γ radiation. The γ rays pass through the tissue without causing damage, but the β particles have a very short range; they are absorbed by the tissue and exert a powerful cytotoxic action that is restricted to the cells of the thyroid follicles, resulting in significant destruction of the tissue. ^{131}I has a half-life of 8 days, so by 2 months its radioactivity has effectively disappeared. It is given as one single dose, but its cytotoxic effect on the gland is delayed for 1–2 months and does not reach its maximum for a further 2 months.

Hypothyroidism will eventually occur after treatment with radioiodine, particularly in patients with Graves' disease, but is easily managed by replacement therapy with T_4. Radioiodine is best avoided in children or pregnant patients (because of potential damage to the fetus). There is theoretically an increased risk of thyroid cancer but this has not been seen following therapeutic treatment.

The uptake of ^{131}I and other isotopes of iodine is also used diagnostically as a test of thyroid function. A tracer dose of the isotope is given orally or intravenously, and the amount accumulated by the thyroid is measured by a γ-scintillation counter placed over the gland. ^{131}I is also used for the treatment of thyroid cancer in combination with surgery, radiotherapy (external or

proton-bean therapy) and/or tyrosine kinase inhibitor chemotherapeutics (**cabozantinib**, **lenvatinib**, **sorafenib**) (see **Ch. 57**).

The thyroid

- Thyroid hormones, tri-iodothyronine (T_3) and thyroxine (T_4), are synthesised by iodination of tyrosine residues on thyroglobulin within the lumen of the thyroid follicle.
- Hormone synthesis and secretion are regulated by TSH (thyrotropin) and influenced by plasma iodide.
- There is a large pool of T_4 in the body; it has a low turnover rate and is found mainly in the circulation.
- There is a small pool of T_3 in the body; it has a fast turnover rate and is found mainly intracellularly.
- Within target cells, T_4 is converted to T_3, which interacts with a nuclear receptor to regulate gene transcription.
- T_3 and T_4 actions:
  - stimulation of metabolism, causing increased oxygen consumption and increased metabolic rate;
  - regulation of growth and development.
- Abnormalities of thyroid function include:
  - hyperthyroidism (thyrotoxicosis): either diffuse toxic goitre or toxic nodular goitre;
  - hypothyroidism: in adults this causes myxoedema; in infants, gross restriction of growth and intellectual disability;

– simple non-toxic goitre caused by dietary iodine deficiency, usually with normal thyroid function.

Thioureylenes

This group of drugs comprises **carbimazole** and **propylthiouracil**. Chemically, they are related to thiourea, and the thiocarbamide (S–C–N) group is essential for antithyroid activity.

Mechanism of action

Thioureylenes decrease the output of thyroid hormones from the gland and cause a gradual reduction in the signs and symptoms of thyrotoxicosis, with the basal metabolic rate and pulse rate returning to normal over a period of 3–4 weeks. Their mode of action is not completely understood, but there is evidence that they reduce the iodination of tyrosyl residues in thyroglobulin (see Figs **34.1** and **34.2**) by inhibiting the thyroperoxidase-catalysed oxidation reactions, possibly by acting as substrates, thus competitively inhibiting the interaction with tyrosine. Propylthiouracil has the additional effect of reducing the deiodination of T_4 to T_3 in peripheral tissues.

Pharmacokinetic aspects

Thioureylenes are given orally. **Carbimazole** is rapidly converted to an active metabolite. An average dose of **carbimazole** produces more than 90% inhibition of thyroid incorporation of iodine within 12 h. The full clinical response to this and other antithyroid drugs, however, may take several weeks (**Fig. 34.6**), partly because T_4 has a long half-life, and also because the thyroid may have large stores

of hormone, which need to be depleted before the drug's action can be fully manifest. **Propylthiouracil** is thought to act somewhat more rapidly because of its additional effect as an inhibitor of the peripheral conversion of T_4 to T_3.

Both drugs may be used during pregnancy but both can cross the placenta and may affect the fetal thyroid gland. They also appear in breast milk, but this effect is less pronounced with **propylthiouracil**, because it is more strongly bound to plasma protein. After degradation, the metabolites of these drugs are excreted in the urine. The thioureylenes may be concentrated in the thyroid.

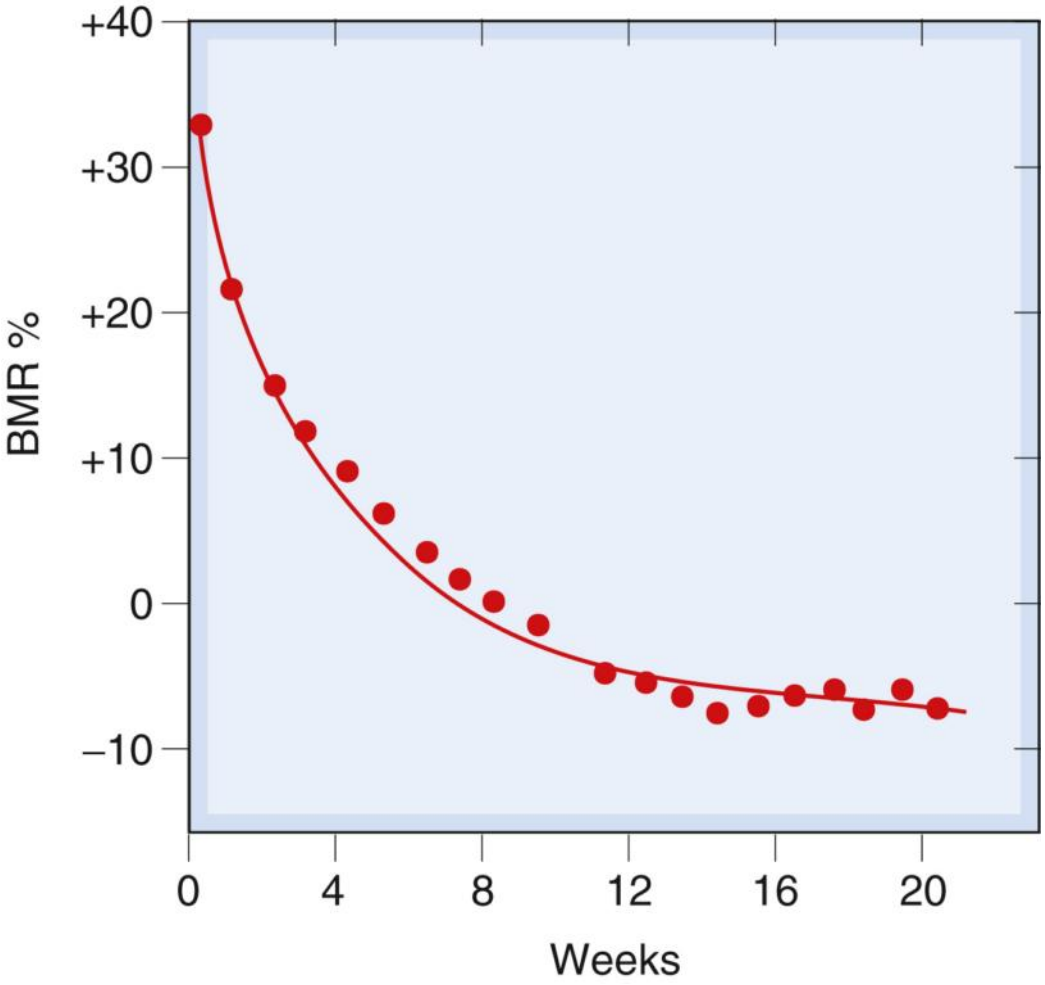

FIG. 34.6 Time course of fall of basal metabolic rate (BMR) during treatment with an antithyroid drug, carbimazole.The curve is exponential, corresponding to a daily decrease in BMR (*red line*) of 3.4%. Modified from Furth, E.D., Becker, D.V., Schwartz, M.S., 1963. Significance of rate of response of basal metabolic rate and serum cholesterol in hyperthyroid patients receiving neomercazole and other antithyroid agents. J. Clin. Endocrinol. Metab. 23, 1130–1140.

Unwanted effects

The most dangerous unwanted effects of thioureylene drugs are neutropenia and agranulocytosis (see **Ch. 24**). These are relatively rare, having an incidence of 0.1%–1.2%, and are reversible on cessation of treatment. Patients must be warned to report symptoms (especially sore throat) immediately and have a blood count. Rashes (2%–25%) and other symptoms, including headaches, nausea, jaundice and arthralgia, are common. Rare cases of fetal abnormalities have been reported with **carbimazole**.

Iodine/Iodide

Iodine is converted in vivo to iodide (I^-), which temporarily inhibits the release of thyroid hormones. When high doses of iodine are given to thyrotoxic patients, the symptoms subside within 1–2 days. There is inhibition of the secretion of thyroid hormones and, over a period of 10–14 days, a marked reduction in vascularity of the gland, which becomes smaller and firmer. Iodine is often given orally in a solution with potassium iodide ('*Lugol iodine*'). With continuous administration, its effect reaches maximum within 10–15 days and then decreases. The mechanism of action is not entirely clear; it may inhibit iodination of thyroglobulin, possibly by reducing the H_2O_2 generation that is necessary for this process.

The main uses of iodine/iodide are for the preparation of hyperthyroid subjects for surgical resection of the gland, and as part of the treatment of severe thyrotoxic crisis (*thyroid storm*). It is also used following exposure to accidental leakage of radioactive iodine from nuclear reactors, to reduce uptake of the radioactive isotope in the thyroid. Allergic reactions can occur; these include

angio-oedema, rashes and drug fever. Lacrimation, conjunctivitis, pain in the salivary glands and a cold-like syndrome are dose-related adverse effects connected to the concentration of iodide by transport mechanisms in tears and saliva.

Other Drugs Used

The β-adrenoceptor antagonists, for example, **propranolol** and **nadolol** (see **Ch. 15**), are not antithyroid agents as such, but they are useful for decreasing many of the signs and symptoms of hyperthyroidism – tachycardia, dysrhythmias, tremor and agitation. They are used during the preparation of thyrotoxic patients for surgery, as well as in most hyperthyroid patients during the initial treatment period while the thioureylenes or radioiodine take effect, or as part of the treatment of acute hyperthyroid crisis. Eye drops containing **guanethidine**, a noradrenergic-blocking agent (see **Ch. 15**), are used to mitigate the exophthalmos of hyperthyroidism (which is not relieved by antithyroid drugs); it acts by relaxing the sympathetically innervated smooth muscle that causes eyelid retraction. Glucocorticoids (e.g. **prednisolone** or **hydrocortisone**) or surgical decompression may be needed to mitigate severe exophthalmia in Graves' disease.

Hypothyroidism

There are no drugs that specifically augment the synthesis or release of thyroid hormones. The only effective treatment for hypothyroidism, unless it is caused by iodine deficiency (which is treated with iodide), is to administer the thyroid hormones themselves as replacement therapy. Synthetic T_4 (official name: **levothyroxine**) and T_3 (official name: **liothyronine**), identical to

the natural hormones, are given orally. **Levothyroxine**, as the sodium salt in doses of 50–100 µg/day, is the usual first-line drug of choice. **Liothyronine** has a faster onset but a shorter duration of action and is generally reserved for acute emergencies such as the rare condition of myxoedema coma, where these properties are an advantage.

Unwanted effects may occur with overdose, and in addition to the signs and symptoms of hyperthyroidism there is a risk of precipitating angina pectoris, cardiac dysrhythmias or even cardiac failure. The effects of less severe overdose are more insidious; the patient feels well but bone resorption is increased, leading to osteoporosis (see **Ch. 36**).

The use of drugs to treat thyroid cancer is a specialist subject and will not be covered here. **Bikas et al. (2016)** and **Laha et al. (2020)** review the latest generation of drugs to be used for this purpose.

Finally, recombinant human TSH (rhTSH) is sometimes used for diagnostic purposes following surgery.

The use of drugs to treat disorders of the thyroid is summarised in the clinical box.

Clinical use of drugs acting on the thyroid

Radioiodine (^{131}I)

- Hyperthyroidism (Graves' disease, multinodular toxic goitre).
- Relapse of hyperthyroidism after failed medical or surgical treatment.

Carbimazole or propylthiouracil

- Hyperthyroidism (diffuse toxic goitre); at least 1 year of treatment is needed.
- Preliminary to surgery for toxic goitre.
- Part of the treatment of thyroid storm (very severe hyperthyroidism); **propylthiouracil** is preferred, combined with a β-adrenoceptor antagonist (e.g. **propranolol**).

Thyroid hormones and iodine

- **Levothyroxine** (T_4) is the standard replacement therapy for hypothyroidism.
- **Liothyronine** (T_3), administered by slow intravenous injection, is used for myxoedema coma.
- Iodine dissolved in aqueous potassium iodide (**'Lugol iodine'**) is used short term to control thyrotoxicosis preoperatively. It reduces the vascularity of the gland.

QUESTIONS

QUESTION 34.1

Synthesis of the thyroid hormones in the follicle cells involves the oxidation of iodide and the iodination of tyrosine residues of thyroglobulin.

Which of the following would reduce iodination?

OPTIONS:

A. Increased pendrin (PDS) expression

B. Increased hydrogen peroxide

C. Increased levels of thyroperoxidase

D. Decreased somatostatin

E. High plasma levels of iodide

QUESTION 34.2

Regulation of thyroid hormone synthesis and secretion is critically important for normal growth and development and for controlling energy metabolism.

The circulating levels of which of the following is increased in Graves' disease?

OPTIONS:

A. Thyrotropin-releasing hormone (TRH)

B. Thyroglobulin

C. Thyroxine (T_4)

D. Thyroid-stimulating hormone (TSH)

E. Thyroxine binding globulin (TBG)

QUESTION 34.3

Graves' disease is a disorder of the thyroid gland associated with the production of thyroid autoantibodies and immune damage to the gland.

Which of the following would not be a symptom of Graves' disease?

OPTIONS:

A. Thickening of the skin

B. Protrusion of the eyeballs

C. Sweating

D. Tachycardia

E. Increased appetite

ANSWERS

ANSWER 34.1

RATIONALE:

A. Pendrin is an I^-/Cl^- porter in the apical membrane involved in the transport of plasma iodide into the lumen. Therefore, an increase in expression will increase the iodination reaction.

B. Hydrogen peroxide is required for the oxidation/organification of iodide in the follicle cells for its incorporation into thyroglobulin.

C. Thyroperoxidase is the enzyme required to carry out the oxidation of the iodide for incorporation into thyroglobulin.

D. Somatostatin naturally inhibits thyroid-stimulating hormone (TSH) release so decreased somatostatin would enable more TSH and hormone synthesis.

E.

CORRECT ANSWER WITH EXPLANATION:

E. High plasma levels of iodide

Whilst physiological levels of iodide stimulate hormone production, high or excess plasma levels suppress thyroid activity; this effect is used therapeutically to treat hyperthyroidism.

ANSWER 34.2

RATIONALE:

A. Graves' disease is an autoimmune condition affecting the peripheral TSH receptors and does not affect TRH release from the hypothalamus.

B. Graves' disease is an autoimmune condition affecting the peripheral TSH receptors and does not affect Thyroglobulin which is a large glycoprotein, synthesised, glycosylated and then secreted into the lumen of the follicle, where iodination of its tyrosine residues occurs.

C.

D. Graves' disease is an autoimmune condition affecting the TSH receptors but does not affect TSH release from the pituitary.

E. Graves' disease is an autoimmune condition affecting the peripheral TSH receptors and does not affect the plasma protein binding of the hormones to TBG.

CORRECT ANSWER WITH EXPLANATION:

C. Thyroxine (T_4)

Diffuse toxic goitre (Graves' Disease) is an organ-specific autoimmune disease caused by autoantibodies to the TSH receptor which, when active, increase T_4 secretion.

ANSWER 34.3

RATIONALE:

A.

B. Patients with exophthalmic or diffuse toxic goitre (Graves' disease) have protrusion of the eyeballs. The pathogenesis of this condition is not fully understood, but it is thought to be caused by the presence of TSH receptor–like proteins in orbital tissues.

C. In thyrotoxicosis there is excessive secretion and activity of the thyroid hormones, resulting in a high metabolic rate, an increase in skin temperature and sweating and heat intolerance.

D. In thyrotoxicosis there is excessive secretion and activity of the thyroid hormones, resulting in tachycardia.

E. In thyrotoxicosis there is excessive secretion and activity of the thyroid hormones, resulting in a high metabolic rate and increased appetite associated with loss of weight occurs.

CORRECT ANSWER WITH EXPLANATION:

A. Thickening of the skin

This is caused by the subcutaneous deposition of glycosaminoglycans and occurs with hypothyroidism.

[1] So called because it is implicated in the pathophysiology of *Pendred syndrome*, named after the eponymous English physician who first described this autosomal recessive form of familial goitre in association with sensorineural deafness.

[2] 'Derbyshire neck' was the name given to this condition in a part of the United Kingdom where sources of dietary iodine were once scarce.

[3] Correcting hypothyroidism by administration of T_4 therefore takes 2–3 weeks to reach equilibrium.

[4] After a Dublin physician who connected 'violent and long continued palpitations in females' with enlargement of the thyroid gland. Their complaints of fluttering hearts and lumps in their throats had previously been attributed to hysteria.

[5] John F. Kennedy Jr suffered from Graves' disease. He inherited a propensity for autoimmune diseases from his father JFK, who himself suffered from the autoimmune *Addison's disease*, in which adrenal glands are the main organs affected. JFK's sister Eunice also suffered from Addison's disease.

[6] These are man-made chemicals such as pesticides or herbicides (e.g. polychlorinated biphenyls) that persist in the environment and are ingested in foodstuffs. The endocrine system is particularly sensitive to these, especially during development.

[7] An older term for this condition, *cretinism*, has been dropped.

35: The reproductive system

OVERVIEW

In this chapter, we describe the endocrine control of the human female and male reproductive systems as the basis for understanding drug actions in sex hormone replacement, contraception, treatment of infertility, management of labour and treatment of erectile dysfunction.

Introduction

Drugs that affect reproduction (both by preventing conception and more recently for treating infertility) transformed society in the latter half of the last century. In this chapter, we briefly summarise salient points in reproductive endocrinology as a basis for understanding the numerous important drugs that work on the male and female reproductive systems. Such drugs are used for contraception, to treat infertility, as sex hormone replacement and in obstetric practice to influence labour. They are also used to influence lifestyle (see **Ch. 59**). The principle of negative feedback is stressed and is central to understanding how hormones interact to control reproduction [1] – many drugs, including agents used to prevent or assist conception, work by influencing negative feedback mechanisms. The chapter concludes with a short section on erectile dysfunction. The endocrinology of transgender medicine (reviewed

by **T'Sjoen et al., 2019**) is a specialised area and the use of puberty blockers and cross sex hormones in children and adolescents with gender dysphoria, is based on limited evidence of long-term outcomes and outside the scope of the chapter.

Endocrine Control of Reproduction

Hormonal control of the reproductive systems in men and women involves sex steroids from the gonads, hypothalamic mediators including the decapeptide gonadotrophin-releasing hormone (GnRH), and glycoprotein gonadotrophins from the anterior pituitary gland (see **Ch. 33**). Kisspeptin, a protein that is a ligand for a G protein–coupled receptor known as GPR54, initiates secretion of GnRH at puberty. GnRH is released from the hypothalamus to act on the anterior pituitary, triggering the release of luteinising hormone (LH) and follicle-stimulating hormone (FSH). These gonadotrophic hormones control sexual maturation and gametogenesis. Kisspeptin has been linked with sexual bonding. The tachykinin neurokinin B (NKB; see **Ch. 17**) is also implicated in controlling the secretion of GnRH in humans, with possible roles in pregnancy, sexual maturation and the menopause. It is present, together with kisspeptin and dynorphin, in the arcuate nucleus of the hypothalamus where these mediators are implicated in generating pulsatile release of GnRH. NKB is implicated in menopausal flushing and NK3 receptor block has reduced such flushing (**Prague et al., 2017**).

Anti-Müllerian hormone (AMH) is a homodimeric glycoprotein belonging to the transforming growth factor (TGF)-β family. It controls sexual development in the male fetus and follicle

formation in adult women. It was identified functionally in the 1940s from its role in the regression of the Müllerian ducts in the male embryo, is synthesised in the Sertoli cells of the testes (see later) and the granulosa cells of the ovaries in postnatal animals and is believed to act both locally and as a blood-borne hormone on AMH receptors which are expressed in the pituitary and hypothalamus as well as the gonads and may regulate fertility (**Barbotin et al., 2019**). Plasma AMH concentration is increased in polycystic ovary syndrome (PCOS), a common but poorly understood condition which causes infertility due to failure to ovulate ("anovulation").

Neurohormonal Control of the Female Reproductive System

Increased secretion of hypothalamic and anterior pituitary hormones occurs in girls at puberty and stimulates secretion of oestrogen from the ovaries. This causes maturation of the reproductive organs, development of secondary sexual characteristics and accelerated linear growth followed by closure of the epiphyses of the long bones. Sex steroids, *oestrogens* and *progesterone*, are thereafter involved in the menstrual cycle, and in pregnancy. A simplified outline is given in Figs **35.1** and **35.2**.

The menstrual cycle begins with menstruation, which lasts for 3–6 days, during which the superficial layer of uterine endometrium is shed. The endometrium regenerates during the follicular phase of the cycle after menstrual flow has stopped. A releasing factor, GnRH, is secreted from peptidergic neurons in the hypothalamus which discharge in a pulsatile fashion, approximately one burst per

hour. GnRH stimulates the anterior pituitary to release gonadotrophic hormones (see **Fig. 35.1**) – *FSH* and *LH*. These act on the ovaries to promote the development of small groups of follicles, each of which contains an ovum. One follicle develops faster than the others and forms the Graafian follicle (see Figs **35.1** and **35.2E**), which secretes oestrogens, and the rest degenerate. The ripening Graafian follicle consists of thecal and granulosa cells surrounding a fluid-filled core, within which lies an ovum. Oestrogens are responsible for the proliferative phase of endometrial regeneration, which occurs from day 5 or 6 until mid-cycle (see **Fig. 35.2B and F**). During this phase, the endometrium increases in thickness and vascularity, and at the peak of oestrogen secretion there is a prolific cervical secretion of mucus of pH 8–9, rich in protein and carbohydrate, which facilitates entry of spermatozoa. Oestrogen has a negative feedback effect on the anterior pituitary, decreasing gonadotrophin release during chronic administration of oestrogen as oral contraception (see later). In contrast, the spike of endogenous oestrogen secretion just before mid-cycle sensitises LH-releasing cells of the pituitary to the action of the GnRH and causes the mid-cycle surge of LH secretion (see **Fig. 35.2C**). This, in turn, causes rapid swelling and rupture of the Graafian follicle, resulting in ovulation. If fertilisation occurs, the fertilised ovum passes down the fallopian tubes to the uterus, starting to divide as it goes.

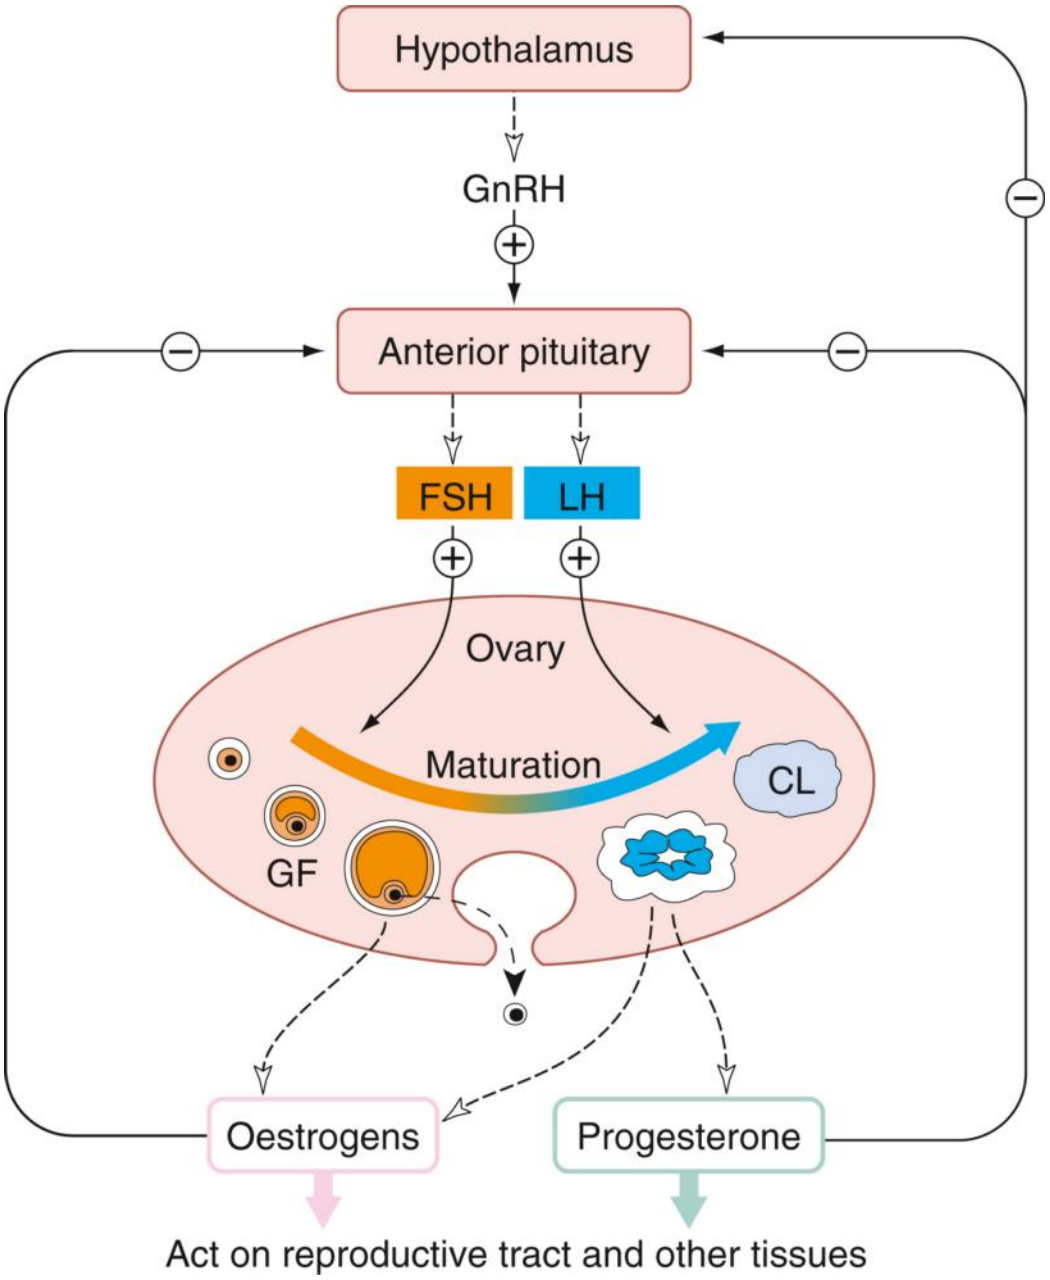

FIG. 35.1 Hormonal control of the female reproductive system.The Graafian follicle (GF) is shown developing on the *left*, then involuting to form the corpus luteum (CL) on the *right*, after the ovum (¤) has been released. *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotrophin-releasing hormone; *LH,* luteinising hormone.

Stimulated by LH, cells of the ruptured follicle proliferate and develop into the *corpus luteum*, which secretes progesterone. Progesterone acts, in turn, on oestrogen-primed endometrium, stimulating the secretory phase of the cycle, which renders the endometrium suitable for the implantation of a fertilised ovum. During this phase, cervical mucus becomes more viscous, less alkaline, less copious and in general less welcoming for sperm (in essence, older sperm are too late at this stage). Progesterone exerts negative feedback on the hypothalamus and pituitary, decreasing the release of LH. It also has a thermogenic effect, causing a rise in body temperature of about 0.5°C at ovulation, which is maintained until the end of the cycle.

The *shaded areas* indicate the entire range of observations. Day 1 is the onset of menstruation. Mean plasma hormone concentrations (A–D) are shown in relation to day of menstrual cycle. (E and F) show diagrammatically the changes in the ovarian follicle and the endometrium during the cycle. Ovulation on day 14 of the menstrual cycle occurs with the mid-cycle peak of luteinising hormone (LH), represented by the *vertical dashed line. A,* arterioles; *FSH,* follicle-stimulating hormone; *V,* venules. After van de Wiele, R. L., Dyrenfurth, I. 1974. Pharmacol. Rev. 25, 189–207.

If implantation of a fertilised ovum does not occur, progesterone secretion stops, triggering menstruation. If implantation does occur the corpus luteum continues to secrete progesterone which, by its effect on the hypothalamus and anterior pituitary, prevents further ovulation. The chorion (an antecedent of the placenta) secretes human chorionic gonadotrophin (HCG), which maintains the lining of the uterus during pregnancy. Modern pregnancy tests detect HCG levels present in urine. For reasons that are not physiologically obvious, HCG has an additional pharmacological action, exploited therapeutically in treating infertility (see later), of stimulating

ovulation. As pregnancy proceeds, the placenta develops further hormonal functions and secretes several hormones, including gonadotrophins, progesterone and oestrogens. Progesterone secreted during pregnancy controls the development of the secretory alveoli in the mammary gland, while oestrogen stimulates the lactiferous ducts. After parturition, oestrogen, along with prolactin (see **Ch. 33**), is responsible for stimulating and maintaining lactation, whereas supraphysiological doses of oestrogen suppress lactation.

Oestrogens, progestogens (progesterone-like drugs), androgens and the gonadotrophins are described later – see **Fig. 35.3** for biosynthetic pathways of the steroid hormones.

Hormonal control of the female reproductive system

- The menstrual cycle starts with menstruation.
- GnRH, released from the hypothalamus, acts on the anterior pituitary to release FSH and LH.
- FSH and LH stimulate follicle development in the ovary. FSH is the main hormone stimulating oestrogen production. LH stimulates ovulation at mid-cycle and is the main hormone controlling subsequent progesterone synthesis and secretion from the corpus luteum.
- Oestrogen controls the proliferative phase of the endometrium and has negative feedback effects on the anterior pituitary. Progesterone controls the later secretory

phase and has negative feedback effects on both the hypothalamus and anterior pituitary.

- If a fertilised ovum is implanted, the corpus luteum continues to secrete progesterone.
- After implantation, HCG from the chorion becomes important, and later in pregnancy progesterone, HCG and other hormones are secreted by the placenta.

Neurohormonal Control of the Male Reproductive System

As in women, hypothalamic, anterior pituitary and gonadal hormones control the male reproductive system. A simplified outline is given in **Fig. 35.4**. GnRH controls the secretion of gonadotrophins by the anterior pituitary. This secretion is not cyclical as in menstruating women, although it is pulsatile in both sexes, as with other anterior pituitary hormones (see **Ch. 33**). There is diurnal secretion of testosterone in males (higher in the morning, lower in the evening) and purported seasonal fluctuation (higher in summer, lower in autumn). FSH is responsible for the integrity of the seminiferous tubules, and after puberty is important in gametogenesis through an action on Sertoli cells, which nourish and support developing spermatozoa. LH, which in the male is also called *interstitial cell-stimulating hormone* (ICSH), stimulates the interstitial cells (Leydig cells) to secrete androgens – in particular *testosterone*. LH/ICSH secretion begins at puberty, and the consequent secretion of testosterone causes maturation of the reproductive organs and development of secondary sexual

characteristics. Thereafter, the primary function of testosterone is the maintenance of spermatogenesis and hence fertility – an action mediated by Sertoli cells. Testosterone is also important in the maturation of spermatozoa as they pass through the epididymis and vas deferens. A further action is a feedback effect on the anterior pituitary, modulating its sensitivity to GnRH and thus influencing secretion of LH/ICSH. Testosterone has marked anabolic effects, causing development of the musculature and increased bone growth which results in the pubertal growth spurt, followed by closure of the epiphyses of the long bones.

Secretion of testosterone is mainly controlled by LH/ICSH, but FSH also plays a part, possibly by releasing a factor similar to GnRH from the Sertoli cells which are its primary target. The interstitial cells that synthesise testosterone also have receptors for prolactin, which may influence testosterone production by increasing the number of receptors for LH/ICSH.

Behavioural Effects of Sex Hormones

As well as controlling the menstrual cycle, sex steroids affect sexual behaviour. Two types of control are recognised: *organisational* and *activational*.

Organisational control refers to the fact that sexual differentiation of the brain can be permanently altered by the presence or absence of sex steroids at key stages in development. In rats, administration of androgens to females within a few days of birth results in long-term virilisation of behaviour. Conversely, neonatal castration of male rats causes them to develop behaviourally as females. Brain development in the absence of sex

steroids follows female lines, but is switched to the male pattern by exposure of the hypothalamus to androgen at a key stage of development. Similar but less complete behavioural virilisation of female offspring has been demonstrated following androgen administration in non-human primates, and probably also occurs in humans if pregnant women are exposed to excessive androgen.

The *activational* effect of sex steroids refers to their ability to modify sexual behaviour after brain development is complete. In general, oestrogens and androgens increase sexual activity in the appropriate sex. **Oxytocin**, which is important during parturition (see later), also has roles in mating and parenting behaviours, its action in the central nervous system being regulated by oestrogen (see **Ch. 33**).

Drugs Affecting Reproductive Function

Oestrogens

Oestrogens are synthesised by the ovary and placenta, and in small amounts by the testis and adrenal cortex. The starting substance for synthesis of oestrogen and other steroids is cholesterol. The immediate precursors to the oestrogens are androgenic substances – androstenedione or testosterone (see **Fig. 35.3**). There are three main endogenous oestrogens in humans: *oestradiol*, *oestrone* and *oestriol* (see **Fig. 35.3**). Oestradiol is the most potent and is the principal oestrogen secreted by the ovary. At the beginning of the menstrual cycle, the plasma concentration is 0.2 nmol/L, rising to ~2.2 nmol/L in mid-cycle.

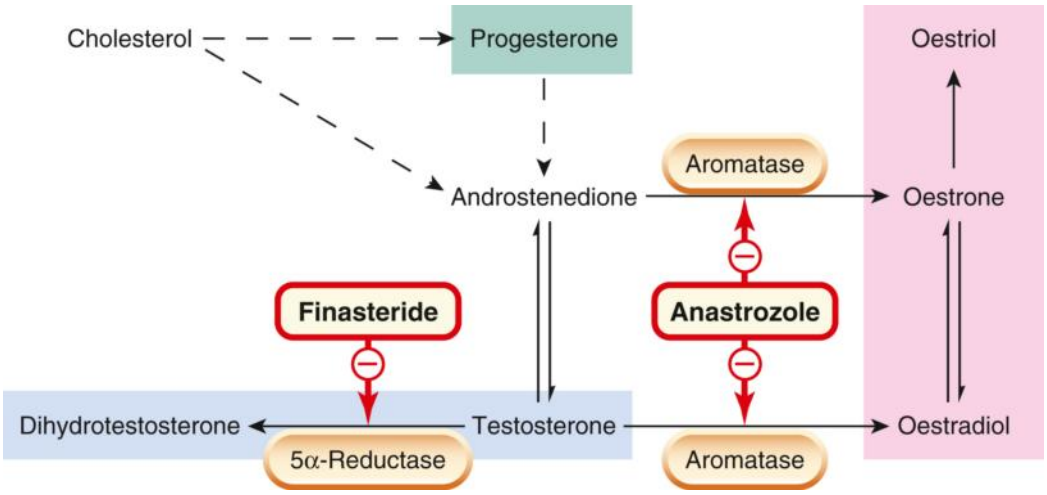

FIG. 35.3 The biosynthetic pathway for the androgens and oestrogens, with sites of drug action.(See also Fig. 33.5.) Finasteride is used in benign prostatic hyperplasia, and anastrozole, to treat breast cancer in postmenopausal women.

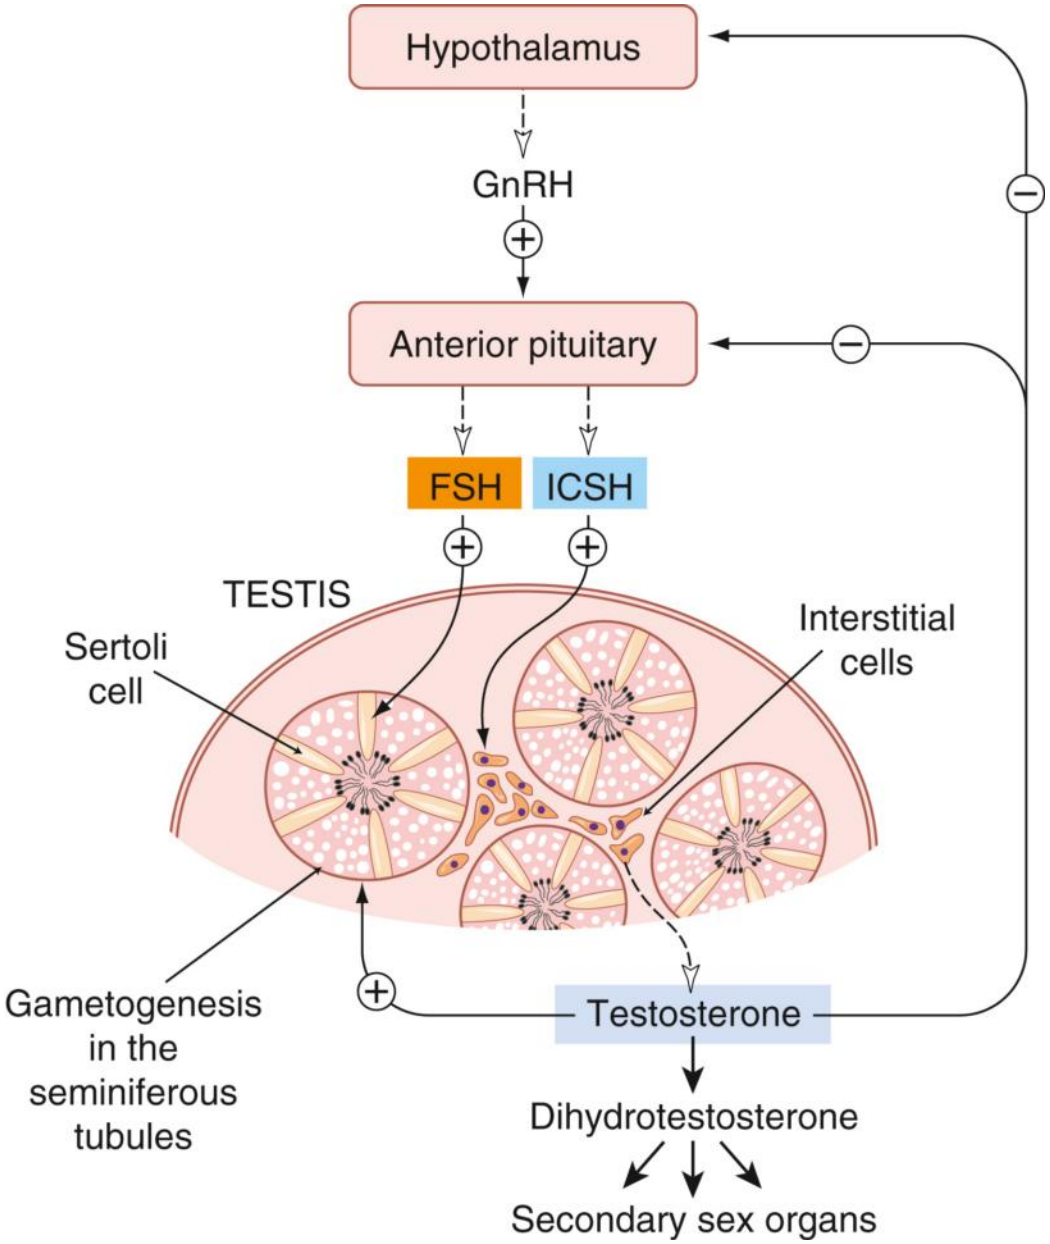

FIG. 35.4 Hormonal control of the male reproductive system. *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotrophin-releasing hormone; *ICSH,* interstitial cell-stimulating hormone.

Actions

Oestrogen acts in concert with progesterone, and induces synthesis of progesterone receptors in uterus, vagina, anterior pituitary and hypothalamus. Conversely, progesterone decreases oestrogen receptor expression in the reproductive tract. *Prolactin* (see **Ch. 33**) also influences oestrogen action by increasing the numbers of oestrogen receptors in the mammary gland, but has no effect on oestrogen receptor expression in the uterus.

The effects of exogenous oestrogen in females depend on the state of sexual maturity when the oestrogen is administered:

- *In primary hypogonadism:* oestrogen stimulates development of secondary sexual characteristics and accelerates growth.
- *In adults with primary amenorrhoea:* oestrogen, given cyclically with a progestogen, induces an artificial cycle.
- *In sexually mature women:* oestrogen (administered with a progestogen, see later) is a contraceptive.
- *At or after the menopause:* oestrogen replacement prevents menopausal symptoms and bone loss.

Oestrogens have several metabolic actions, including mineralocorticoid (retention of salt and water) and mild anabolic actions. They increase the coagulability of blood and, in pharmacological doses, increase the risk of thromboembolism.

Mechanism of action

Oestrogen binds to nuclear receptors (see **Ch. 3**). There are at least two types of oestrogen receptor, termed ERα and ERβ. Binding is followed by interaction of the resultant complexes with nuclear

sites and subsequent genomic effects. In addition to these 'classic' intracellular receptors, some oestrogen effects, in particular its rapid vascular actions, are initiated by interaction with membrane receptors, including a G protein–coupled oestrogen receptor (GPER), which was cloned from vascular endothelial cells and plays a part in regulating vascular tone and cell growth as well as in lipid and glucose homeostasis (**Barton and Prossnitz, 2015**). Acute vasodilatation caused by 17-β-oestradiol is mediated by nitric oxide, and a plant-derived (phyto-) oestrogen called **genistein** (which is selective for ERβ, as well as having quite distinct effects due to inhibition of protein kinase C) is as potent as 17-β-oestradiol in this regard (**Walker et al., 2001**).

Preparations

Many preparations (oral, transdermal, intramuscular, implantable and topical) of oestrogens are available for a wide range of indications. These include natural (e.g. **oestradiol**, **oestriol**) and synthetic (e.g. **mestranol**, **ethinylestradiol**, **diethylstilbestrol**) oestrogens. Oestrogens are presented either as single agents or combined with progestogen.

Pharmacokinetic aspects

Natural and synthetic oestrogens are well absorbed in the gastrointestinal (GI) tract, but after absorption the natural oestrogens are rapidly metabolised in the liver, whereas synthetic oestrogens are degraded less rapidly. There is variable enterohepatic cycling. Most oestrogens are readily absorbed from the skin and mucous membranes. They may be given as intravaginal creams or pessaries for local effect. In the plasma, natural oestrogens are

bound to albumin and to a sex steroid-binding globulin. Natural oestrogens are excreted in the urine as glucuronide and sulfate metabolites.

Unwanted effects

Unwanted effects of oestrogens range from the common and tiresome to the life-threatening but rare: breast tenderness, nausea, vomiting, anorexia, retention of salt and water with resultant oedema and increased risk of thromboembolism. More details of the unwanted effects of oral contraceptives are given later.

Used intermittently for postmenopausal replacement therapy, oestrogens cause menstruation-like withdrawal bleeding. Oestrogen causes endometrial hyperplasia unless given cyclically with a progestogen. When administered to males, oestrogens result in feminisation.

There is current concern regarding environmental effects of oestrogens, including various pesticides that act on oestrogen receptors as well as oestrogens excreted in urine. Either of these sources of oestrogen can pollute groundwater and damage aquatic wildlife as well as posing risks to human health (**Adeel et al., 2017**; **McLachlan, 2016**).

Oestrogen administration to pregnant women can cause genital abnormalities in their offspring: carcinoma of the vagina was more common in young women whose mothers were given diethylstilbestrol in early pregnancy in a misguided attempt to prevent miscarriage (see **Ch. 58**).

The clinical uses of oestrogens and antioestrogens are summarised in the box. In addition, see the section later on

postmenopausal hormone replacement therapy (HRT).

Antioestrogens, Aromatase Inhibitors, and Selective Oestrogen Receptor Modulators (SERMs)

Raloxifene, a 'selective [o]estrogen receptor modulator' (SERM), has anti-oestrogenic effects on breast and uterus but oestrogenic effects on bone, lipid metabolism and blood coagulation. It is used for the prevention and treatment of postmenopausal osteoporosis (see **Ch. 36**) and reduces the incidence of oestrogen receptor-positive breast cancer similarly to **tamoxifen** but with fewer adverse events (**Barrett-Connor et al., 2006**; **Vogel et al., 2006**). The US FDA has supported its use to reduce the risk of invasive breast cancer in postmenopausal women with osteoporosis and in postmenopausal women at high risk for invasive breast cancer. Unlike oestrogen, it does not prevent menopausal flushes and menopausal symptoms are common adverse effects; it increases the risk of thromboembolic disease and is less used against osteoporosis than bisphosphonates (see **Ch. 36**).

Tamoxifen has an antioestrogenic action on mammary tissue but oestrogenic actions on plasma lipids, endometrium and bone. It produces mild oestrogen-like adverse effects consistent with partial agonist activity. The tamoxifen–oestrogen receptor complex does not readily dissociate, interfering with receptor recycling.

Tamoxifen upregulates TGF-β, a cytokine that retards the progression of malignancy, and that also has a role in controlling the balance between bone-producing osteoblasts and bone-resorbing osteoclasts (see **Ch. 36**).

The use of tamoxifen to treat and prevent breast cancer is discussed further in **Chapter 57**.

Blocking oestrogen synthesis provides an alternative to blocking oestrogen receptors; *aromatase inhibitors* (see **Ch. 57**) such as **anastrozole** block oestrogen synthesis in the adrenal (**Fig. 35.3**) but not in the ovary and are an alternative to receptor antagonists in postmenopausal but not in premenopausal women with breast cancer. **Clomiphene** inhibits oestrogen binding to its receptors in the anterior pituitary, so preventing negative feedback and acutely increasing secretion of GnRH and gonadotrophins; it also possesses some oestrogen agonist activity and is classified as a SERM. It is administered by mouth as a 5-day course starting around day 5 of a menstrual cycle for the treatment of infertility caused by failure of ovulation. The resulting increase in GnRH and gonadotrophin levels stimulates and enlarges the ovaries, increases oestrogen secretion and induces ovulation which can be monitored by intravaginal ultrasound. Twins are common, but multiple pregnancy is unusual.

See the clinical box on oestrogens and antioestrogens for a summary of clinical uses.

Oestrogens and antioestrogens

- The endogenous oestrogens are oestradiol (the most potent), oestrone and oestriol; there are numerous exogenous synthetic forms (e.g. **ethinylestradiol**).
- Mechanism of action involves interaction with nuclear receptors (ERα or ERβ) in target tissues, resulting in

modification of gene transcription. Some of the rapid vascular and metabolic effects of oestrogens are mediated by a GPER.

- Their pharmacological effects depend on the sexual maturity of the recipient:
  - before puberty, they stimulate development of secondary sexual characteristics;
  - given cyclically in the female adult, they induce an artificial menstrual cycle and are used for contraception;
  - given at or after the menopause, they prevent menopausal symptoms and protect against osteoporosis, but increase thromboembolism.
- Antioestrogens are competitive antagonists or partial agonists. **Tamoxifen** is used in oestrogen-dependent breast cancer. **Clomiphene** induces ovulation by inhibiting the negative feedback effects on the hypothalamus and anterior pituitary.
- Selective modulators of the oestrogen receptor are oestrogen agonists in some tissues but antagonists in others. **Raloxifene** (one such drug) is used to treat and prevent osteoporosis in women who are at increased risk of breast cancer.

Clinical uses of oestrogens and antioestrogens

Oestrogens

- Replacement therapy:

  - primary ovarian failure (e.g. Turner's syndrome);
  - secondary ovarian failure (menopause) for flushing, vaginal dryness and to preserve bone mass. Such use should be short term because of an excess risk of thromboembolism.
- Contraception.
- Prostate and breast cancer (these uses have largely been superseded by other hormonal manipulations; see **Ch. 57**).

Antioestrogens/SERMs and aromatase inhibitors

- To treat oestrogen-sensitive breast cancer (**tamoxifen**, **toremifene**, **fulvestrant**).
- Aromatase inhibitors (e.g. **anastrozole**) are an alternative for breast cancer in post-menopausal women.
- To induce ovulation (**clomiphene**) in treating infertility caused by anovulation.

Progestogens

The natural progestational hormone (progestogen) is *progesterone* (see Figs **35.2** and **35.3**). This is secreted by the corpus luteum in the second part of the menstrual cycle, and by the placenta during pregnancy. Small amounts are also secreted by the testis and adrenal cortex.

Progestogens act on nuclear receptors. The density of progesterone receptors is controlled by oestrogens (see earlier discussion).

Preparations

There are two main groups of progestogens:

1. The naturally occurring hormone and its derivatives (e.g. **hydroxyprogesterone**, **medroxyprogesterone**, **dydrogesterone**). Progesterone itself is virtually inactive orally, because of presystemic hepatic metabolism. Other derivatives are available for oral administration, intramuscular injection or administration via the vagina or rectum.
2. Testosterone derivatives (e.g. **norethisterone**, **norgestrel** and **ethynodiol**) can be given orally. The first two have some androgenic activity and are metabolised to give oestrogenic products. Newer progestogens used in contraception include **desogestrel** and **gestodene**; they are an option for women who experience adverse effects such as acne, depression or breakthrough bleeding with the older drugs but have been associated with higher risks of venous thromboembolic disease (see later).

Actions

The pharmacological actions of the progestogens are in essence the same as the physiological actions of progesterone described previously. Specific effects relevant to contraception are detailed later.

Pharmacokinetic aspects

Injected progesterone is bound to albumin, not to the sex steroid–binding globulin. Some is stored in adipose tissue. It is metabolised

in the liver, and the products, pregnanolone and pregnanediol, are conjugated with glucuronic acid and excreted in the urine.

Unwanted effects

The unwanted effects of progestogens include weak androgenic actions. Other unwanted effects include acne, fluid retention, weight change, depression, change in libido, breast discomfort, premenstrual symptoms, irregular menstrual cycles and breakthrough bleeding. Some of the newer progestogens increase the incidence of thromboembolism.

Clinical uses of progestogens are summarised in the clinical box.

Antiprogestogens

Mifepristone is a partial agonist at progesterone receptors. It sensitises the uterus to the action of prostaglandins (PGs). It is given orally and has a plasma half-life of 21 h. Mifepristone is used, in combination with a PG (e.g. **gemeprost**; see later), as a medical alternative to surgical termination of pregnancy (see clinical box). **Ulipristal** is a selective progesterone receptor modulator which blocks ovulation. It is available over the counter and is used for emergency contraception within 120 h of vaginal intercourse and also to reduce the size of uterine fibroids (benign tumours of the uterus) preoperatively.

Progestogens and antiprogestogens

- The endogenous hormone is progesterone. Examples of synthetic drugs are the progesterone derivative

medroxyprogesterone and the testosterone derivative **norethisterone.**

- The mechanism of action involves intracellular receptor/altered gene expression. Oestrogen stimulates synthesis of progesterone receptors, whereas progesterone inhibits synthesis of oestrogen receptors.
- Main therapeutic uses are in oral contraception and oestrogen replacement regimens, and to treat endometriosis.
- The antiprogestogen **mifepristone**, in combination with PG analogues, is an effective medical alternative to surgical termination of early pregnancy.

Clinical uses of progestogens and antiprogestogens

Progestogens

- Contraception:
  - with **oestrogen** (usually ethinylestradiol) in *combined oral contraceptive pill*;
  - as *progesterone-only contraceptive pill*;
  - as *injectable* or *implantable* progesterone-only contraception;
  - as part of an *intrauterine* contraceptive system.
- Combined with **oestrogen** for *oestrogen replacement therapy* in women with an intact uterus, to prevent endometrial hyperplasia and carcinoma.

- For endometriosis.
- In endometrial carcinoma.

Antiprogestogens

- Medical termination of pregnancy: **mifepristone** (partial agonist) combined with a PG (e.g. **gemeprost**).
- Emergency contraception (morning-after pill): **ulipristal** (selective progesterone receptor modulator), also used to reduce the size of uterine fibroids pre-operatively.

Postmenopausal Hormone Replacement Therapy (HRT)

At the menopause, whether natural or surgically induced, ovarian function decreases and oestrogen levels fall. There is a long history of disagreement regarding the pros and cons of HRT in this context, with the prevailing wisdom undergoing several revisions over the years (see **Davis et al., 2005**). HRT normally involves the cyclic or continuous administration of low doses of one or more oestrogens, with or without a progestogen. Short-term HRT has some clear-cut benefits:

- improvement of symptoms caused by reduced oestrogen, for example, hot flushes and vaginal dryness;
- prevention and treatment of osteoporosis, but other drugs (e.g. bisphosphonates) are usually preferred (see **Ch. 36**).

Oestrogen replacement does not reduce the risk of coronary heart disease, despite earlier hopes, nor is there evidence that it reduces age-related decline in cognitive function. Drawbacks include:

- cyclical withdrawal bleeding;
- adverse effects related to progestogen (see later);
- increased risk of endometrial cancer if oestrogen is given unopposed by progestogen;
- increased risk of breast cancer, related to the duration of HRT use and disappearing within 5 years of stopping;
- increased risk of venous thromboembolism (risk approximately doubled in women using combined HRT for 5 years).

The web link in the reference list provides best estimates as of 2019 of risks of cancer (breast, endometrium, ovary), venous thromboembolism, stroke and coronary artery disease in relation to age and duration of HRT use.

Oestrogens used in HRT can be given orally (conjugated oestrogens, oestradiol, oestriol), vaginally (oestriol), by transdermal patch (oestradiol) or by subcutaneous implant (oestradiol). **Tibolone** is marketed for the short-term treatment of symptoms of oestrogen deficiency and for postmenopausal prophylaxis of osteoporosis in women at high risk of fracture when other prophylaxis is contraindicated or not tolerated. It has oestrogenic, progestogenic and weak androgenic activity, and can be used continuously without cyclical progesterone (avoiding the inconvenience of withdrawal bleeding).

Androgens

Testosterone is the main natural androgen. It is synthesised (see **Fig. 35.3** for the biosynthetic pathway) mainly by the interstitial cells of the testis, and in smaller amounts by the ovaries and adrenal cortex. Several other steroid hormones (e.g. progestogens) have some androgenic action as do a number of synthetic drugs,

Actions

In general, the effects of exogenous androgens are the same as those of testosterone and depend on the age and sex of the recipient. If prepubertal boys are given androgens, they do not reach their full predicted height because of premature closure of the epiphyses of the long bones. In boys at the age of puberty, there is rapid development of secondary sexual characteristics (i.e. growth of facial, axillary and pubic hair, deepening of the voice), maturation of the reproductive organs and a marked increase in muscular strength. There is a growth spurt with an acceleration in the usual increase in height that occurs year on year in younger children, followed by fusion of the bony epiphyses and cessation of linear growth. In adults, the anabolic effects can be accompanied by retention of salt and water. The skin thickens and may darken, and sebaceous glands become more active, predisposing to acne. Body weight and muscle mass increase, partly due to water retention. Androgens cause a feeling of well-being and an increase in physical vigour and may increase libido. Whether they are responsible for sexual behaviour as such is controversial, as is their contribution to aggressive behaviour. Supraphysiological testosterone concentrations inhibit spermatogenesis – the apparent paradox

being a consequence of negative feedback of testosterone on GnRH – thereby reducing male fertility.

Mechanism of action

In most target cells, testosterone works through an active metabolite, dihydrotestosterone, to which it is converted locally by a 5α-reductase enzyme. In contrast, testosterone itself causes virilisation of the genital tract in the male embryo and regulates LH/ICSH production in anterior pituitary cells. Testosterone and dihydrotestosterone modify gene transcription by interacting with nuclear receptors.

Preparations

Testosterone can be given by subcutaneous implantation or by transdermal patches. Various esters (e.g. enanthate and propionate) are given by intramuscular depot injection. Testosterone undecanoate and mesterolone can be given orally.

Pharmacokinetic aspects

If given orally, testosterone is rapidly metabolised in the liver to androstenedione which is a weak androgen. Virtually all testosterone in the circulation is bound to plasma protein – mainly to the sex steroid–binding globulin. Approximately 90% of endogenous testosterone is eliminated as metabolites. The elimination half-life of the free hormone is short (10–20 min). Synthetic androgens are less rapidly metabolised, and some are excreted in the urine unchanged.

Androgens and the hormonal control of the male reproductive system

- GnRH from the hypothalamus acts on the anterior pituitary to release both FSH, which stimulates gametogenesis, and LH (also called interstitial cell-stimulating hormone), which stimulates androgen secretion.
- The main endogenous hormone is testosterone; intramuscular depot injections of testosterone esters are used for replacement therapy.
- Mechanism of action is via intracellular receptors/altered gene expression.
- Effects depend on age/sex and include development of male secondary sexual characteristics in prepubertal boys and masculinisation in women.

Clinical uses of androgens and anti-androgens

- Androgens (**testosterone** preparations) as hormone replacement in:
  - male hypogonadism due to pituitary or testicular disease.
- Anti-androgens (e.g. **flutamide**, **cyproterone**) are used as part of the treatment of prostatic cancer.
- 5α-Reductase inhibitors (e.g. **finasteride**) are used in benign prostatic hyperplasia (see **Ch. 29**).

Unwanted effects

The unwanted effects of androgens include decreased GnRH release during continued use, with resultant male infertility, [2] and salt and water retention leading to oedema. Adenocarcinoma of the liver has been reported. Androgens impair growth in children (via premature fusion of epiphyses), cause acne and lead to masculinisation in girls. The adverse effects of testosterone replacement and monitoring for these are reviewed by **Rhoden and Morgentaler (2004)**.

The clinical uses of androgens are given in the clinical box.

Anabolic Steroids

Androgens can be modified chemically to alter the balance of anabolic and other effects. 'Anabolic steroids' (e.g. **nandrolone**) increase protein synthesis and muscle development disproportionately, but clinical use (e.g. in debilitating or muscle wasting disease) has been disappointing. They are used in the therapy of aplastic anaemia and (notoriously) abused by some athletes (see **Ch. 59**), as is testosterone itself. Unwanted effects are described previously. In addition, cholestatic jaundice, liver tumours and increased risk of coronary heart disease are recognised adverse effects of high-dose anabolic steroids.

Anti-Androgens

Both oestrogens and progestogens have anti-androgen activity, oestrogens mainly by inhibiting GnRH secretion and progestogens (some of which are weak partial agonists at androgen receptors, see earlier discussion) by competing at androgen receptors in target

organs. **Cyproterone** is a derivative of progesterone and has weak progestational activity. It is a partial agonist at androgen receptors, competing with dihydrotestosterone for receptors in androgen-sensitive target tissues. Through its effect in the hypothalamus, it depresses the synthesis of gonadotrophins. It is used as an adjunct in the treatment of prostatic cancer during initiation of GnRH agonist treatment (see later). It is also used in the therapy of precocious puberty in males, and of masculinisation and acne in women. It decreases libido and has been used to treat hypersexuality in male sexual offenders. [3]

Flutamide is a non-steroidal anti-androgen used with GnRH agonists in the treatment of prostate cancer.

Drugs can have anti-androgen action by inhibiting synthetic enzymes. **Finasteride** inhibits the enzyme (5α-reductase) that converts testosterone to its active metabolite dihydrotestosterone (see **Fig. 35.3**). Finasteride is well absorbed after oral administration, has a half-life of about 7 h and is excreted in the urine and faeces. It is used to treat benign prostatic hyperplasia (see **Ch. 29**).

Gonadotrophin-Releasing Hormone (GnRH): Agonists and Antagonists

GnRH is a decapeptide that controls the secretion of FSH and LH by the anterior pituitary. Secretion of GnRH is controlled by neural input from other parts of the brain, and through negative feedback by the sex steroids (Figs **35.1** and **35.5**). Exogenous androgens, oestrogens and progestogens all inhibit GnRH secretion, but only progestogens exert this effect at doses that do not have marked

hormonal actions on peripheral tissues, presumably because progesterone receptors in the reproductive tract are sparse unless they have been induced by previous exposure to oestrogen. **Danazol** (see later) is a synthetic steroid that inhibits release of GnRH and, consequently, of gonadotrophins (FSH and LH). **Clomiphene** is a SERM that functions mainly as an oestrogen antagonist that stimulates gonadotrophin release by inhibiting the negative feedback effects of endogenous oestrogen; it is used to treat infertility (see clinical box and **Fig. 35.5**).

Synthetic GnRH is termed ***gonadorelin*** . Numerous analogues of GnRH, both agonists and antagonists, have been synthesised. **Buserelin**, **leuprorelin**, **goserelin** and **nafarelin** are agonists, the last being 200 times more potent than endogenous GnRH (good examples of superagonists, in that their efficacies are greater than the efficacy of the natural agonist at the receptor, GnRH).

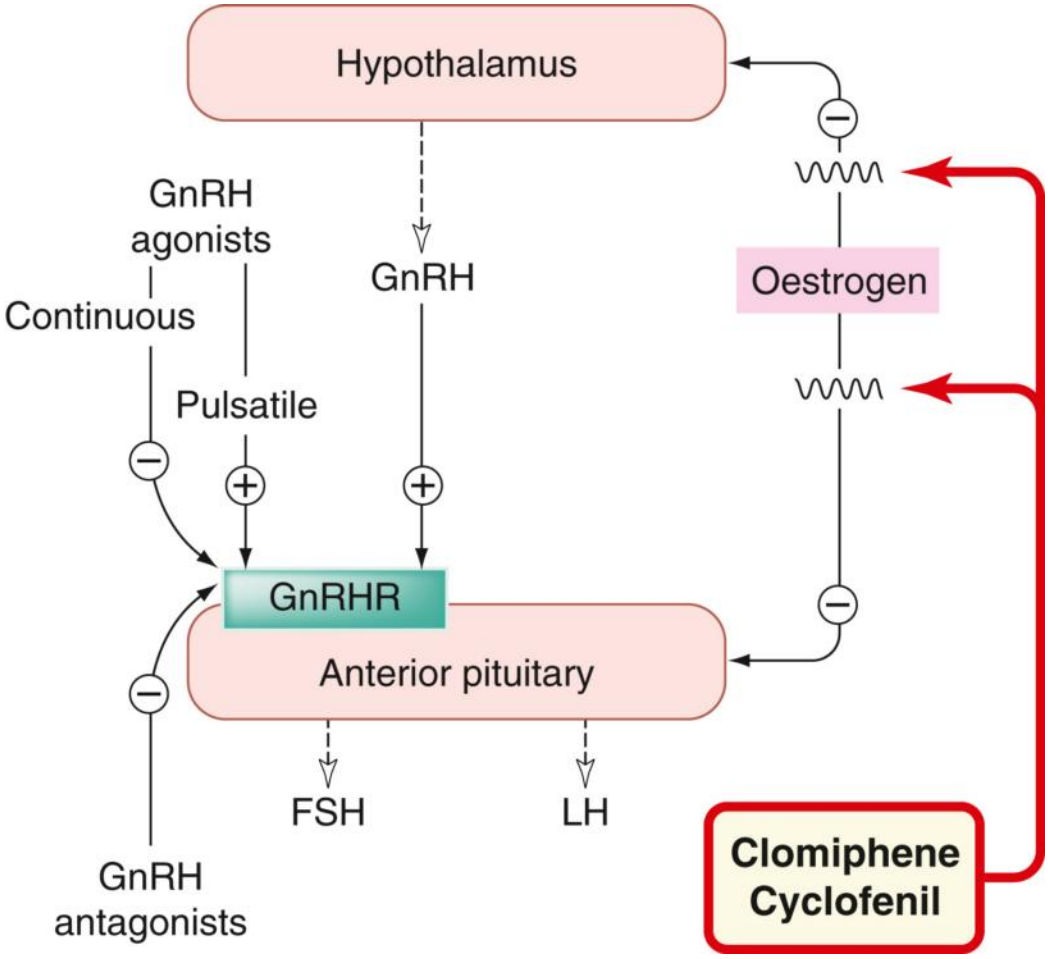

FIG. 35.5 Regulation of gonadotrophin release from the anterior pituitary. *FSH,* Follicle-stimulating hormone; *GnRHR,* gonadotrophin-releasing hormone receptor; *LH,* luteinising hormone.

Pharmacokinetics and clinical use

GnRH agonists, given by subcutaneous infusion in pulses to mimic physiological secretion of GnRH, stimulate gonadotrophin release (see **Fig. 35.5**) and induce ovulation. They are absorbed intact following nasal administration (see **Ch. 9**). Continuous use, by nasal spray or as depot preparations, stimulates gonadotrophin

release transiently, but then *inhibits* gonadotrophin release (see **Fig. 35.5**) because of down-regulation (desensitisation) of GnRH receptors in the pituitary. GnRH analogues are given in this fashion to cause gonadal suppression in various sex hormone–dependent conditions, including prostate and breast cancers, endometriosis (endometrial tissue outside the uterine cavity) and large uterine fibroids. Continuous, non-pulsatile administration inhibits spermatogenesis and ovulation. GnRH agonists are used by specialists in infertility treatment, not to stimulate ovulation (which is achieved using gonadotrophin preparations) but to suppress the pituitary before administration of FSH or HCG.

Unwanted effects of GnRH analogues

The unwanted effects of GnRH agonists in women, for example, flushing, vaginal dryness and bone loss, result from hypo-oestrogenism. The initial stimulation of gonadotrophin secretion on starting treatment can transiently worsen pain from bone metastases in men with prostate cancer, so treatment is started only after the patient has received an androgen receptor antagonist such as **flutamide** (see earlier and **Ch. 57**).

Danazol

Actions and pharmacokinetics

Danazol inhibits gonadotrophin secretion (especially the mid-cycle surge), and consequently reduces oestrogen synthesis in the ovary. In men, it reduces androgen synthesis and spermatogenesis. It has androgenic activity. It is orally active and metabolised in the liver.

Danazol is used in sex hormone-dependent conditions including endometriosis, breast dysplasia (benign breast lumps) and gynaecomastia. A distinct use is to prevent attacks of swelling in hereditary angio-oedema (see **Ch. 28**); its mechanism when used for this indication is not known.

Unwanted effects are common, and include virilisation, GI disturbance, weight gain, fluid retention, dizziness, menopausal symptoms, muscle cramps and headache.

Gonadotrophins and Analogues

Gonadotrophins (FSH, LH and HCG) are glycoproteins produced and secreted by the anterior pituitary (FSH and LH, see **Ch. 33**) or chorion and placenta (HCG). Large amounts of gonadotrophins are present in the urine of women following the menopause, because oestrogen levels fall abolishing feedback inhibition on the pituitary, which consequently secretes large amounts of FSH and LH. [4]

Preparations

Gonadotrophins are extracted from urine of pregnant (HCG) or postmenopausal women (human menopausal gonadotrophin, which contains a mixture of FSH and LH). Recombinant FSH (**follitropin**) and LH (**lutropin**) are also available.

Pharmacokinetics and clinical use

Gonadotrophin preparations are given by injection. They are used to treat infertility caused by lack of ovulation as a result of hypopituitarism or following failure of treatment with **clomiphene**; they are also used by specialists to induce ovulation to enable eggs to be collected for in vitro fertilisation.

Gonadotrophins are also sometimes used in men with infertility caused by a low sperm count as a result of hypogonadotrophic hypogonadism (a disorder that is sometimes accompanied by lifelong anosmia, i.e. lack of sense of smell). HCG has been used to stimulate testosterone synthesis in boys with delayed puberty, but testosterone is usually preferred.

Gonadotrophin-releasing hormone (GnRH) and gonadotrophins

- GnRH is a decapeptide; **gonadorelin** is the name of the synthetic form used therapeutically. **Nafarelin** is a potent analogue.
- Given in pulsatile fashion, GnRHs stimulate gonadotrophin release; given continuously, they inhibit it.
- The gonadotrophins, FSH and LH, are glycoproteins.
- Preparations of gonadotrophins (e.g. chorionic gonadotrophin) are used to treat infertility caused by failure of ovulation.
- **Danazol** is a modified progestogen that inhibits gonadotrophin production by actions on the hypothalamus and anterior pituitary.

Drugs Used for Contraception

Oral Contraceptives

There are two main types of oral contraceptives:

1. Combinations of an oestrogen with a progestogen (the combined pill).
2. Progestogen alone (the progestogen-only pill).

THE COMBINED PILL

The combined oral contraceptive pill is extremely effective, at least in the absence of intercurrent illness and of treatment with potentially interacting drugs (see later). The oestrogen in most combined preparations (second-generation pills) [5] is **ethinylestradiol**, although a few preparations contain **mestranol**. The progestogen may be **norethisterone**, **levonorgestrel**, **ethynodiol**, or – in 'third-generation' pills – **desogestrel** or **gestodene**, which are more potent, have less androgenic action and cause less change in lipoprotein metabolism, but which possibly cause a greater risk of thromboembolism than do second-generation preparations. The oestrogen content is generally 20–50 µg of ethinylestradiol or its equivalent, and a preparation is chosen with the lowest oestrogen and progestogen content that is well tolerated and gives good cycle control. This combined pill is taken for 21 consecutive days followed by 7 pill-free days, which causes a withdrawal bleed. Normal cycles of menstruation usually commence fairly soon after discontinuing treatment, and permanent loss of fertility (which may be a result of early menopause rather than a long-term consequence of the contraceptive pill) is rare.

Tailored regimens with so-called 'monophasic' combined hormonal contraceptive preparations containing ethinylestradiol (unlicensed use) are an option; they offer the choice of either a

shortened, or less frequent, or no hormone-free interval based on personal preference (see NICE on treatment regimens in the British National Formulary (BNF), **https://bnf.nice.org.uk/treatment-summary/contraceptives-hormonal.html**).

The mode of action is as follows:

- Oestrogen inhibits secretion of FSH via negative feedback on the anterior pituitary, and thus suppresses development of the ovarian follicle.
- Progestogen inhibits secretion of LH and thus prevents ovulation; it also makes the cervical mucus less suitable for the passage of sperm.
- Oestrogen and progestogen act in concert to alter the endometrium in such a way as to discourage implantation.

They may also interfere with the coordinated contractions of the cervix, uterus and fallopian tubes that facilitate fertilisation and implantation (see later).

Hundreds of millions of women worldwide have used this method since the 1960s, and in general the combined pill constitutes a safe and effective method of contraception. There are distinct health benefits from taking the pill (see later), and serious adverse effects are rare. However, minor unwanted effects constitute drawbacks to its use, and several important questions need to be considered.

Common adverse effects

The common adverse effects are:

- weight gain, owing to fluid retention or an anabolic effect, or both;
- mild nausea, flushing, dizziness, depression or irritability;
- skin changes (e.g. acne and/or an increase in pigmentation);
- amenorrhoea of variable duration on cessation of taking the pill.

Questions that need to be considered

Is there an increased risk of cardiovascular disease (venous thromboembolism, myocardial infarction, stroke)?

With second-generation pills (oestrogen content less than 50 μg), the risk of thromboembolism is small (incidence approximately 15 per 100,000 users per year, compared with 5 per 100,000 non-pregnant non-users per year or 60 episodes of thromboembolism per 100,000 pregnancies). The risk is greatest in subgroups with additional factors, such as smoking (which increases risk substantially) and long-continued use of the pill, especially in women over 35 years of age. The incidence of thromboembolic disease is approximately 25 per 100,000 users per year in users of preparations containing **desogestrel** or **gestodene**, which is still a small absolute risk compared with the risk of thromboembolism in an unwanted pregnancy. In general, provided that risk factors, e.g. smoking, hypertension and obesity, have been identified, combined oral contraceptives are safe for most women for most of their reproductive lives.

Is cancer risk affected?

Ovarian and endometrial cancer risk is *reduced*.

Is blood pressure increased?

A marked increase in arterial blood pressure occurs in a small percentage of women shortly after starting the combined oral contraceptive pill. This is associated with increased circulating angiotensinogen and disappears when treatment is stopped. Blood pressure is therefore monitored when oral contraceptive treatment is started, and an alternative contraceptive substituted if necessary.

Beneficial effects

Besides avoiding unwanted pregnancy, other desirable effects of the combined contraceptive pill include decreased menstrual symptoms such as irregular periods and intermenstrual bleeding. Iron-deficiency anaemia and premenstrual tension are reduced, as are benign breast disease, uterine fibroids and functional cysts of the ovaries.

The Progestogen-Only Pill

The drugs used in progestogen-only pills include **norethisterone**, **levonorgestrel** or **ethynodiol**. The pill is taken daily without interruption. The mode of action is primarily on the cervical mucus, which is made inhospitable to sperm. The progestogen probably also hinders implantation through its effect on the endometrium (see **Fig. 35.2**) and on the motility and secretions of the fallopian tubes.

Potential beneficial and unwanted effects

Progestogen-only contraceptives offer a suitable alternative to the combined pill for some women in whom oestrogen is contraindicated and are suitable for women whose blood pressure increases unacceptably during treatment with oestrogen. However,

their contraceptive effect is less reliable than that of the combination pill and missing a dose may result in conception. Disturbances of menstruation (especially irregular bleeding) are common. Only a small proportion of women use this form of contraception, so long-term safety data are less reliable than for the combined pill.

Pharmacokinetics of Oral Contraceptives: Drug Interactions

Combined and progestogen-only oral contraceptives are metabolised by hepatic cytochrome P450 enzymes. Because the minimum effective dose of oestrogen is used to minimise excess risk of thromboembolism, any increase in its clearance may result in contraceptive failure, and indeed enzyme-inducing drugs can have this effect, not only for combined but also for progesterone-only pills. Such drugs include **rifampicin** and **rifabutin**, as well as **carbamazepine**, **phenytoin** and others, including the herbal preparation St John's Wort (see **Ch. 48**).

Oral contraceptives

The combined pill

- The combined oestrogen plus progestogen pill is taken for 21 consecutive days out of 28; alternatively tailored regimens that offer the choice of either a shortened, or less frequent, or no hormone-free interval are an option.
- Mode of action: oestrogen inhibits FSH release and therefore follicle development; progestogen inhibits LH release and

therefore ovulation, and makes cervical mucus inhospitable for sperm; together, they render the endometrium unsuitable for implantation.

- Drawbacks: weight gain, nausea, mood changes and skin pigmentation can occur.
- Serious unwanted effects are rare. A small proportion of women develop reversible hypertension; there is a small increase in the diagnosis of breast cancer, possibly attributable to earlier diagnosis, and of cervical cancer. There is an increased risk of thromboembolism with third-generation pills, especially in women with additional risk factors (e.g. smoking) and with prolonged use.
- There are several beneficial effects, not least the avoidance of unwanted pregnancy, which itself carries risks to health.

The progestogen-only pill

- The progestogen-only pill is taken continuously. It differs from the combined pill in that the contraceptive effect is less reliable and is mainly a result of the alteration of cervical mucus. Irregular bleeding is common.

Other Drug Regimens Used for Contraception

Postcoital (Emergency) Contraception

Oral administration of **levonorgestrel**, alone or combined with oestrogen, is effective if taken within 72 h of unprotected intercourse and repeated 12 h later. Nausea and vomiting are

common (and the pills may then be lost: replacement tablets can be taken with an antiemetic such as **domperidone**). Insertion of an intrauterine device is more effective than hormonal methods and works up to 5 days after intercourse.

Long-Acting Progestogen-Only Contraception

Medroxyprogesterone can be given intramuscularly as a contraceptive. This is effective and safe. However, menstrual irregularities are common, and infertility may persist for many months after the final dose.

Levonorgestrel implanted subcutaneously in non-biodegradable capsules is used by approximately 3 million women worldwide. This route of administration avoids first-pass metabolism. The capsules release their progestogen content slowly over 5 years. Irregular bleeding and headache are common.

A levonorgestrel-impregnated intrauterine system provides prolonged, reliable contraception and, in contrast to standard copper containing devices, *reduces* menstrual bleeding.

The Uterus

The physiological and pharmacological responses of the uterus vary at different stages of the menstrual cycle and during pregnancy.

The Motility of the Uterus

Uterine muscle contracts rhythmically both in vitro and in vivo, contractions originating in the muscle itself. Myometrial cells in the fundus act as pacemakers and give rise to conducted action

potentials. The electrophysiological activity of these pacemaker cells is regulated by the sex hormones.

The non-pregnant human uterus contracts spontaneously but weakly during the first part of the cycle, and more strongly during the luteal phase and during menstruation. Uterine movements are depressed in early pregnancy because oestrogen, potentiated by progesterone, hyperpolarises myometrial cells. This suppresses spontaneous contractions. Towards the end of gestation, however, contractions recommence; these increase in force and frequency, and become fully coordinated during parturition. The nerve supply to the uterus includes both excitatory and inhibitory sympathetic components: adrenaline, acting on β_2 adrenoceptors, inhibits uterine contraction, whereas noradrenaline, acting on α adrenoceptors, stimulates contraction.

Drugs that Stimulate the Uterus

Drugs that stimulate the pregnant uterus and are important in obstetrics include **oxytocin**, **ergometrine** and PGs.

Oxytocin

The neurohypophyseal hormone oxytocin (an octapeptide) regulates myometrial activity, causing uterine contraction (see **Ch. 33**). Oxytocin release is stimulated by cervical dilatation, and by suckling; its role in parturition is incompletely understood but the fact that an antagonist (**atosiban**, see later) is effective in delaying the onset of labour implicates it in the physiology of parturition.

Oestrogen induces oxytocin receptor synthesis and, consequently, the uterus at term is highly sensitive to this hormone. Given by slow intravenous infusion to induce labour, oxytocin causes regular

coordinated contractions that travel from fundus to cervix. Both the amplitude and frequency of these contractions are related to dose, the uterus relaxing completely between contractions during low-dose infusion. Larger doses further increase the frequency of the contractions, and there is incomplete relaxation between them. Still higher doses cause sustained contractions that interfere with blood flow through the placenta and cause fetal distress or death.

Oxytocin contracts myoepithelial cells in the mammary gland, which causes 'milk let-down' – the expression of milk from the alveoli and ducts. It also has a vasodilator action. A weak antidiuretic action can result in water retention, which can be problematic in patients with cardiac or renal disease, or with pre-eclampsia. [6] Oxytocin and oxytocin receptors are also found in the brain, particularly in the limbic system, and are believed to play a role in mating and parenting behaviour.

The therapeutic use of synthetic oxytocin is summarised in the clinical box.

Oxytocin can be given by intravenous injection or intramuscularly but is most often given by intravenous infusion. It is inactivated in the liver and kidneys, and by circulating placental oxytocinase.

Unwanted effects of oxytocin include dose-related hypotension, due to vasodilatation, with associated reflex tachycardia. Its antidiuretic hormone-like effect on water excretion by the kidney causes water retention and, unless water intake is curtailed, consequent hyponatraemia (see **Ch. 29**).

Ergometrine

Ergot (*Claviceps purpurea*) is a fungus that grows on rye and contains a surprising variety of pharmacologically active substances (see **Ch. 16**). Ergot poisoning, which was once common, was often associated with abortion. In 1935, **ergometrine** was isolated and recognised as the oxytocic principle in ergot.

Ergometrine contracts the human uterus. This action depends partly on the contractile state of the organ. On a contracted uterus (the normal state following delivery), ergometrine has relatively little effect. However, if the uterus is inappropriately relaxed, ergometrine initiates strong contraction and reduces bleeding from the placental bed (the raw surface from which the placenta has detached). Ergometrine also has a moderate vasoconstrictor action.

The mechanism of action of ergometrine on smooth muscle is not understood. It is possible that it acts partly on α adrenoceptors, like the related alkaloid ergotamine (see **Ch. 15**), and partly on 5-hydroxytryptamine receptors.

The use of ergometrine is given in the clinical box, below.

Ergometrine can be given orally, intramuscularly or intravenously. It has a very rapid onset of action and its effect lasts for 3–6 h.

Ergometrine can produce vomiting, probably by an effect on dopamine D_2 receptors in the chemoreceptor trigger zone (see **Ch. 31**, **Fig. 31.5**). Vasoconstriction with an increase in blood pressure associated with nausea, blurred vision and headache can occur, as can vasospasm of the coronary arteries, resulting in angina.

Prostaglandins

PGs are discussed in detail in **Chapter 17**. The endometrium and myometrium have substantial PG-synthesising capacity, particularly in the second, proliferative phase of the menstrual cycle. $PGF_{2\alpha}$ is generated in large amounts and has been implicated in the ischaemic necrosis of the endometrium that precedes menstruation (although it has relatively little vasoconstrictor action on many human blood vessels, in contrast to some other mammalian species). Vasodilator PGs, PGE_2 and PGI_2 (prostacyclin), are also generated by the uterus.

In addition to their vasoactive properties, the E and F PGs contract uterine smooth muscle, whose sensitivity to these PGs increases during gestation. Their role in parturition is not fully understood, but as cyclo-oxygenase inhibitors can delay labour (see later), they probably play some part in this.

PGs also play a part in two of the main disorders of menstruation: *dysmenorrhoea* (painful menstruation) and *menorrhagia* (excessive blood loss). Dysmenorrhoea is associated with increased production of PGE_2 and $PGF_{2\alpha}$; non-steroidal anti-inflammatory drugs, which inhibit PG biosynthesis (see **Ch. 25**), are used to treat dysmenorrhoea. Menorrhagia, in the absence of other uterine pathology, may be caused by a combination of increased vasodilatation and reduced haemostasis. Increased generation by the uterus of PGI_2 (which inhibits platelet aggregation) could impair haemostasis as well as causing vasodilatation. Non-steroidal anti-inflammatory drugs (e.g. **mefenamic acid**) are used to treat menorrhagia as well as dysmenorrhoea.

Prostaglandin preparations

PGs of the E and F series promote coordinated contractions of the body of the pregnant uterus, while relaxing the cervix. E and F PGs reliably cause abortion in early and middle pregnancy, unlike oxytocin which generally does not cause expulsion of the uterine contents at this stage. The PGs used in obstetrics are **dinoprostone** (PGE_2), **carboprost** (15-methyl $PGF_{2\alpha}$) and **gemeprost** or **misoprostol** (PGE_1 analogues). Dinoprostone can be given intravaginally as a gel or as tablets. Carboprost is given by deep intramuscular injection. Gemeprost and misoprostol are given intravaginally.

Unwanted effects

Unwanted effects include uterine pain, nausea and vomiting and diarrhoea. Dinoprost can cause hypotension. When combined with mifepristone, a progestogen antagonist that sensitises the uterus to PGs, lower doses of the PGs (e.g. misoprostol) can be used to terminate pregnancy and adverse effects are reduced.

The clinical box shows the clinical uses of PGs (see also **Ch. 17**).

Drugs acting on the uterus

- At parturition, **oxytocin** causes regular coordinated uterine contractions, each followed by relaxation; **ergometrine**, an ergot alkaloid, causes uterine contractions with an increase in basal tone. **Atosiban**, an antagonist of oxytocin, delays labour.
- PG preparations, for example, **dinoprostone** (PGE_2) and **dinoprost** ($PGF_{2\alpha}$), contract the pregnant uterus but relax

the cervix. Cyclo-oxygenase inhibitors inhibit PG biosynthesis and delay labour but are not used clinically for this indication because they delay closure of the ductus arteriosus in the fetus. They also alleviate symptoms of dysmenorrhoea and menorrhagia.

- The β_2-adrenoceptor agonists (e.g. **ritodrine**) inhibit spontaneous and oxytocin-induced contractions of the pregnant uterus.

Drugs that Inhibit Uterine Contraction

Selective β_2-adrenoceptor agonists, such as **ritodrine** or **salbutamol**, inhibit spontaneous or oxytocin-induced contractions of the pregnant uterus. These uterine relaxants are used in selected patients to prevent premature labour occurring between 22 and 33 weeks of gestation in otherwise uncomplicated pregnancies. They can delay delivery by 48 h, time that can be used to administer glucocorticoid therapy to the mother to mature the lungs of the baby and reduce neonatal respiratory distress. It has been difficult to demonstrate that any of the drugs used to delay labour improve the outcome for the baby. Risks to the mother, especially pulmonary oedema, increase after 48 h, and myometrial response is reduced, so prolonged treatment is avoided. Cyclo-oxygenase inhibitors (e.g. **indometacin**) inhibit labour, but their use could cause problems in the baby, including renal dysfunction and delayed closure of the ductus arteriosus, both of which are influenced favourably by endogenous PGs.

An oxytocin receptor antagonist, **atosiban**, provides an alternative to a β_2-adrenoceptor agonist. It is given as an intravenous bolus followed by an intravenous infusion for not more than 48 h. Adverse effects include vasodilatation, nausea, vomiting and hyperglycaemia.

Clinical uses of drugs acting on the uterus

Myometrial stimulants (oxytocics)

- **Oxytocin** is infused intravenously to *induce or augment labour* when the uterine muscle is not functioning adequately. It can also be used to treat *postpartum haemorrhage*.
- **Ergometrine** is used to treat *postpartum haemorrhage*. **Carboprost** can be used if patients do not respond to **ergometrine.**
- A preparation containing both **oxytocin** and **ergometrine** is used for the management of the third stage of labour; the two agents together can also be used, before surgery, to control bleeding due to incomplete abortion.
- **Gemeprost** (intravaginally) or **misoprostol** (following mifepristone) are used to terminate pregnancy.

Myometrial relaxants

- β-Adrenoceptor agonists (e.g. **ritodrine**): to delay *preterm labour*.
- **Atosiban** (oxytocin antagonist) also delays preterm labour.

Erectile Dysfunction

Erectile function depends on complex interactions between physiological and psychological factors. Erection is caused by vasorelaxation in the arteries and arterioles supplying the erectile tissue. This increases penile blood flow; the consequent increase in sinusoidal filling compresses the venules, occluding venous outflow and causing erection. During sexual intercourse, reflex contraction of the ischiocavernosus muscles compresses the base of the corpora cavernosa, and the intracavernosal pressure can reach several hundred millimetres of mercury during this phase of rigid erection. Innervation of the penis includes autonomic and somatic nerves. Nitric oxide (neuronal and endothelium derived) is the main mediator of erection (see **Ch. 19**).

Erectile function is adversely affected by several therapeutic drugs (including many antipsychotic, antidepressant and antihypertensive agents), and psychiatric and vascular disease (especially in association with endothelial dysfunction) can themselves cause erectile dysfunction, which is common in middle-aged and older men, even if they have no psychiatric or cardiovascular problems. [7] There are several organic causes, including hypogonadism, hyperprolactinaemia (see **Ch. 33**), arterial disease and various causes of neuropathy (most commonly diabetes), but often no organic cause is identified.

Over the centuries, there has been a huge trade in parts of various creatures that have the misfortune to bear some fancied resemblance to human genitalia, in the pathetic belief that

consuming these will restore virility or act as an aphrodisiac (i.e. a drug that stimulates libido). Alcohol (see **Ch. 50**) 'provokes the desire but takes away the performance', and cannabis (see **Ch. 18**) can also release inhibitions and probably does the same. **Yohimbine** (an α_2-adrenoceptor antagonist; see **Ch. 15**) may have some positive effect in this regard, but trials have proved inconclusive. **Apomorphine** (a dopamine agonist) causes erections in humans as well as in rodents when injected subcutaneously, but it is a powerful emetic, a disadvantage in this context. The picture picked up somewhat when it was found that injecting vasodilator drugs directly into the corpora cavernosa causes penile erection. **Papaverine** (see **Ch. 21**), if necessary with the addition of **phentolamine**, was used in this way. The route of administration is not acceptable to most men but those with diabetes, in particular, are often not needle-shy, and this approach was a real boon to many such patients. **PGE_1** (**alprostadil**) is often combined with other vasodilators when given intracavernosally. It can also be given transurethrally as an alternative (albeit still a somewhat unromantic one) to injection. Adverse effects of all these drugs include priapism (prolonged and painful erection with risk of permanent tissue damage), which is no joke. Treatment consists of aspiration of blood and, if necessary, cautious intracavernosal administration of a vasoconstrictor such as **phenylephrine**. Intracavernosal and transurethral preparations are still available to treat erectile failure, but orally active phosphodiesterase inhibitors are now generally the drugs of choice.

Phosphodiesterase Type V Inhibitors

Sildenafil, the first selective phosphodiesterase type V inhibitor (see also Chs **19** and **21**), was found accidently to influence erectile function. [8] **Tadalafil** and **vardenafil** are similar. Tadalafil is longer acting than sildenafil. In contrast to intracavernosal vasodilators, phosphodiesterase type V inhibitors do not cause erection independent of sexual desire but enhance the erectile response to sexual stimulation (both physical and psychological). They have transformed the treatment of erectile dysfunction.

Mechanism of action

Phosphodiesterase V is the isoform that inactivates cGMP. Nitrergic nerves release nitric oxide (or a related nitrosothiol) which diffuses into smooth muscle cells, where it activates guanylyl cyclase. The resulting increase in cytoplasmic cGMP mediates vasodilatation via activation of protein kinase G (see **Ch. 4**, **Fig. 4.10**). Consequently, inhibition of phosphodiesterase V potentiates the effect on penile vascular smooth muscle of endothelium-derived nitric oxide and of nitrergic nerves that are activated by sexual stimulation (**Fig. 35.6**). Pulmonary vasculature is also affected by PDFE5 inhibitors, leading to use in pulmonary hypertension (see **Ch. 21**).

Pharmacokinetic aspects and drug interactions

Peak plasma concentrations of sildenafil occur approximately 30–120 min after an oral dose and are delayed by eating, so it is taken an hour or more before sexual activity. It is given as a single dose as needed. It is metabolised by CYP3A4, which is induced by **carbamazepine**, **rifampicin** and **barbiturates**, and inhibited by **cimetidine**, macrolide antibiotics, antifungal imidazolines and some antiviral drugs (such as **ritonavir**). These drugs can interact

with sildenafil. Tadalafil has a longer half-life than sildenafil, so can be taken longer before sexual activity. A clinically important pharmacodynamic interaction of all phosphodiesterase V inhibitors occurs with all organic nitrates, which work through increasing cGMP (see **Ch. 19**) and are therefore markedly potentiated by sildenafil (see **Fig. 35.6**). Consequently, concurrent nitrate use, including use of **nicorandil**, contraindicates the concurrent use of any phosphodiesterase type V inhibitor. [9]

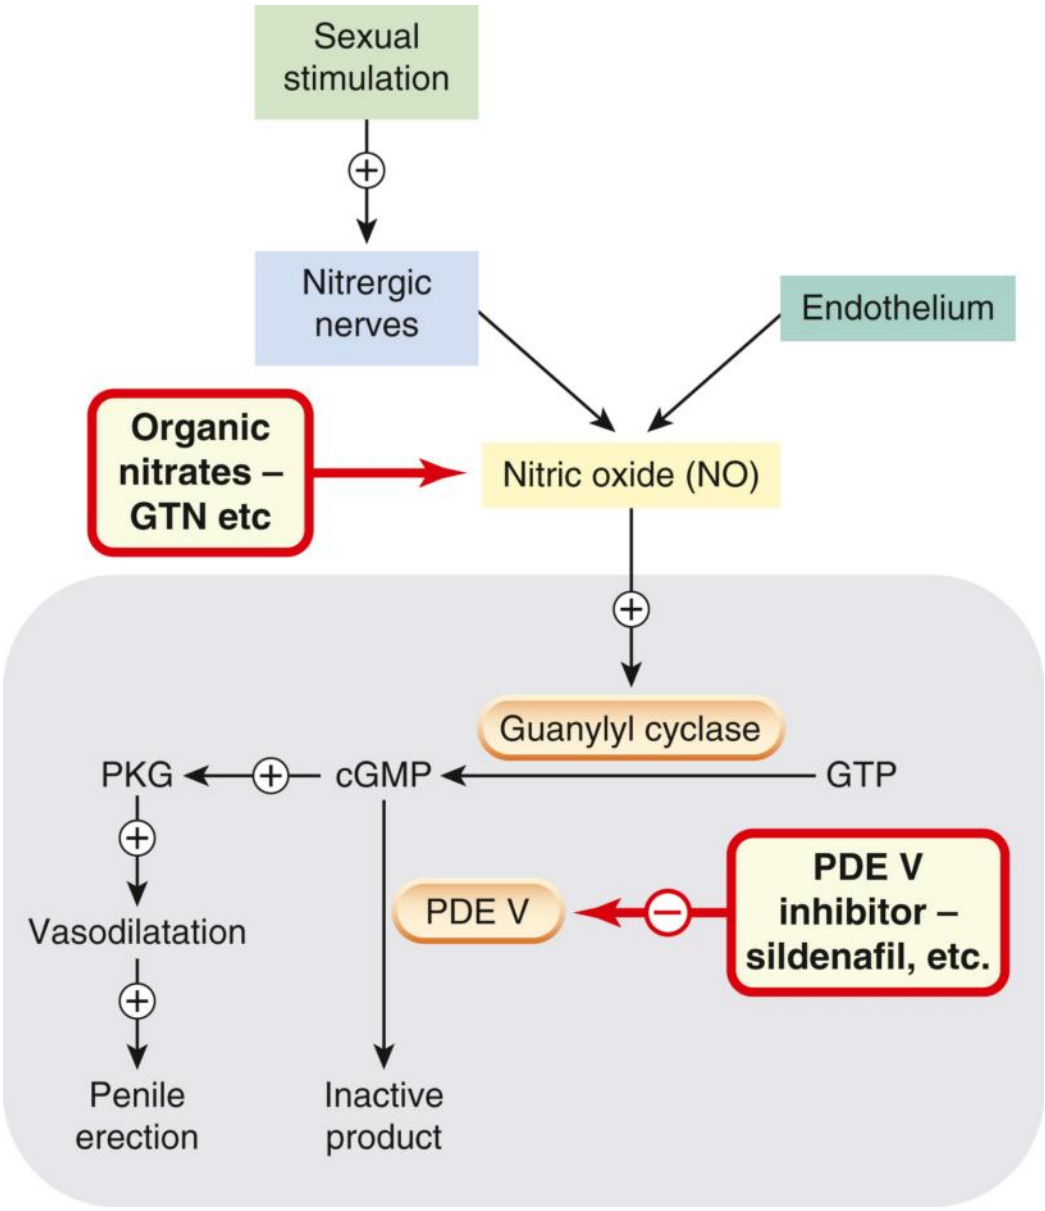

FIG. 35.6 Mechanism of phosphodiesterase V (PDE V) inhibitors on penile erection, and of the interaction of PDE V inhibitors with organic nitrates.The *large grey rectangle* denotes a vascular smooth muscle cell in the corpora cavernosa. Sexual stimulation releases nitric oxide (NO) from nitrergic nerves and this activates guanylyl cyclase, increasing cGMP

production and hence activating protein kinase G (PKG), causing vasodilatation and penile erection. cGMP is inactivated by PDE V, so PDE V inhibitors (e.g. sildenafil) potentiate NO and promote penile erection. NO from organic nitrates such as glyceryl trinitrate (GTN) is also potentiated leading to generalised vasodilatation and hypotension.

Unwanted effects

Many of the unwanted effects of phosphodiesterase type V inhibitors are caused by vasodilatation in other vascular beds; these effects include hypotension, flushing and headache. Visual disturbances have occasionally been reported and are of concern because sildenafil has some action on phosphodiesterase VI, which is present in the retina and important in vision (which is also cGMP-dependent). The manufacturers advise that sildenafil should not be used in patients with hereditary retinal degenerative diseases (such as retinitis pigmentosa) because of the theoretical risk posed by this. Vardenafil is more selective for the type V isozyme than is sildenafil (reviewed by **Doggrell, 2005**), but is also contraindicated in patients with hereditary retinal disorders.

QUESTIONS

QUESTION 35.1

The female reproductive cycle is tightly regulated by the coordinated release of hormones.

Which of the statements about the functions of the regulatory hormones controlling the menstrual cycle is correct?

OPTIONS:

A. Progesterone mediates the thickening of the endometrial lining.

B. Luteinising hormone (LH) stimulates the maturation of the developing ovum.

C. Progesterone inhibits the release of LH from the anterior pituitary.

D. Progesterone secretion from the corpus luteum maintains the lining of the uterus during pregnancy.

E. Oestrogen increases viscous mucus secretion during the latter half of the cycle to block the entry of spermatozoa.

QUESTION 35.2

The male reproductive system is also regulated by the coordinated release of hormones.

Which of the following statements about the male reproductive system is incorrect?

OPTIONS:

A. Gonadotrophin-releasing hormone (GnRH) controls the secretion of gonadotrophins by the anterior pituitary.

B. Follicle-stimulating hormone (FSH) acts on Sertoli cells, which nourish and support developing spermatozoa.

C. LH stimulates the Sertoli cells to secrete testosterone.

D. Testosterone is important in the maturation of spermatozoa as they pass through the epididymis and vas deferens.

E. Testosterone exerts a negative feedback on the anterior pituitary to reduce LH production.

QUESTION 35.3

An understanding of the hormonal control of the reproductive cycle has led to the development of the combined pill as an effective mechanism of contraception.

Which of the following statements about the combined pill is incorrect?

OPTIONS:

A. The combined pill can cause a decrease in blood pressure requiring careful monitoring and possible change to a progestogen-only pill.

B. Levonorgestrel reduces the chance of pregnancy by alteration of cervical mucus to reduce sperm entry.

C. Taking St. John's Wort can reduce the effectiveness of the combined contraceptive pill.

D. The combined pill can decrease the risk of endometrial cancer.

E. Thromboembolic risk is related to the age of the patient and duration of use of the combined pill.

QUESTION 35.4

Understanding the physiological and psychological factors controlling erectile function has enabled the development of pharmacological agents to treat conditions of erectile dysfunction.

Which of the following statements about the mechanisms and use of sildenafil in erectile dysfunction is correct?

OPTIONS:

A. Sildenafil causes an increase in the release of nitric oxide to mediate vasodilatation.

B. Sildenafil potentiates the effects of glyceryl nitrates in patients with angina.

C. Sildenafil exerts its therapeutic effects by inhibiting phosphodiesterase (PDE) VI enzymes.

D. The main side effect of sildenafil is hypertension.

E. Sildenafil should always be taken with food.

ANSWERS

ANSWER 35. 1

RATIONALE:

A. Oestrogen mediates the thickening of the endometrial lining.

B. LH stimulates the release of the mature ovum.

C.

D. Human chorionic gonadotrophin (HCG) maintains the uterus lining during pregnancy.

E. Progesterone increases viscous mucus secretion during the latter half of the cycle to block the entry of spermatozoa.

CORRECT ANSWER WITH EXPLANATION:

C. Progesterone inhibits the release of LH from the anterior pituitary.

In a negative feedback pathway, progesterone acts on the hypothalamus and anterior pituitary to decrease LH release preventing further ovulation.

ANSWER 35.2

RATIONALE:

A. This secretion is not cyclical as in menstruating women, although it is pulsatile in both sexes, as with other anterior pituitary hormones.

B. FSH is responsible for the integrity of the seminiferous tubules, and after puberty is important in gametogenesis through an action on Sertoli cells, which nourish and support developing spermatozoa.

C.

D. After puberty, the primary function of testosterone is the maintenance and maturation of spermatozoa and hence fertility.

E. Testosterone exerts a feedback effect on the anterior pituitary, modulating its sensitivity to GnRH and thus influencing secretion of LH/interstitial cell-stimulating hormone (ICSH).

CORRECT ANSWER WITH EXPLANATION:

C. LH stimulates the Sertoli cells to secrete testosterone.

LH, which in the male is also called *interstitial cell-stimulating hormone* (ICSH), stimulates the interstitial cells (Leydig cells) to secrete testosterone.

ANSWER 35.3

RATIONALE:

A.

B. The progestogen component of the pill helps to reduce the chance of pregnancy by altering the cervical mucus to make it inhospitable to sperm and decreasing the chance of implantation.

C. St. John's Wort can increase the metabolism and clearance of oestrogen so decreasing its effectiveness.

D. The combined pill can decrease the risk of endometrial and ovarian cancer.

E. With reduced oestrogen dose in the second-generation combined pills, the risk of thromboembolism is small but is increased with age, duration and certain lifestyle factors such as smoking.

CORRECT ANSWER WITH EXPLANATION:

A. The combined pill can cause an increase in arterial blood pressure due to an increase in circulating angiotensinogen requiring careful monitoring and possible change to a progestogen-only pill.

ANSWER 35.4

RATIONALE:

A. Sildenafil inhibits PDE V enzymes so prolonging the effect of nitric oxide–mediated cGMP vasodilatation.

B.

C. The therapeutic effects of sildenafil are due to its inhibition of PDE V in penile vascular smooth muscle. However, it does have

some inhibitory effect on PDE VI in the retina causing visual disturbances.

D. Due to its vasodilatory effects, the main side effect is hypotension.

E. The effects of sildenafil are delayed by eating.

CORRECT ANSWER WITH EXPLANATION:

B. Sildenafil potentiates the effects on glyceryl nitrates in patients with angina.

As sildenafil increases the levels of cGMP as do the glyceryl nitrates, concurrent use of these drugs is contraindicated due to potentiation of the effects.

---

[1] Recognition that negative feedback is central to endocrine control was a profound insight, made in 1930 by Dorothy Price, a laboratory assistant are the University of Chicago experimenting on the effects of testosterone in rats. She referred to it as 'reciprocal influence' and it explains how many reproductive hormones seem, confusingly, to cause both an effect and its opposite if given in different doses or over different time courses.

[2] Large doses of androgens also adversely affect female fertility, whereas physiological concentrations of androgen are implicated in female fertility (Prizant et al., 2014).

[3] Very different doses are used for these different conditions, for example, 2 mg/day in combination with ethinylestradiol for acne, 100 mg/day for hypersexuality and up to 300 mg/day for prostatic cancer.

[4] This forms the basis for the standard blood test, estimation of plasma LH/FSH concentrations, to confirm whether a woman is postmenopausal.

[5] The first-generation pills, containing more than 50 μg of oestrogen, were shown in the 1970s to be associated with an increased risk of deep vein thrombosis and pulmonary embolism.

[6] Eclampsia is a pathological condition (involving, among other things, high blood pressure, swelling and seizures) that occurs in pregnant women – it is usually preceded by milder changes ('pre-eclampsia').

[7] In randomised controlled trials, an appreciable proportion of men who discontinued treatment because of erectile dysfunction had been receiving placebo.

[8] Sildenafil was originally intended to treat angina, but bulging bedclothes were noticed in early clinical trials, providing the opportunity for the drug to be developed for a less crowded and more profitable indication than angina.

[9] This is important not only for sufferers from angina who take nitrates such as glyceryl trinitrate or isosorbide mononitrate therapeutically or prophylactically and are at risk of hypotension because of coronary artery disease, but also asymptomatic individuals who take amyl nitrate recreationally ('poppers').

36: Bone metabolism

OVERVIEW

In this chapter we consider first the cellular and biochemical processes involved in bone remodelling, and the various mediators that regulate these processes. Pathological disruption of the bony skeleton is clinically manifest in conditions such as osteoporosis, Paget's disease, osteomalacia and metastatic tumour deposits. We describe the drugs used to treat these disorders of bone, including new agents in the management of osteoporosis.

Introduction

The human skeleton undergoes a continuous process of remodelling throughout life – some bone being resorbed and new bone being laid down continuously – resulting in the complete skeleton being replaced every 10 years. Structural deterioration and decreased bone mass (osteoporosis) occur with advancing age and constitute a worldwide health problem. Other conditions that lead to treatable pathological changes in bone include nutritional deficiencies, certain endocrine disorders and malignancy. There have recently been significant advances in the understanding of bone biology, which have led in turn to several valuable new drugs.

Bone Structure and Composition

The human skeleton consists of 80% (by mass) cortical bone and 20% trabecular bone. Cortical bone is the dense, compact outer part, and trabecular bone, the inner meshwork. The former predominates in the shafts of long bones, the latter in the vertebrae, the epiphyses of long bones and the iliac crest. Trabecular bone, having a large surface area, is metabolically more active and more affected by factors that lead to bone loss (see later).

The main minerals in bone are calcium and phosphates. More than 99% of the calcium in the body is in the skeleton, mostly as crystalline hydroxyapatite but some as non-crystalline phosphates and carbonates; together, these make up half the bone mass.

The main bone cells are *osteoblasts*, *osteoclasts* and *osteocytes*.

- Osteoblasts are bone-forming cells derived from precursor cells in the bone marrow and the periosteum: they secrete important components (particularly collagen) of the extracellular matrix of bone – which is known as *osteoid*. They also have a role in the activation of osteoclasts (Figs **36.1** and **36.2**).
- Osteoclasts are multinucleated bone-resorbing cells derived from precursor cells of the macrophage/monocyte lineage.
- Osteocytes are derived from osteoblasts which, during the formation of new bone, become embedded in the bony matrix and differentiate into osteocytes. These cells form a connected cellular network that, along with nerve fibres located in bone, influences the response to mechanical loading. Osteocytes sense mechanical strain and respond by

triggering bone remodelling (see later) and secreting *sclerostin*, a glycoprotein that binds to receptors on osteoblasts to suppress bone formation (**McClung, 2017**). **Romosozumab** is a sclerostin inhibitor that has received regulatory approval for treatment of osteoporosis (see later).

- Other important cells in bone include monocytes/macrophages, lymphocytes and vascular endothelial cells; these secrete cytokines and other mediators implicated in bone remodelling.

Osteoid is the organic matrix of bone and its principal component is collagen. Other components such as *proteoglycans*, *osteocalcin* and various phosphoproteins are also important; one of these, *osteonectin*, binds to both calcium and collagen and thus links these two major constituents of bone matrix.

Calcium phosphate crystals are deposited as hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] in the osteoid, converting it into hard bone matrix.

In addition to its structural function, bone plays a major role in calcium homeostasis.

Bone Remodelling

There has been substantial progress in our understanding of bone remodelling (see review by **Kim et al., 2021**).

The process of remodelling involves:

- activity of osteoblasts and osteoclasts (see **Fig. 36.1**);
- actions of various cytokines (see Figs **36.1** and **36.2**);

- turnover of bone minerals – particularly calcium and phosphate;
- actions of several hormones: parathyroid hormone (PTH), the vitamin D family, oestrogens, growth hormone, steroids, calcitonin and various cytokines.

Diet, drugs and physical factors (exercise, loading) also affect remodelling. Bone loss – of 0.5%–1% per year – starts at age 35–40 years in both sexes and accelerates by as much as 10-fold during the menopause in women or with castration in men, and then gradually settles at 1%–3% per year. The loss during the menopause is due to increased osteoclast activity and affects mainly trabecular bone; the later loss in both sexes with increasing age is due to decreased osteoblast numbers and affects mainly cortical bone.

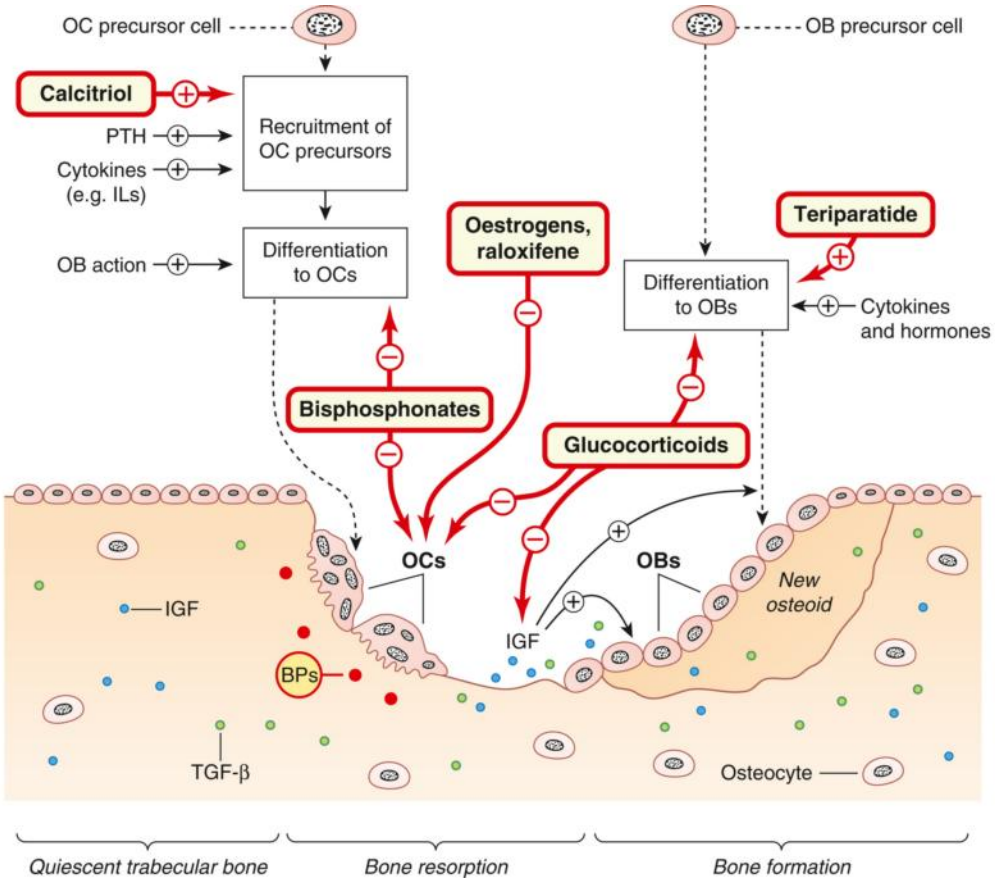

FIG. 36.1 The bone-remodelling cycle and the action of hormones, cytokines and drugs. *Quiescent trabecular bone:* Cytokines such as insulin-like growth factor (IGF) and transforming growth factor (TGF)-β, shown as dots, are embedded in the bone matrix. *Bone resorption* and *bone formation* are illustrated. Embedded bisphosphonates (BPs) are ingested by osteoclasts (OCs) when bone is resorbed (not shown). *IL,* Interleukin; *OB,* osteoblasts; *PTH,* parathyroid hormone.

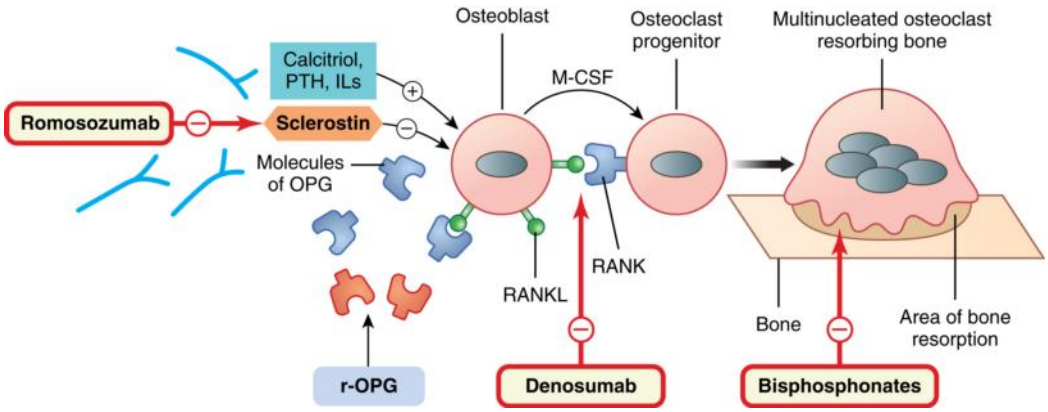

FIG. 36.2 Schematic diagram of the role of the osteoblast and cytokines in the differentiation and activation of the osteoclast and the action of drugs thereon.The osteoblast is stimulated to express a surface ligand, the RANK ligand (RANKL). RANKL interacts with a receptor on the osteoclast – an osteoclast differentiation and activation receptor termed *RANK* (receptor activator of nuclear factor κB), which causes differentiation and activation of the osteoclast progenitors to form mature osteoclasts. Bisphosphonates inhibit bone resorption by osteoclasts. Anti-RANKL antibodies (e.g. denosumab) bind RANKL and prevent the RANK–RANKL interaction. Sclerostin inhibits proliferation of osteoblasts and stimulates RANKL secretion. Romosozumab binds to and inhibits sclerostin. Drugs used clinically are in *red-bordered boxes*. *IL,* Interleukin; *M-CSF,* macrophage colony-stimulating factor; *OPG,* osteoprotegerin; *PTH,* parathyroid hormone.

The Action of Cells and Cytokines

A cycle of remodelling starts with recruitment of osteoclast precursors followed by cytokine-induced differentiation of these to mature multinucleated osteoclasts (see **Fig. 36.1**). The osteoclasts adhere to an area of trabecular bone, developing a ruffled border at the attachment site. They move along the bone, digging a pit by secreting hydrogen ions and proteolytic enzymes, mainly *cathepsin K*. This process gradually liberates cytokines such as insulin-like growth factor (IGF)-1 and transforming growth factor (TGF)-β, which have been embedded in the osteoid (see **Fig. 36.1**); these in turn recruit and activate successive teams of osteoblasts that have been stimulated to develop from precursor cells and are awaiting the call to duty (see **Fig. 36.1**). The osteoblasts invade the site, synthesising and secreting osteoid and secreting IGF-1 and TGF-β (which become embedded in the osteoid, as just mentioned). Some osteoblasts become embedded in the osteoid, forming osteocytes; others interact with and activate osteoclast precursors – and we are back to the beginning of the cycle.

Cytokines other than IGF-1 and TGF-β involved in bone remodelling include other members of the TGF-β family, including *bone morphogenic proteins* (BMPs), several interleukins, various hormones and members of the tumour necrosis factor (TNF) family. A member of this last family – a ligand for a receptor on the osteoclast precursor cell – is of particular importance. The receptor is termed (wait for it – biological terminology has fallen over its own feet here) *RANK*, which stands for ***r*** *eceptor* ***a*** *ctivator of* ***n*** *uclear factor* ***k*** *appa B* (NF-κB), NF-κB being the principal transcription factor involved in osteoclast differentiation and

activation. And the ligand is termed, unsurprisingly, *RANK ligand* (RANKL).

Osteoblasts synthesise and release *osteoprotegerin* (OPG) which belongs to the same TNF receptor superfamily as RANK. In a sibling-undermining process by osteoblast and osteoclast precursor cells, OPG can function as a decoy receptor that binds to RANKL [1] (generated by the very same cells as OPG), thus inhibiting RANKL's binding to the functional receptor, RANK, on the osteoclast precursor cell (see **Fig. 36.2**). The ratio of RANKL to OPG is critical in the formation and activity of osteoclasts and the RANK, RANKL, OPG system is fundamental to bone remodelling (reviewed by **Boyce and Xing, 2008**). Denosumab is an antibody directed against RANKL that is used clinically to treat osteoporosis (see later).

The Turnover of Bone Minerals

The main bone minerals are calcium and phosphates.

Calcium Metabolism

The daily turnover of bone minerals during remodelling involves about 700 mg of calcium. Calcium has numerous roles in physiological functioning. Intracellular Ca^{2+} is part of the signal transduction mechanism of many cells (see **Ch. 4**), so the concentration of ionised Ca^{2+} in the extracellular fluid and the plasma, normally 1.1–1.3 mmol/L in adult humans, needs to be controlled with great precision. The plasma Ca^{2+} concentration is regulated by interactions between PTH and various forms of vitamin D (Figs **36.3** and **36.4**); calcitonin also plays a part.

Calcium absorption in the intestine involves a Ca^{2+}-binding protein, the synthesis of which is regulated by calcitriol (see **Fig. 36.3**). It is probable that the overall calcium content of the body is regulated largely by this absorption mechanism, because urinary Ca^{2+} excretion normally remains more or less constant. However, with high blood Ca^{2+} concentrations urinary excretion increases, and with low blood concentrations urinary excretion can be reduced by PTH and calcitriol, both of which enhance Ca^{2+} reabsorption in the renal tubules (see **Fig. 36.3**).

Phosphate Metabolism

Phosphates are important constituents of bone and are also critically important in the structure and function of all the cells of the body. They are constituents of nucleic acids, provide energy in the form of ATP and control – through phosphorylation – the activity of many functional proteins. They also have roles as intracellular buffers and in the excretion of hydrogen ions in the kidney.

Phosphate absorption is an energy-requiring process regulated by *calcitriol*. Phosphate deposition in bone, as hydroxyapatite, depends on the plasma concentration of PTH, which, with calcitriol, mobilises both Ca^{2+} and phosphate from the bone matrix. Phosphate is excreted by the kidney; here PTH inhibits reabsorption and thus increases excretion.

Bone remodelling

- Bone is continuously remodelled throughout life. The events of the remodelling cycle are as follows:
  - osteoclasts, having been activated by osteoblasts, resorb bone by digging pits in trabecular bone. Into these pits the bone-forming osteoblasts secrete osteoid (bone matrix), which consists mainly of collagen but also contains osteocalcin, osteonectin, phosphoproteins and the cytokines insulin growth factor (IGF) and transforming growth factor (TGF)-β;
  - the osteoid is then mineralised, i.e. complex calcium phosphate crystals (hydroxyapatites) are deposited.
- Bone metabolism and mineralisation involve the action of parathyroid hormone, the vitamin D family and various cytokines (e.g. IGF, the TGF-β family and interleukins). Declining physiological levels of oestrogens, therapeutic levels of glucocorticoids and pathologically raised concentrations of thyroid hormones can result in bone resorption not balanced by bone formation – leading to osteoporosis.

Hormones Involved in Bone Metabolism and Remodelling

The main hormones involved in bone metabolism and remodelling are PTH, members of the vitamin D family, oestrogens and calcitonin. Glucocorticoids (see **Ch. 33**) and thyroid hormone (see **Ch. 34**) also affect bone promoting catabolism of osteoid and, in excess, causing osteoporosis.

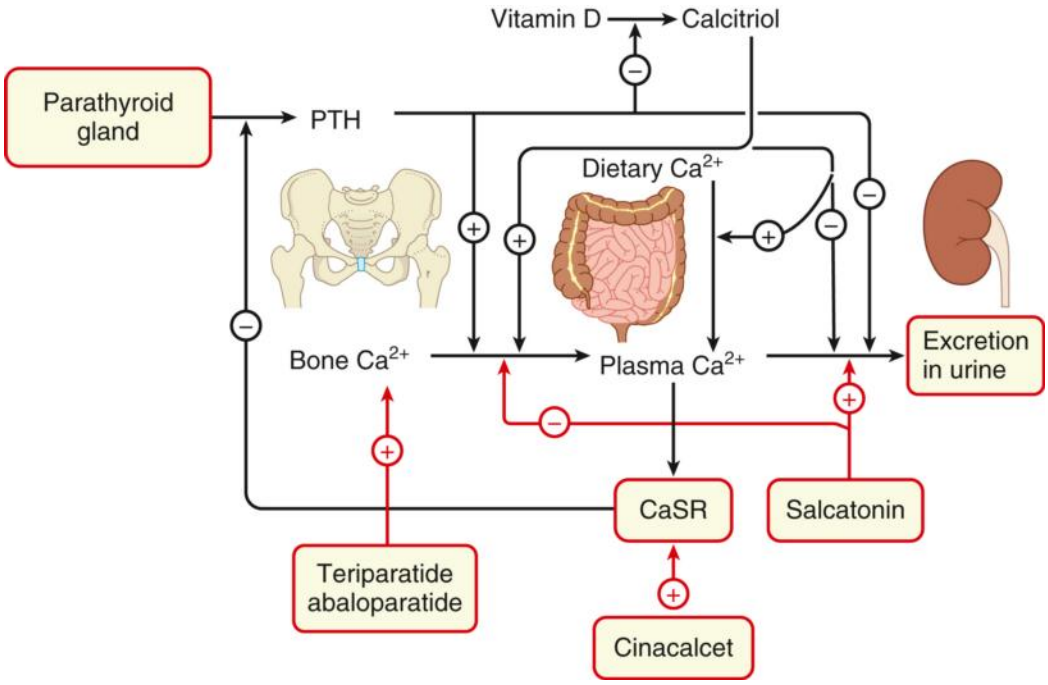

FIG. 36.3 The main factors involved in maintaining the concentration of Ca^{2+} in the plasma and the action of drugs.The calcium receptor on the parathyroid cell is a G protein–coupled receptor. Endogenous calcitonin, secreted by the thyroid, inhibits Ca^{2+} mobilisation from bone and decreases its reabsorption in the kidney, thus reducing blood Ca^{2+}. *CaSR*, Calcium-sensing receptor; *PTH,* parathyroid hormone.

Parathyroid Hormone

PTH, which consists of a single-chain polypeptide of 84 amino acid residues, is an important physiological regulator of Ca^{2+} metabolism. It acts on PTH type 1 receptor, [2] G protein–coupled receptors present in various tissues, especially bone – where it is

expressed on osteoblast cell membranes and kidney to maintain the plasma Ca^{2+} concentration via activation of adenylyl cyclase and phospholipase C. A closely related molecule, known as PTH-related peptide (PTHrP), bears the same N-terminal end as PTH, and can activate PTH receptors in broadly similar ways (**Chen, 2021**). When PTH activates the osteoblast PTH type 1 receptor, osteoblasts express RANKL, which binds to RANK on osteoclasts, activating them and increasing the resorption rate.

PTH mobilises Ca^{2+} from bone, promotes its reabsorption by the kidney and stimulates the synthesis of calcitriol, which in turn increases Ca^{2+} absorption from the intestine and synergises with PTH in mobilising bone Ca^{2+} (see Figs **36.3** and **36.4**). PTH promotes phosphate excretion, and thus its net effect is to increase the concentration of Ca^{2+} in the plasma and lower that of phosphate.

PTH receptors exist in two conformations (Ro and RG). Shorter duration of activation (and anabolic effect) is seen with ligands that have greater affinity for the RG conformation, whereas ligands that bind to the Ro state have a more prolonged duration of action that leads to bone resorption. Sustained elevated levels of PTH mobilise Ca^{2+} from bone and reduce renal Ca^{2+} excretion. In contrast, low intermittent therapeutic doses of PTH stimulate osteoblast activity and enhance bone formation.

PTH is synthesised in the cells of the parathyroid glands and stored in vesicles. The principal factor controlling secretion is the concentration of ionised calcium in the plasma, low plasma Ca^{2+} stimulating secretion, high plasma Ca^{2+} decreasing it by binding to and activating a Ca^{2+}-sensing G protein–coupled surface receptor

(CaSR; see **Ch. 3** and **Fig. 36.3**). (For reviews, see **Chen, 2021**; **Kim et al., 2021**.) **Cinacalcet** increases the sensitivity of CaSR to plasma Ca^{2+}, thereby reducing PTH secretion.

Teriparatide and **abaloparatide** are shorter-chain synthetic analogues of PTH and PTHrP, respectively, licensed for treatment of osteoporosis (see later).

Vitamin D

Vitamin D (calciferol) consists of a group of lipophilic precursors that are converted in the body into biologically active metabolites that function as true hormones, circulating in the blood and regulating the activities of various cell types (see **Reichel et al., 1989**). Their main action, mediated by nuclear receptors of the steroid receptor superfamily (see **Ch. 3**), is the maintenance of plasma Ca^{2+} by increasing Ca^{2+} absorption in the intestine, mobilising Ca^{2+} from bone and decreasing its renal excretion (see **Fig. 36.3**). In humans, there are two important forms of vitamin D, termed D_2 and D_3:

1. Dietary *ergocalciferol* (D_2), derived from ergosterol in plants.
2. *Cholecalciferol* (D_3), generated in the skin from 7-dehydrocholesterol by the action of ultraviolet irradiation during sun exposure, or formed from cholesterol in the wall of the intestine.

Cholecalciferol is converted to *calcifediol* (25-hydroxy-vitamin D_3) in the liver, and this is converted to a series of other metabolites of varying activity in the kidney, the most potent of which is *calcitriol* (1,25-dihydroxy-vitamin D_3); see **Fig. 36.4**.

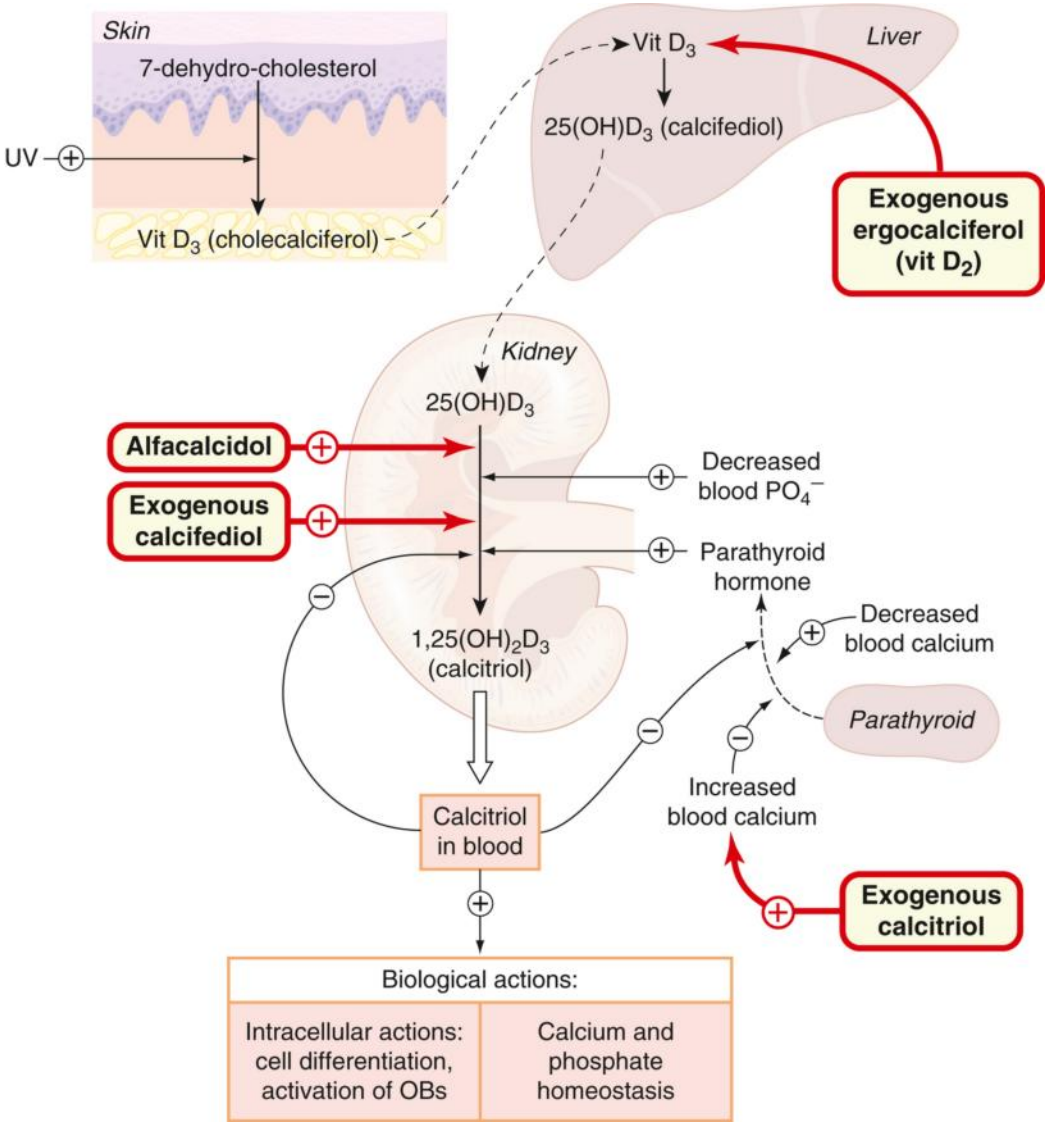

FIG. 36.4 Summary of the actions of the vitamin D endocrine system and the action of drugs.Exogenous ergocalciferol, vitamin *(vit)* D_2 (formed in plants by ultraviolet [UV] light), is converted to the corresponding D_2 metabolites in liver and kidney, as is the D_2 analogue dihydrotachysterol (not shown). Calcifediol and calcitriol are metabolites of vitamin D_3 and constitute the 'hormones' 25-hydroxy-vitamin D_3

and 1,25-dihydroxy-vitamin D_3, respectively. Alfacalcidol (1α-hydroxycholecalciferol) is 25-hydroxylated to calcitriol in the liver. *OB,* Osteoblast.

The synthesis of calcitriol from calcifediol is regulated by PTH, and is also influenced by the phosphate concentration in the plasma and by the calcitriol concentration itself through a negative feedback mechanism (see **Fig. 36.4**). Receptors for calcitriol are ubiquitous, and calcitriol is important in the functioning of many cell types.

The main actions of calcitriol are to stimulate absorption of Ca^{2+} and phosphate in the intestine and to mobilise Ca^{2+} from bone, but it also increases Ca^{2+} reabsorption in the kidney tubules (see **Fig. 36.3**). It promotes maturation of osteoclasts and stimulates their activity (see Figs **36.1** and **36.3**). It decreases collagen synthesis by osteoblasts. However, the effect on bone is complex and not confined to mobilising Ca^{2+}, because in clinical vitamin D deficiency (see later section on Vitamin D Preparations), in which the mineralisation of bone is impaired, administration of vitamin D restores bone formation. One explanation may lie in the fact that calcitriol stimulates synthesis of *osteocalcin*, the Ca^{2+}-binding protein of bone matrix.

Oestrogens

Oestrogens have an important role in maintaining bone integrity in adult women, acting on osteoblasts and osteoclasts (see **Ch. 35**). Oestrogen inhibits the cytokines that recruit osteoclasts and opposes the bone-resorbing, Ca^{2+}-mobilising action of PTH. It

increases osteoblast proliferation, augments the production of TGF-β and BMPs and inhibits apoptosis. Withdrawal of oestrogen, as happens physiologically at the menopause, frequently leads to osteoporosis.

Calcitonin

Calcitonin is a peptide hormone secreted by 'C' cells found in the thyroid follicles (see **Ch. 34**).

The main action of calcitonin is on bone; it inhibits bone resorption by binding to an inhibitory receptor on osteoclasts. In the kidney, it decreases the reabsorption of Ca^{2+} and phosphate in the proximal tubules. Its overall effect is to decrease the plasma Ca^{2+} concentration (see **Fig. 36.3**).

Secretion is determined mainly by the plasma Ca^{2+} concentration. A calcitonin analogue, **salcatonin**, is used clinically (see later).

Other Hormones

Physiological concentrations of glucocorticoids are required for osteoblast differentiation. Higher concentrations inhibit bone formation by inhibiting osteoblast differentiation and activity, and may stimulate osteoclast action – leading to osteoporosis, which is a feature of Cushing's syndrome (see **Fig. 33.7**) and an important adverse effect of glucocorticoid administration (see **Ch. 33**).

Thyroxine stimulates osteoclast action, reducing bone density and liberating Ca^{2+}. Osteoporosis occurs in association with thyrotoxicosis, and it is important not to use excessive thyroxine for treating hypothyroidism (see **Ch. 34**).

Parathyroid hormone, vitamin D and bone mineral homeostasis

- The vitamin D family give rise to true hormones; precursors are converted to calcifediol in the liver, then to the main hormone, calcitriol, in the kidney.
- Calcitriol increases plasma Ca^{2+} by mobilising it from bone, increasing its absorption in the intestine and decreasing its excretion by the kidney.
- Parathyroid hormone (PTH) acts mainly on the PTH type 1 receptor on osteoblasts and in the kidney. Intermittent stimulation of PTH receptors with synthetic PTH analogues stimulates bone formation.
- Calcitonin (secreted from the thyroid) reduces Ca^{2+} resorption from bone by inhibiting osteoclast activity.

Disorders of Bone

The reduction of bone mass with distortion of the microarchitecture is termed *osteoporosis*; a reduction in the mineral content is termed *osteopenia*. Dual-energy X-ray absorptiometry (DXA) and quantitative computed tomography are the standard methods for assessing osteoporosis severity and monitoring the effect of treatment (**Riggs et al., 2012**). Osteoporotic bone fractures easily after minimal trauma. The commonest causes of osteoporosis are postmenopausal deficiency of oestrogen and age-related deterioration in bone homeostasis. It is estimated that 50% of

women and 20% of men over the age of 50 will have a fracture due to osteoporosis. With increasing life expectancy, osteoporosis has increased to epidemic proportions and is an important public health problem, affecting about 75 million people in the United States, Japan and Europe. Other predisposing factors include catabolic hormones that favour protein breakdown such as excessive thyroxine or glucocorticoid administration. Other preventable or treatable diseases of bone include *osteomalacia* and *rickets* (the juvenile form of osteomalacia), in which there are defects in bone mineralisation due to vitamin D deficiency, due to either dietary deficiency of vitamin D and lack of sunlight or renal disease resulting in reduced synthesis of the active calcitriol hormone (see **Ch. 29**). In *Paget's disease* there is distortion of the processes of bone resorption and remodelling as a consequence of mutation in the gene that codes for a ubiquitin-binding protein [3] called sequestosome 1 (**Rea et al., 2013**), which is a scaffold protein in the RANK/NF-κB signalling pathway (see earlier).

Drugs Used in Bone Disorders

Two types of agent are currently used for treatment of *osteoporosis*:

1. *Antiresorptive drugs* that decrease bone loss, e.g. bisphosphonates, calcitonin, *s*elective [o]*e*strogen *r*eceptor *m*odulators (SERMs), **denosumab**, calcium.
2. *Anabolic agents* that increase bone formation, e.g. PTH, **teriparatide.**

Rickets and *osteomalacia* are treated with vitamin D preparations.

Paget's disease of bone is common but only a small percentage of patients are symptomatic; if medical treatment is needed for symptoms such as bone pain, intermittent courses of bisphosphonates such as risedronate, **pamidronate** or **zoledronate** (see later) can provide benefit that lasts for a number of years. This is much more convenient than frequent injections of **salcatonin**, previously the only effective medical treatment.

Bisphosphonates

Bisphosphonates (**Fig. 36.5**) are analogues of pyrophosphate, a normal constituent of tissue fluids that accumulates in bone and has a role in regulating bone resorption. Bisphosphonates inhibit bone resorption by an action mainly on the osteoclasts. They form tight complexes with calcium in the bone matrix and are released slowly as bone is resorbed by the osteoclasts, which are thus exposed to high local bisphosphonate concentrations.

Mechanism of action

Bisphosphonates reduce the rate of bone turnover. They can be grouped into two classes:

1. Simple compounds that are very similar to pyrophosphate (e.g. **etidronate, clodronate**). These are incorporated into ATP analogues that accumulate within the osteoclasts and promote their apoptosis.
2. Potent amino-bisphosphonates (e.g. **pamidronate**, **alendronate**, **risedronate**, **ibandronate**, **zoledronate**). These prevent bone resorption by interfering with the anchoring of cell surface proteins to the osteoclast

membrane by prenylation, thereby preventing osteoclast attachment to bone (see **Kim et al., 2021**).

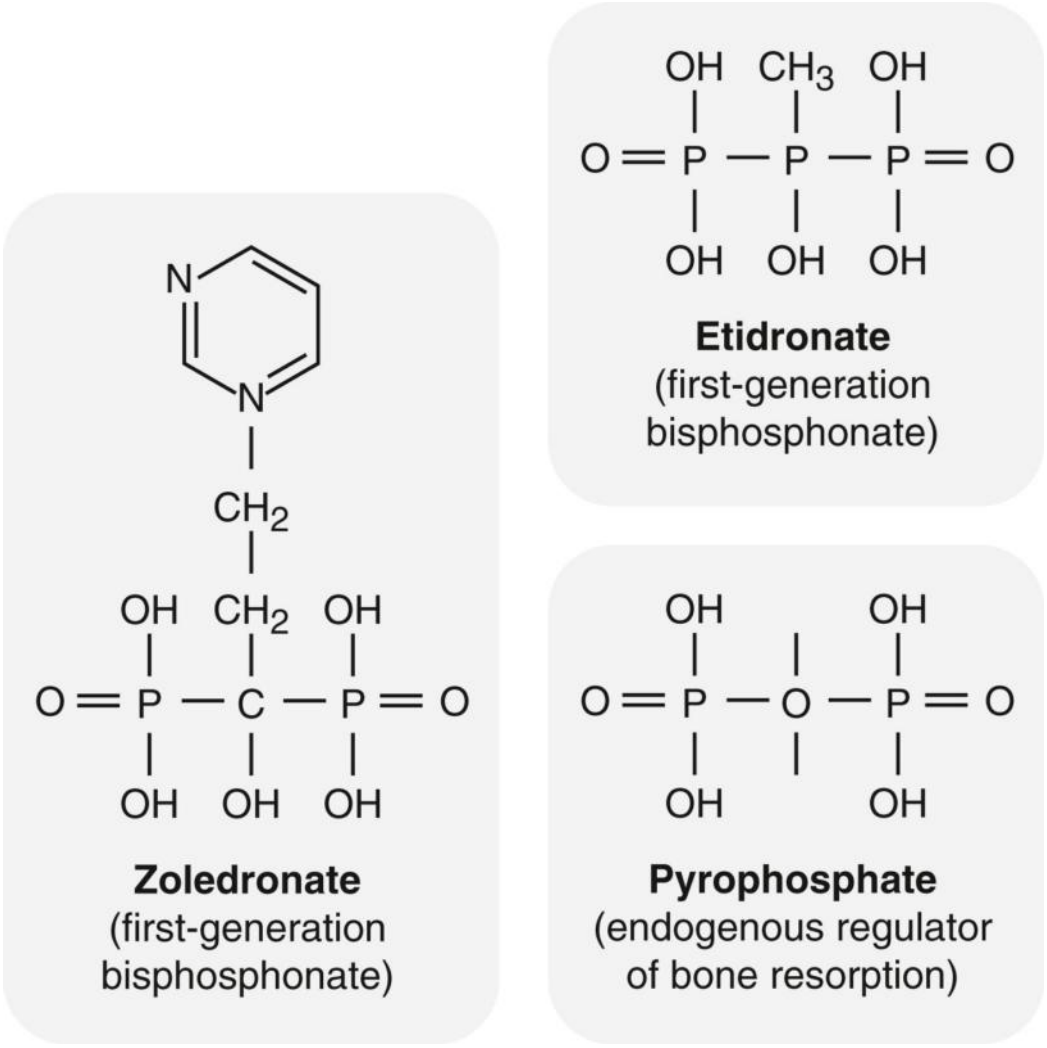

FIG. 36.5 Structure of bisphosphonates.Replacement of the oxygen atom in pyrophosphate renders the compounds enzyme-resistant. Addition of an N-containing side chain alters the mechanism of action (see text) and greatly increases potency.

Pharmacokinetic aspects

Bisphosphonates given orally are taken on an empty stomach with plenty of water in a sitting or standing position at least 30 min before breakfast because of their propensity to cause severe oesophageal problems. Pamidronate, and zoledronate are administered intravenously. They are poorly absorbed from the gut. About 50% of absorbed drug accumulates at sites of bone mineralisation, where it remains adsorbed onto hydroxyapatite crystals, potentially for months or years, until the bone is resorbed. The free drug is excreted unchanged by the kidney.

Absorption is impaired by food, particularly milk, so orally administered drugs must be taken on an empty stomach.

Unwanted effects include gastrointestinal (GI) disturbances including peptic ulcers and oesophagitis (sometimes with erosions or stricture formation). Bone pain occurs occasionally. Atypical femoral fractures are described during long-term treatment, especially of osteoporosis, and the need for continued use should be re-evaluated periodically (e.g. after 5 years). Given intravenously, some bisphosphonates (in particular zoledronate) can lead to osteonecrosis (literally 'death of bone') of the jaw, especially in patients with malignant disease; a dental check is needed before treatment, followed by any indicated remedial work before initiating treatment. After zoledronate infusion supplemental calcium and vitamin D are administered for at least 10 days.

Clinical use

Alendronate, ibandronate and risedronate are given orally for prophylaxis and treatment of osteoporosis. Etidronate is an

alternative. Clodronate is used in patients with malignant disease involving bone and pamidronate is given by intravenous infusion to treat hypercalcaemia of malignancy or to treat Paget's disease. Ibandronate can also be given intravenously every 3–4 weeks in patients with breast cancer metastatic to bone, or every 3 months to treat postmenopausal osteoporosis. Zoledronate, which is given as an intravenous infusion, is used for advanced malignancy involving bone, for Paget's disease and for selected cases of osteoporosis (postmenopausal or in men) when it is administered once a year or even less frequently (see next clinical box).

Bisphosphonates

- Orally active, stable analogues of pyrophosphate, which are incorporated into remodelling bone and remain there for months to years.
- Released when osteoclast-mediated bone resorption occurs, exposing osteoclasts to their effects.
- First-generation compounds (e.g. **etidronate**) act by promoting apoptosis of osteoclasts.
- Second-generation compounds (e.g. **risedronate**) with N-containing side chains are much more potent, and prevent osteoclast action by inhibiting prenylation reactions required for membrane anchoring of functional surface proteins.
- Used long term for prevention and treatment of osteoporosis, and for symptomatic Paget's disease.
- Main unwanted effect is gastrointestinal (especially oesophageal) disturbance; a rare but serious adverse effect of

the most potent drugs (notably **zoledronate**) is osteonecrosis of the jaw.

Clinical uses of bisphosphonates

- Osteoporosis:
  - 'primary' prevention of fractures in high-risk individuals (e.g. with established osteoporosis, several risk factors for osteoporosis, chronic treatment with systemic glucocorticoids);
  - 'secondary' prevention after an osteoporotic fracture;
  - **alendronate** by mouth, given daily or once weekly in addition to calcium with vitamin D_3. **Risedronate** or **etidronate** are alternatives; **zoledronate** is given once a year by intravenous infusion; it is the most potent bisphosphonate and more likely to cause osteonecrosis of the jaw – dental check and remedial dental work are prerequisites of treatment.
- *Malignant disease* involving bone (e.g. metastatic breast cancer, multiple myeloma):
  - to reduce bone damage, pain and hypercalcaemia (e.g. **clodronate**, **ibandronate**, **zoledronate**).
- *Paget's disease* of bone (e.g. **risedronate**, **pamidronate, zoledronate**) administered intermittently as required in patients who are symptomatic.

Oestrogens and Related Compounds

The decline in endogenous oestrogen is a major factor in postmenopausal osteoporosis, and there is evidence that giving oestrogen as hormone replacement therapy (HRT; see **Ch. 35**) can ameliorate this. But HRT has actions on many systems, and newer agents (e.g. **raloxifene**; see **Ch. 35**) have been developed that exhibit agonist actions on some tissues and antagonist actions on others. These are termed ***s*** *elective o* ***e*** *strogen* ***r*** *eceptor* ***m*** *odulators* (SERMs).

Raloxifene

Raloxifene is a SERM that stimulates osteoblasts and inhibits osteoclasts. It also has agonist actions on the cardiovascular system, and antagonist activity on mammary tissue and the uterus.

It is well absorbed in the GI tract and undergoes extensive first-pass metabolism in the liver, yielding the glucuronide, which undergoes enterohepatic recycling. Overall bioavailability is only about 2%. Despite the low plasma concentration, raloxifene is concentrated in tissues, and is converted to an active metabolite in liver, lungs, bone, spleen, uterus and kidney. Its half-life averages 32 h. It is excreted mainly in the faeces.

Unwanted effects include hot flushes, leg cramps, flu-like symptoms and peripheral oedema. Less common are thrombophlebitis and thromboembolism. Other uncommon adverse effects are thrombocytopenia, GI disturbances, rashes, raised blood pressure and arterial thromboembolism. Raloxifene is not recommended for primary prevention of osteoporotic fractures but

is one alternative to a bisphosphonate for secondary prevention in postmenopausal women who cannot tolerate a bisphosphonate.

Parathyroid Hormone and Analogues

PTH and fragments of PTH given in small doses paradoxically *stimulate* osteoblast activity and *enhance* bone formation, and are used to treat osteoporosis, especially in those who are receiving systemic corticosteroids. The main compound currently used is **teriparatide** – the peptide fragment (1–34) of recombinant PTH. A closely related molecule, abaloparatide (consisting of the 34 amino acids in human PTHrP), is licensed for postmenopausal women with osteoporosis who are at high risk of fracture. It is thought that the greater affinity of abaloparatide for the RG conformation of the PTH-1 receptor can result in increased bone formation without provoking bone resorption.

Teriparatide reverses osteoporosis by stimulating new bone formation. It increases bone mass, structural integrity and bone strength by increasing the number of osteoblasts and by activating those osteoblasts already in bone. It also reduces osteoblast apoptosis.

Teriparatide is given subcutaneously once daily. It is well tolerated, and serious adverse effects are few. Nausea, dizziness, headache and arthralgias can occur. Mild hypercalcaemia, transient orthostatic hypotension and leg cramps have been reported. Owing to concerns regarding long-term efficacy and safety, the maximal treatment duration of teriparatide should be limited to 24 months and must not be repeated.

Vitamin D Preparations

Vitamin D preparations are used in the treatment of vitamin D deficiencies, bone problems associated with renal failure ('renal osteodystrophy') and hypoparathyroidism – acute hypoparathyroidism is treated with intravenous calcium and injectable vitamin D preparations.

The main vitamin D preparation used clinically is **ergocalciferol**. Other preparations are **alfacalcidol** and **calcitriol**. All can be given orally and are well absorbed unless there is obstructive liver disease (vitamin D is fat soluble, and bile salts are necessary for absorption). **Paricalcitol,** a synthetic vitamin D analogue with less potential to cause hypercalcaemia, is used to treat and prevent the secondary hyperparathyroidism that occurs in patients with chronic renal failure because of associated hyperphosphataemia.

Given orally, vitamin D is bound to a specific α-globulin in the blood and exogenous vitamin D persists in fat for many months after dosing. The main route of elimination is in the faeces.

The clinical uses of vitamin D preparations are given in the box.

Excessive intake of vitamin D causes hypercalcaemia. If hypercalcaemia persists, especially in the presence of elevated phosphate concentrations, calcium salts are deposited in the kidney and urine, causing renal failure and kidney stones.

Clinical uses of vitamin D

- Deficiency states: prevention and treatment of *rickets*, *osteomalacia* and vitamin D deficiency owing to *malabsorption* and *liver disease* (**ergocalciferol**).

- Hypocalcaemia caused by *hypoparathyroidism* (**ergocalciferol**).
- *Osteodystrophy* of *chronic renal failure*, which is the consequence of decreased calcitriol generation (**calcitriol** or **alfacalcidol**).

Plasma Ca^{2+} levels should be monitored during therapy with vitamin D.

Biopharmaceuticals

Denosumab is a recombinant human monoclonal antibody that inhibits RANKL, the primary signal for bone resorption (see earlier), and is particularly useful when bisphosphonates are not appropriate. It is licensed for use in men and postmenopausal women with osteoporosis who are at high risk of fracture. Denosumab can be used for prevention of skeleton-related adverse events in patients with bone metastases from solid tumours, as well as to treat bone loss in patients who are receiving hormone ablation therapy for breast or prostate cancer. Calcium and vitamin D deficiencies need to be corrected and necessary dental work needs to be undertaken before treatment with denosumab to reduce the risk of osteonecrosis of the jaw (as with potent bisphosphonates, see clinical box). It is administered as subcutaneous injections (60 mg) every 6 months for women with postmenopausal osteoporosis or men with prostate cancer at increased risk of osteoporosis because of hormone ablation, or more frequently (monthly) in patients with bone metastases. Adverse effects include altered bowel habit (diarrhoea or constipation), dyspnoea, hypocalcaemia,

hypophosphataemia, infection (including respiratory, ear, cellulitis) or rash as well as (rarely) osteonecrosis of the jaw.

Romosozumab is a monoclonal antibody that binds to and inhibits sclerostin. Clinical data show that romosozumab enhances bone formation through greater recruitment of osteoprogenitor cells and increased bone matrix production by osteoblasts. There is also reduced bone resorption through inhibition of osteoclasts (**McClung, 2017**). The dual effect of romosozumab (**Fig 36.2**) is evidenced by demonstrable increases in procollagen Type I N terminal (a marker of bone formation) accompanied by reduction in type-1 collagen C-telopeptide (a marker of bone resorption).

Romosozumab is indicated for severe osteoporosis in postmenopausal women at high risk of fracture. It is given by subcutaneous injection once a month for a maximum treatment period of a year, following which patients should be offered antiresorptive therapy. There are still ongoing uncertainties surrounding possible cardiovascular risk with romosozumab, and it is currently contraindicated in women with a history of myocardial infarction or stroke.

Calcitonin

The main preparation available for clinical use (see the clinical box) is **salcatonin** (synthetic salmon calcitonin). Synthetic human calcitonin is also available. Calcitonin is given by subcutaneous or intramuscular injection, and there may be a local inflammatory action at the injection site. It can also be given intranasally, which is more convenient but less effective. Its plasma half-life is 4–12 min, but its action lasts for several hours.

Unwanted effects include nausea and vomiting. Facial flushing may occur, as may a tingling sensation in the hands and an unpleasant taste in the mouth.

Clinical uses of calcitonin/salcatonin

These agents are now less used.

- *Hypercalcaemia* (e.g. associated with neoplasia).
- *Paget's disease* of bone (to relieve pain and reduce neurological complications) – but it is much less convenient than an injected high-potency bisphosphonate.
- Postmenopausal and corticosteroid-induced *osteoporosis* (with other agents). Calcitonin can also be used to relieve severe back pain in patients with acute osteoporotic vertebral fractures.

Calcium Salts

Calcium salts used therapeutically include **calcium gluconate** and **calcium lactate**, given orally. Calcium gluconate is also used for intravenous injection in emergency treatment of hyperkalaemia (see **Ch. 29**); intramuscular injection is not used because it causes local necrosis.

Calcium carbonate, an antacid and phosphate binder (see **Ch. 29**), is usually very poorly absorbed from the gut (an advantage since an effect within the stomach or intestine is the desired outcome for a drug intended to buffer gastric acid and to reduce ileal phosphate absorption), but there is concern that low-level

systemic absorption has the potential to cause arterial calcification in patients with renal failure, especially if complicated by hyperphosphataemia (the product of calcium and phosphate ion concentrations is sometimes used clinically to estimate the risk of tissue deposition of insoluble calcium phosphate).

Unwanted effects: oral calcium salts can cause GI disturbance. Intravenous administration in emergency treatment of hyperkalaemia requires care, especially in patients receiving cardiac glycosides, the toxicity of which is influenced by extracellular calcium ion concentration (see **Ch. 20**).

The clinical uses of calcium salts are given in the clinical box.

Clinical uses of calcium salts

- Dietary deficiency.
- Hypocalcaemia caused by *hypoparathyroidism* or *malabsorption* (intravenous for acute tetany).
- Calcium carbonate is an antacid; it is poorly absorbed and binds phosphate in the gut. It is used to treat *hyperphosphataemia* (see **Ch. 29**).
- Prevention and treatment of *osteoporosis* (often with oestrogen or SERMs in women, bisphosphonate, vitamin D).
- Cardiac dysrhythmias caused by severe *hyperkalaemia* (intravenous; see **Ch. 29**).

Calcimimetic Compounds

Calcimimetics enhance the sensitivity of the parathyroid Ca^{2+}-sensing receptor to the concentration of blood Ca^{2+}, with a consequent decrease in secretion of PTH and reduction in serum Ca^{2+} concentration. There are two types of calcimimetics:

1. Type I are agonists and include various inorganic and organic cations; Sr^{2+} is an example.
2. Type II are allosteric activators (see **Ch. 3**) that activate the receptor indirectly. Examples include **cinacalcet**, which is an oral preparation used for the treatment of hyperparathyroidism (see **Fig. 36.3**), and **etelcalcetide,** an injectable formulation that has a longer elimination half-life than cinacalcet (**Hamano et al., 2017**). Etelcalcetide is used to treat secondary hyperparathyroidism in patients with chronic renal failure undergoing haemodialysis. It is administered intravenously at the end of dialysis.

QUESTIONS

QUESTION 36.1

Bone remodelling occurs through a fine balance between the actions of osteoblasts and osteoclasts, regulated by a range of cytokines and hormones.

Which of the following statements about bone remodelling is correct?

OPTIONS:

A. Increased secretion of osteoprotegerin (OPG) by osteoblasts promotes osteoclast differentiation.

B. Osteoblast maturation and recruitment are driven by parathyroid hormone (PTH).

C. Insulin-like growth factor (IGF) stimulates bone resorption by osteoclasts.

D. Nuclear factor (NF)κB stimulates osteoclast activation.

E. Transforming growth factor (TGF)-β is secreted by osteocytes to break down the osteoid, to aid remodelling.

QUESTION 36.2

More than 99% of the calcium in the body is in the skeleton; however, calcium also has numerous roles in physiological functioning, so the concentration of ionised Ca^{2+} in the extracellular fluid and the plasma needs to be controlled with great precision.

Which of the following would have the most effect in decreasing circulating plasma calcium levels?

OPTIONS:

A. Increased secretion of PTH

B. Increased secretion of calcitonin

C. Increased synthesis of calcitriol

D. A decrease in dietary vitamin D_2

E. Decreasing levels of oestrogen during the menopause

QUESTION 36.3

Osteoporosis is a bone disorder associated with a loss of bone mass and distortion of the microarchitecture.

Which of the following would potentially to lead to osteoporosis?

OPTIONS:

A. An increase in the synthesis/secretion of osteoid

B. A decrease in the secretion of sclerostin

C. Increased levels of TGF-β

D. Increased levels of RANK ligand (RANKL)

E. Raised levels of OPG

ANSWERS

ANSWER 36.1

RATIONALE:

A. Increased secretion of OPG by osteoblasts competes with receptor activator of NFκB and hence decreases the differentiation and activation of osteoclasts.

B. PTH binding to receptors on osteoblasts causes activation of osteoclasts to drive bone resorption.

C. IGF is involved in the stimulation of osteoblasts to secrete new osteoid.

D.

E. TGF-β is secreted by osteoblasts and is embedded in the osteoid. TGF-β released from the osteoid by osteoclasts stimulates osteoblast function.

CORRECT ANSWER WITH EXPLANATION:

D. NFκB stimulates osteoclast activation.

NFκB, a transcription factor activated by RANK-L binding to RANK on the surface of osteoclasts, drives osteoclast differentiation and activation.

ANSWER 36.2

RATIONALE:

A. PTH enhances Ca^{2+} reabsorption in the renal tubules.

B.

C. Calcitriol enhances calcium absorption in the intestine and also enhances Ca^{2+} reabsorption in the renal tubules.

D. The main role of Vitamin D is the maintenance of plasma Ca^{2+} by increasing Ca^{2+} absorption in the intestine, mobilising Ca^{2+} from bone and decreasing its renal excretion.

E. Oestrogen opposes the bone-resorbing, Ca^{2+}-mobilising action of PTH.

CORRECT ANSWER WITH EXPLANATION:

B. Increased secretion of calcitonin

The main action of calcitonin is on bone; it inhibits bone resorption by binding to an inhibitory receptor on osteoclasts. In the kidney, it decreases the reabsorption of Ca^{2+} and phosphate in the

proximal tubules. Its overall effect is to decrease the plasma Ca^{2+} concentration.

ANSWER 36.3

RATIONALE:

A. Osteoblasts secrete important components of the extracellular matrix of bone, which is known as osteoid.

B. Sclerostin is a glycoprotein that binds to receptors on osteoblasts to suppress bone formation.

C. TGF-β, embedded in the osteoid, recruits and activates successive teams of osteoblasts.

D.

E. OPG, synthesised by osteoblasts, can function as a decoy receptor that binds to RANKL thus inhibiting RANK-mediated activation of osteoclasts.

CORRECT ANSWER WITH EXPLANATION:

D. Increased levels of RANKL

The ratio of RANKL (bone resorbing) to OPG (bone forming) is critical in the formation and activity of osteoclasts and the RANK, RANKL, OPG system is fundamental to bone remodelling.

---

[1] RANKL is also sometimes confusingly termed *OPG ligand*.

[2] The type 1 receptor is the main one; the PTH type 2 receptor is also a transmembrane-spanning G protein–coupled receptor expressed in a number of tissues including central nervous system, pancreas, testis and placenta. Its functions are less well understood.

[3] Ubiquitin (Ch. 6) is a small regulatory protein present in almost all cells of the body (‘ubiquitous’). It directs proteins to

compartments in the cell, including the proteasome which destroys and recycles proteins. Ubiquitin-binding proteins interact with ubiquitinated targets and regulate diverse biological processes, including endocytosis, signal transduction, transcription and DNA repair.

37: Chemical transmission and drug action in the central nervous system

OVERVIEW

Brain function is the single most important aspect of physiology that defines human beings. Disorders of brain function, whether primary or secondary to malfunction of other systems, are a major concern of human society, and a field in which pharmacological intervention plays a key role. In this chapter we introduce some basic principles of neuropharmacology and, importantly, recognise that much of how the brain works is still not well understood and incredibly complex. This can make understanding how drugs interact with the central nervous system (CNS) challenging, particularly when trying to relate molecular mechanisms to functional effects.

Introduction

There are two reasons why understanding the action of drugs on the central nervous system (CNS) presents a particularly challenging problem. The first is that centrally acting drugs are of special significance to humankind. Not only are they of major therapeutic importance, [1] but they are also the drugs that humans most

commonly administer to themselves for non-medical reasons (e.g. alcohol, tea and coffee, nicotine, cannabis, MDMA (ecstasy), opioids, cocaine, amphetamines and so on). The second reason is that the CNS is functionally far more complex than any other system in the body (also uniquely protected by a blood–brain barrier), and this makes the understanding of drug effects very much more difficult. The relationship between the behaviour of individual cells and that of the organ, as a whole, is far less direct in the brain than in other organs. Currently, the links between a drug's action at the biochemical and cellular level and its effects on brain function remain largely mysterious. Functional brain imaging is beginning to reveal relationships between brain activity in specific regions and mental function, and this tool is being used increasingly to probe drug effects. Despite sustained progress in understanding the cellular and biochemical effects produced by centrally acting drugs, and the increasing use of brain imaging to study brain function and drug effects, the gulf between our understanding of drug action at the cellular level and at the functional and behavioural level remains, for the most part, very wide.

Unlike other examples in medicine, the causes of most diseases which affect the brain remain poorly understood and the drugs used in their treatment act to modify the symptoms rather than targeting a known underlying cause. An exception to this is the relationship between dopaminergic pathways in the extrapyramidal system and the effects of drugs in alleviating or exacerbating the motor symptoms associated with Parkinson's disease (see **Ch. 40**).

Many CNS drugs are used to treat psychiatric disorders and the original treatments on which all current medications are based were

first discovered without any knowledge of the underlying causes of the symptoms. With advances in pharmacology, we now have a good understanding of the molecular mechanisms through which these drugs exert their effects and some insights into how these relate to their clinical effects versus side effects. This knowledge has guided the development of drugs with better tolerability but the limited knowledge of the underlying pathophysiology has prevented a more rational approach to designing drugs which can prevent or cure the disorder. Studies are starting to reveal how complex genetic, environmental and psychological factors contribute to psychiatric disorders, and disease-related cognitive deficits may further contribute to the behavioural symptoms. In many CNS disorders, cognitive and emotional symptoms can develop alongside the primary illness leading to comorbid psychiatric symptoms. For example in chronic pain the affective state (mood) of the sufferer may be changed and exacerbate the painful condition. Much effort is going into pinning down the biological basis of psychiatric disorders – a necessary step to improve the design of better drugs for clinical use – but the task is daunting and progress is slow.

In this chapter we outline the general principles governing the action of drugs on the CNS. Most neuroactive drugs work by interfering with the chemical signals that underlie brain function, and the next two chapters discuss the major CNS transmitter systems and the ways in which drugs affect them.

Background information will be found in neurobiology and neuropharmacology textbooks such as **Kandel et al. (2021)**, **Nestler et al. (2020)** and **Stahl (2021)**.

Chemical Signalling in the Nervous System

Brain activity is essentially mediated by electrical signals which are modulated and refined by chemical signalling to control the main functions across timescales ranging from milliseconds (e.g. returning a 100 mph tennis serve) to years (e.g. remembering how to ride a bicycle). [2] The chemical signalling mechanisms cover a correspondingly wide dynamic range, as summarised, in a very general way, in **Fig. 37.1**. Currently, we understand much about drug effects on events at the fast end of the spectrum – synaptic transmission and neuromodulation – but much less about long-term adaptive processes including the interactions between chemical signalling and psychological processes. It is quite evident that the latter are of great importance for neurological and psychiatric disorders and are susceptible to drug treatment.

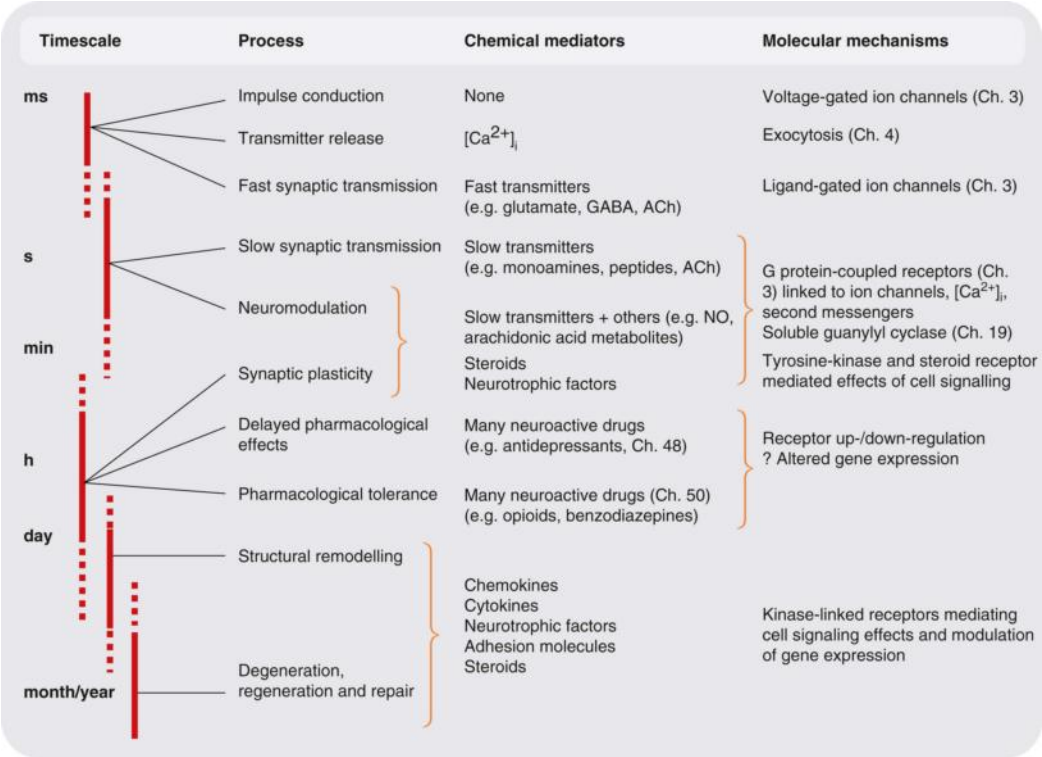

FIG. 37.1 Chemical signalling in the nervous system.Knowledge of the mediators and mechanisms becomes sparser as we move from the rapid events of synaptic transmission to the slower ones involving remodelling and alterations of gene expression. *ACh,* Acetylcholine; *CNS,* central nervous system; *NO,* nitric oxide.

The original concept of neurotransmission envisaged a substance released by one neuron and acting rapidly, briefly and at short range on the membrane of an adjacent (postsynaptic) neuron, causing excitation or inhibition. The principles outlined in **Chapter 13** apply to the central as well as the peripheral nervous system. It is now clear that chemical mediators within the brain also produce slow and long-lasting effects, that they can act rather diffusely, at a

considerable distance from their site of release (e.g. GABA acting at extrasynaptic $GABA_A$ receptors (see **Ch. 38**) and monoamine transmitters (see **Ch. 39**) and that they can also produce other diverse effects, for example on transmitter synthesis, on the expression of receptors and on neuronal morphology, in addition to affecting the ionic conductance of the postsynaptic cell membrane. The term *neuromodulator* is often used to denote a mediator, the actions of which do not conform to the original neurotransmitter concept. The term is not clearly defined, and it covers not only the monoamine transmitters and diffusely acting neuropeptide mediators, but also mediators such as nitric oxide (NO; see **Ch. 19**) and arachidonic acid metabolites (see **Ch. 17**), which are not stored and released like conventional neurotransmitters, and may come from non-neuronal cells, particularly glia, as well as neurons. In general, *neuromodulation* relates to signalling which alters the outcome of the primary signal. This can include inducing changes in intrinsic firing activity, modulation of voltage-dependent currents, regulation of presynaptic transmitter release and longer-term adaptations including synaptic plasticity. **Fig 37.2** shows a confocal microscopy image of a noradrenergic neuron illustrating the varicosities along the axon where the neuromodulator is released. Longer-term *neurotrophic* effects are involved in regulating the growth and morphology of neurons, as well as their functional properties. **Table 37.1** summarises the types of chemical mediator that operate in the CNS.

Glial cells are the main non-neuronal cells in the CNS and outnumber neurons by 10 to 1. Once thought of mainly as housekeeping cells, whose function was merely to look after the

fastidious neurons, glial cells, particularly astrocytes, are increasingly seen as ‘inexcitable neurons’ with major communications roles (see **Matsas and Tsacopolous, 2013**; **Vasile et al., 2017**). These cells express a range of receptors and transporters, and also release a wide variety of mediators, including glutamate, D-serine, ATP, lipid mediators and growth factors. They respond to chemical signals from neurons, and also from neighbouring astrocytes and microglial cells (the CNS equivalent of macrophages, which function much like inflammatory cells in peripheral tissues). Electrical coupling between astrocytes means they can respond in concert in a particular brain region, thus controlling the chemical environment in which the neurons operate. Although they do not conduct action potentials, and do not send signals to other parts of the body, astrocytes are otherwise very similar to neurons and play a crucial communication role within the brain. Astrocytes are now thought to play an important role in synaptic plasticity and express dynamic calcium signalling events. However, despite an increasing fundamental knowledge about the role of glial cells, the development of drugs which target these mechanisms still requires more research.

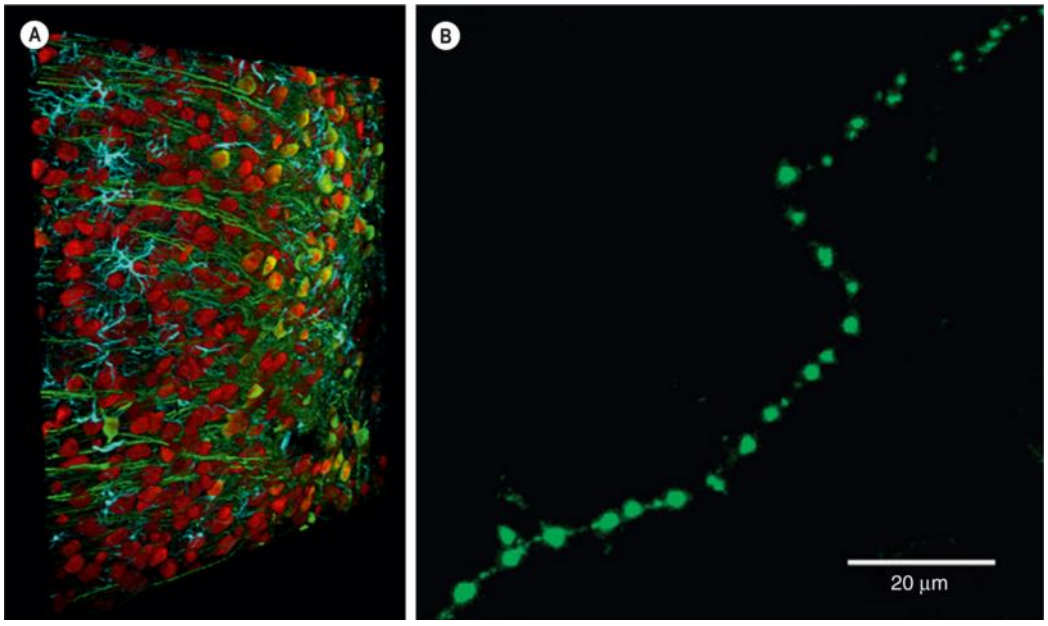

FIG. 37.2 Cellular imaging methods using fluorescence conjugated antibodies provide a means to visualise specific neuronal populations based on their expression of unique proteins.Here are selected example illustrations. (A) Confocal image of the rat prefrontal cortex illustrating glutamatergic *(green/yellow)*, GABAergic *(red)* and glia *(blue)*. (B) A single noradrenergic axon with varicosities, the sites where noradrenaline release is expected to occur. Image A, kindly provided by Dr Abigail Benn and B, by Dr Anja Teschemacher.

Table 37.1

[a] Most central nervous system pharmacology has been centred on small-molecule mediators and, less commonly, neuropeptides. Other mediator types are now being targeted for therapeutic purposes.

Chemical transmission in the central nervous system

- The basic processes of synaptic transmission in the CNS are essentially similar to those operating in the periphery (see **Ch. 13**).
- Glial cells, particularly astrocytes, participate actively in chemical signalling, functioning essentially as 'inexcitable neurons'.
- The terms *neurotransmitter*, *neuromodulator* and *neurotrophic factor* refer to chemical mediators that operate over different timescales. In general:
  - *neurotransmitters* are released by presynaptic terminals and produce rapid excitatory or inhibitory responses in postsynaptic neurons;
  - fast neurotransmission (e.g. glutamate, GABA) operates through ligand-gated ion channels
  - slow neurotransmission (e.g. dopamine, neuropeptides, prostanoids) operate mainly through G protein–coupled receptors including pre-synaptic inhibition;

  - *neuromodulators* are released by neurons and by astrocytes, and produce slower pre- or postsynaptic responses mediated through G protein-coupled receptors;
  - *neurotrophic factors* are released by neuronal and non-neuronal cells and act on tyrosine kinase–linked receptors that regulate gene expression and control neuronal growth and phenotypic characteristics.
- The same agent (e.g. glutamate, 5-hydroxytryptamine, acetylcholine) may act through both ligand-gated channels and G protein–coupled receptors, and mediate fast and slow synaptic responses.
- Many chemical mediators, including glutamate, nitric oxide and arachidonic acid metabolites, are produced by glia as well as neurons.
- Many mediators (e.g. cytokines, chemokines, growth factors and steroids) control long-term changes in the brain (e.g. synaptic plasticity and structural remodelling) by inducing changes in gene transcription and/or modulating neurotrophic factors.

Targets for Drug Action

To recapitulate what was discussed in **Chapters 2** and **3**, neuroactive drugs act primarily on one of four types of target proteins, namely ion channels, receptors, enzymes and transport proteins. Of the four main receptor families – ionotropic receptors, G protein–coupled receptors, kinase-linked receptors and nuclear receptors – current neuroactive drugs target mainly the first two.

Since the first psychiatric drugs were discovered in the 1950s, knowledge about these targets in the CNS has accumulated rapidly, particularly as follows:

- As well as 40 or more small-molecule and peptide mediators, the importance of other 'non-classical' mediators – NO, eicosanoids, growth factors, etc. – has become apparent.
- Considerable molecular diversity of known receptor molecules and ion channels (see **Ch. 3**) has been revealed.
- Receptors and channels are often expressed in several subtypes, and many possess sites for allosteric modulation and exist in multiple heteromeric complexes, all of which add to the diversity of potential drug targets. In most cases, we are only beginning to discover what this diversity means at a functional level. The molecular diversity of such targets raises the possibility of developing drugs with improved selectivity of action, e.g. interacting with one kind of $GABA_A$ receptor without affecting others (see **Ch. 44**). The potential of these new approaches in terms of improved drugs for neurological and psychiatric diseases is large but as yet unrealised.

Our knowledge of the neurobiology of the CNS and pathophysiology of disorders such as epilepsy, neurodegenerative and psychiatric disorders is advancing and hopefully this will result in new strategies for treating these disabling conditions. Some hints of the progress which can be achieved when the underlying causes are understood can be seen with the development of the gene therapy **onasemnogene abeparvovec,** which provides a new

copy of the gene that makes the human SMN protein (**Ch. 40**). Unfortunately though, most research is revealing just how complicated diseases of the CNS are and so there are still many challenges for the field.

Drug Action in the Central Nervous System

As already emphasised, the molecular and cellular mechanisms underlying drug action in the CNS and in the periphery have much in common. Translating from these molecular mechanisms to functional outcomes is however much more challenging for the CNS. One difficulty is the complexity of neuronal connections in the brain and the fact that much of how these neuronal networks function is not understood. In contrast to the periphery, within any region of the brain there are many different cell types and chemical mediators and the output from any single neuron arises from the integration of all these signals. **Fig 37.2** illustrates this complexity in a confocal image taken from the prefrontal cortex of the rat brain where three major cell types have been visualised using specific antibodies.

The relationship between a drug's molecular effects and the functional consequences of its agonism or antagonism in the brain often causes confusion. This can be because it is assumed that the signalling mechanism associated with that receptor translates into the functional outcome, e.g. agonism of a Gi/o coupled GPCR will inhibit brain function. However, there is an important step needed when relating molecular mechanisms to effects on neuronal activity and that relates to where the receptor is located. **Fig 37.3** provides a

schematic diagram illustrating a simple synapse with glutamatergic, GABAergic and neuromodulatory inputs. Depending on where a drug acts within this local circuit will have a major influence on the final output. For example:

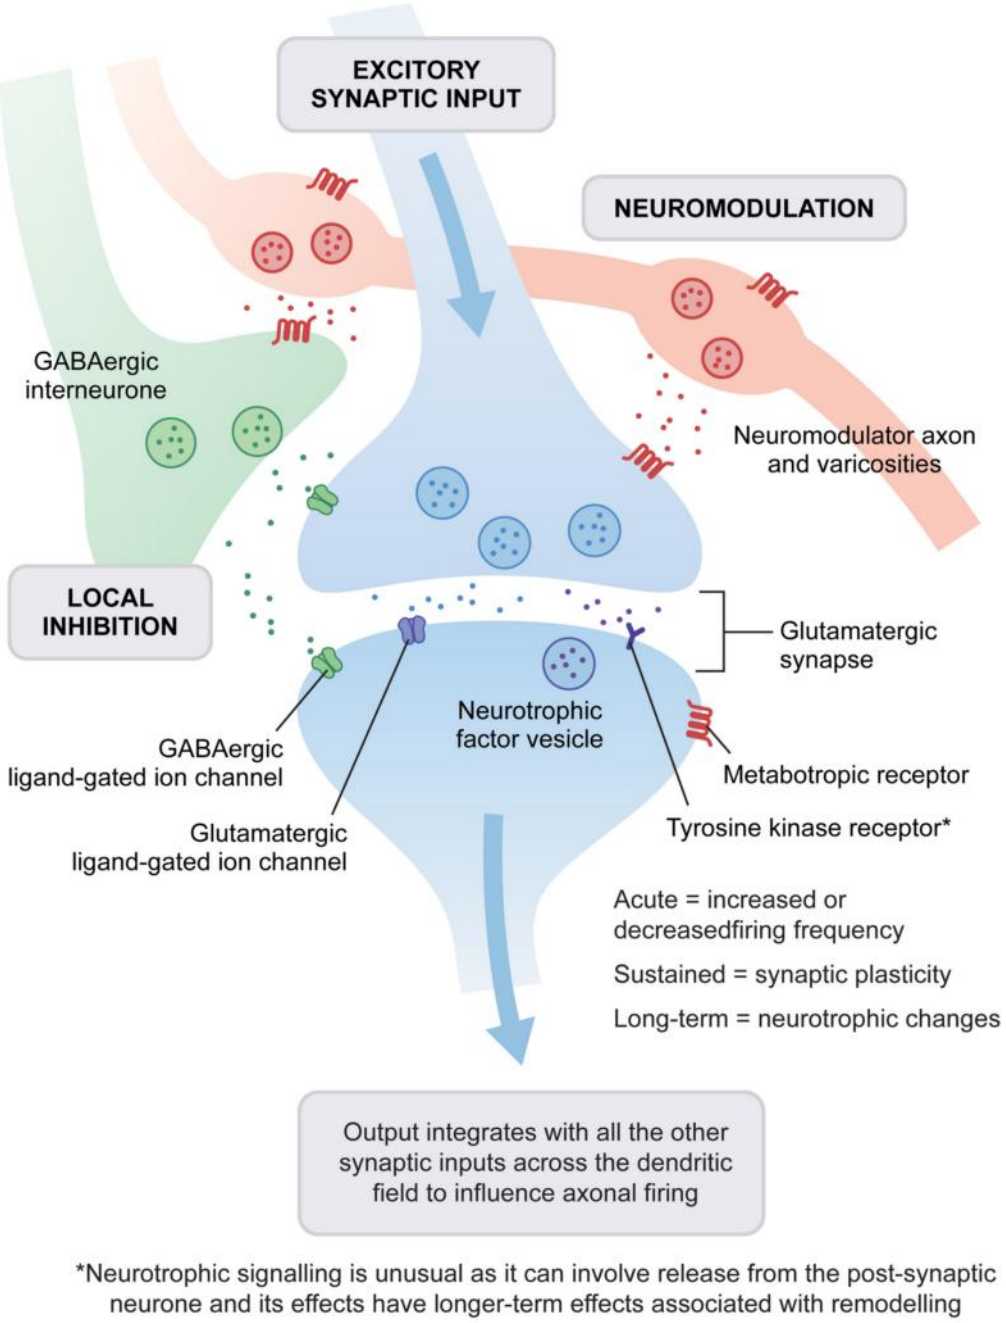

FIG 37.3 Simplified diagram of the chemical signalling at a single synapse.The amino acid transmitters together generate a balance in excitation and inhibition and this is further refined through neuromodulation. A single

neuron will receive inputs across its dendritic field from both glutamatergic and GABAergic neurons as well as different neuromodulators. This figure illustrates just one of those dendritic inputs. For ease of understanding, only a single neuromodulator input is illustrated but a single neuron receives many chemical signals as well as expressing a multitude of receptors. Understanding how drugs interact within these micro- as well as macro-circuits is complicated and not fully understood.

- An inhibitory receptor reduces activity or transmitter release in the neuron. However, if that neuron is a GABAergic interneuron then the functional consequence will be reduced inhibition or disinhibition and an increase in activity from that region.
- An excitatory receptor increases activity or transmitter release in the neuron. However, if that neuron is a GABAergic interneuron then the consequence will be increased inhibition and a decrease in activity from that region.

Different types of interactions between neurons also add to this complexity. **Fig. 37.4** provides a very simplified illustration of a neuronal network involving three neurons. In this diagram we can see different examples of the connections between neurons in the CNS including:

- *Reciprocal connections* where neuron A inputs to neuron B and neuron B also inputs to neuron A. Neuron B can modulate the function of neuron A either directly or indirectly for example via an interneuron, neuron C.
- *Presynaptic modulation of release* where either the same transmitter released by the neuron (via autoreceptors) or transmitter from a different neuron (via heteroreceptors) can alter the amount of transmitter released into the synapse. These can be inhibitory (negative feedback) or excitatory (positive feedback).
- *Multiple inputs* where any single neuron is integrating inputs from multiple chemical signals.
- Even at this grossly oversimplified level, the effects at a system level of blocking or enhancing the release or actions of one or other of the transmitters are difficult to predict and will depend greatly on the relative strength of the excitatory and inhibitory synaptic connections, and neuromodulatory inputs. Added to this complexity is the influence of glial cells, mentioned previously.

The majority of drugs being used to treat CNS disorders are given over prolonged periods of time and this introduces the potential for secondary, adaptive responses set in train by any drug-induced perturbation of the system. Homeostatic responses are activated when neurotransmission is disrupted for example by an increase in transmitter release, or interference with transmitter reuptake, and countered by activation of receptor-mediated feedback mechanisms, adaptive changes such as inhibition of transmitter synthesis, enhanced transporter expression or decreased receptor expression.

These changes, which can involve altered gene expression, generally take time (hours, days or weeks) to develop and are not evident in acute pharmacological experiments.

In the clinical situation, the effects of psychotropic drugs often take weeks to develop, and this has been linked to these adaptive responses rather than the immediate pharmacodynamic effects of the drug. This is well documented for antipsychotic and antidepressant drugs (see Chs **47** and **48**). The development of dependence on opioids, benzodiazepines and psychostimulants is similarly gradual in onset (see **Ch. 50**). Thus one has to take into account not only the primary interaction of the drug with its target but also the longer-term secondary response of the brain to this primary effect; it is often this secondary response, rather than the primary effect, which is thought to lead to clinical benefit. There are also important psychological effects where the drugs change behaviour which in turn impacts on the inputs the brain receives and hence its neurochemistry, connectivity and ultimately brain morphology.

Blood–Brain Barrier

A key factor in CNS pharmacology is the blood–brain barrier (see **Ch. 9**), penetration of which requires molecules to traverse the vascular endothelial cells rather than going between them. Inflammation can disrupt the integrity of the blood–brain barrier, allowing previously impermeable drugs such as **penicillin** to cross. In general, only small non-polar molecules can diffuse passively across cell membranes. Some neuroactive drugs penetrate the blood–brain barrier in this way, but many do so via transporters,

which either facilitate entry into the brain or diminish it by pumping the compound from the endothelial cell interior back into the bloodstream. Drugs that gain entry in this way include **levodopa** (see **Ch. 40**), **valproate** (see **Ch. 46**) and various sedative histamine antagonists (see **Ch. 17**). Active extrusion of drugs from the brain occurs via P-glycoprotein, an ATP-driven drug efflux transporter, and related transporter proteins (see **Ch. 9**). Many antibacterial and anticancer drugs are excluded from the brain while some CNS-acting drugs – including certain opioid, antidepressant, antipsychotic and anti-epileptic drugs – are actively extruded from the brain (see **Linnet and Ejsing, 2008**). Variation in the activity of efflux transporters between individuals is an important consideration (see Chs **9** and **12**).

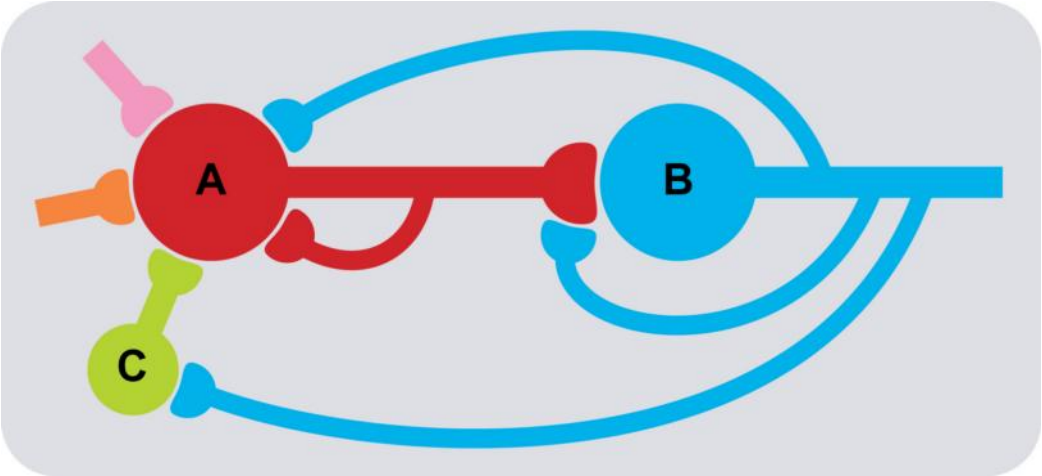

FIG. 37.4 Simplified scheme of neuronal interconnections in the central nervous system.Neurons *A*, *B* and *C* which may release excitatory or inhibitory neurotransmitters. Boutons of neuron *A* input to neuron *B*, but also neuron *A* itself. Neuron *B* also feeds back on neuron *A* either directly or indirectly via interneuron *C*. Even with such a simple network, the effects of drug-induced interference with specific transmitter systems can be difficult to predict.

Drug action in the central nervous system

- The basic types of drug target (ion channels, receptors, enzymes and transporter proteins) described in **Chapter 3** apply in the CNS, as elsewhere.
- Most of these targets occur in several different molecular isoforms, giving rise to subtle differences in function and

pharmacology.

- Many of the currently available neuroactive drugs are relatively non-specific, affecting several different targets at clinically relevant doses.
- The relationship between the pharmacological profile and the therapeutic effect of neuroactive drugs is often unclear. Drugs with different primary targets may be used to treat the same condition whilst the same drug may exhibit efficacy in more than one condition.
- Slowly developing secondary responses to the primary interaction of the drug with its target may be important (e.g. the delay in clinical improvements with conventional antidepressant drugs, and tolerance and dependence with opioids).

The Classification of Psychotropic Drugs

Psychotropic drugs are defined as those that affect mood and behaviour. Because these indices of brain function are difficult to define and measure, there is no consistent basis for classifying psychotropic drugs. Instead, we find a confusing mêlée of terms relating to chemical structure (*benzodiazepines*, *butyrophenones*, etc.), biochemical target (*monoamine oxidase inhibitors*, *serotonin reuptake inhibitors*, etc.), behavioural effect (*hallucinogens*, *psychomotor stimulants*) or clinical use (*antidepressants*, *antipsychotic agents*, *anti-epileptic drugs*, etc.), together with a number of indefinable rogue categories (*atypical antipsychotic drugs*, *nootropic drugs*) thrown in for good measure.

Some drugs defy classification in this scheme, for example **lithium** (see **Ch. 48**), which is used in the treatment of bipolar disorder, and **ketamine** (see **Ch. 42**), which is classed as a dissociative anaesthetic and analgesic (see **Ch. 42**) but produces psychotropic effects rather similar to those produced by phencyclidine (PCP, see **Ch. 49**) and at low doses is a rapid acting antidepressant (see **Ch. 48**).

Table 37.2 provides a general classification of centrally acting drugs. In practice, the use of drugs in psychiatric illness frequently cuts across specific therapeutic categories. For example, antipsychotic drugs can be useful for managing both acute and chronic behavioural disorders, including being used for acute drug-induced psychosis and short-term management of agitation and aggression in dementia patients (see **Ch. 47**). Certain antidepressant drugs are also first-line treatment for most anxiety disorders (see **Ch. 45**) as well as neuropathic pain (see **Ch. 43**), and certain psychostimulants are effective at reducing the symptoms of ADHD (see **Ch. 49**). Here we adhere to the conventional pharmacological categories, but it needs to be emphasised that in clinical use these distinctions are often disregarded. [3] An illustration of the diversity of clinical uses of some exemplar drugs is given in **Table 37.3**.

Table 37.2

DMT, N-Dimethyltryptamine; *MDMA,* 3,4-methylenedioxymethamphetamine; *NMDA, N*-methyl-D-aspartate; *PCP,* phenylcyclohexyl piperidine.

Table 37.3

Examples of some of the different clinical uses for CNS drugs

Drug (class)	Mechanism of action	Clinical uses [a]
Amitriptyline (tricyclic antidepressant)	Serotonin and noradrenaline re-uptake inhibitor	**Major depressive disorder** Generalised anxiety disorder Chronic pain
Pregabalin (gabapentinoid)	α2δ subunit-containing voltage-gated calcium channel inhibitor	**Epilepsy** Generalised anxiety disorder Chronic pain
Carbamazepine (anticonvulsant)	Voltage-gated sodium channel blocker	**Epilepsy** Bipolar disorder Chronic pain

QUESTIONS

QUESTION 37.1

Brain activity is mediated by electrical signals which are modulated and refined by chemical mediators known as

neuromodulators.

The best definition of a neuromodulator is an agent which...

OPTIONS:

A. has a mechanism of action that does not conform to the original neurotransmitter concept.

B. is released from neurones alongside the conventional neurotransmitters.

C. alters the outcome of the primary neuronal signal.

D. can induce changes in intrinsic firing activity.

E. causes longer-term adaptations including synaptic plasticity.

QUESTION 37.2

Glial cells, including astrocytes, are the main non-neuronal cells in the central nervous system (CNS) and outnumber neurons by 10 to 1.

Which of the following is NOT a feature of astrocytes?

OPTIONS:

A. Release of chemical mediators

B. Electrical coupling

C. Synaptic plasticity

D. Action potentials

E. Dynamic calcium signalling events

QUESTION 37.3

Disorders of brain function, whether primary or secondary to malfunction of other systems, are a major concern of human

society, and a field in which pharmacological intervention plays a key role.

The main challenge to the development of drugs to target CNS disorders is…

OPTIONS:

A. A lack of knowledge on the underlying cause of the disorder

B. The lack of knowledge of the molecular mechanisms of the drugs

C. The presence of the blood–brain barrier

D. The diversity of molecular targets

E. The complexity of the brain

QUESTION 37.4

Due to the presence of multiple synergistic and antagonistic neuronal inputs onto a synapse, the functional outcome can be difficult to predict.

Which of the following would lead to an increase in neurone 'A' function?

OPTIONS:

A. Activation of a GABAergic reciprocal neurone 'B'

B. Inhibition of a GABAergic reciprocal neurone 'B'

C. Inhibition of a glutaminergic reciprocal neurone 'B'

D. Activation of an inhibitory presynaptic autoreceptor on neurone 'A'

E. Activation of an inhibitory presynaptic heteroreceptor on neurone 'A'

ANSWERS

ANSWER 37.1

RATIONALE:

A. The term *neuromodulator* is often used to denote a mediator, the actions of which do not conform to the original neurotransmitter concept; however, the term is not clearly defined.

B. Neuromodulators are released by neurons but also by astrocytes.

C.

D. Neuromodulators exert a range of physiological effects which can include but is not restricted to inducing changes in intrinsic firing activity longer-term adaptations including synaptic plasticity.

E. Neuromodulators exert a range of physiological effects which can include but is not restricted to longer-term adaptations including synaptic plasticity.

CORRECT ANSWER WITH EXPLANATION:

C. alters the outcome of the primary neuronal signal.

Neuromodulation relates to signalling with alters the outcome of the primary signal.

ANSWER 37.2

RATIONALE:

A. These cells express a range of receptors and transporters, and also release a wide variety of mediators, including glutamate, D-serine, ATP, lipid mediators and growth factors.

B. Electrical coupling between astrocytes means they can respond in concert in a particular brain region, thus controlling the chemical environment in which the neurons operate.

C. Astrocytes are now thought to play an important role in synaptic plasticity.

D.

E. Astrocytes express dynamic calcium signalling events.

CORRECT ANSWER WITH EXPLANATION:

D. Action potentials

Labelled ‘inexcitable neurons’, they do not conduct action potentials, and do not send signals to other parts of the body; however, they do play a crucial communication role within the brain.

ANSWER 37.3

RATIONALE:

A. Our knowledge of the neurobiology of the CNS and pathophysiology of disorders such as epilepsy, neurodegenerative and psychiatric disorders is advancing and hopefully this will result in new strategies for treating these disabling conditions.

B. The molecular and cellular mechanisms underlying drug action in the CNS and in the periphery have much in common, albeit that translating from these molecular mechanisms to functional outcomes is much more challenging for the CNS.

C. The blood–brain barrier does introduce a further complexity in terms of drug delivery to the CNS but can be partially overcome

with small diffusible drugs or those that can be actively transported.

D. The molecular diversity of such targets raises the possibility of developing drugs with improved selectivity of action.

E.

CORRECT ANSWER WITH EXPLANATION:

E. The complexity of the brain

Most research is revealing just how complicated diseases of the CNS are and so there are still many challenges for the field. The effects at a system level of blocking or enhancing the release or actions of one or other of the transmitters are difficult to predict and will depend greatly on the relative strength of the excitatory and inhibitory synaptic connections, and neuromodulatory inputs. Added to this complexity is the influence of glial cells.

ANSWER 37.4

RATIONALE:

A. Reciprocal connections where neurone A inputs to neurone B and neurone B also inputs to neurone A. Neurone B can modulate the function of neurone A either directly or indirectly. GABA released from neurone ‘B’ would decrease activation and release from neurone ‘A’.

B.

C. Reciprocal connections where neurone A inputs to neurone B and neurone B also inputs to neurone A. Neurone B can modulate the function of neurone A either directly or indirectly. Reduction in glutaminergic transmission from neurone ‘B’ would reduce activation and release from neurone ‘A’.

D. Inhibitory presynaptic modulation of release is where the same transmitter released by neurone ‘A’ acts via autoreceptors to reduce the amount of transmitter released from neurone ‘A’ into the synapse.

E. Inhibitory presynaptic modulation of release is where a transmitter from a different neurone ‘B’ acts via heteroreceptors to reduce the amount of transmitter released from neurone ‘A’ into the synapse.

CORRECT ANSWER WITH EXPLANATION:

B. Inhibition of a GABAergic reciprocal neurone

Reciprocal connections where neurone A inputs to neurone B and neurone B also inputs to neurone A. Neurone B can modulate the function of neurone A either directly or indirectly. A decrease in the inhibitory GABA signal from neurone ‘B’ would increase activation and release from neurone ‘A’.

[1] In England between November 2020 and October 2021, there were nearly 220 million prescriptions, costing £1.46 billion, for CNS drugs as defined by the *British National Formulary section 4*. This amounted to over three prescriptions per person across the whole population.

[2] Memory of drug names and the basic facts of pharmacology seems to come somewhere in the middle of this range (skewed towards the short end).

[3] The Neuroscience based Nomenclature (NbN) is a publication and a digital application of psychiatric medications developed by the European College of Neuropsychopharmacology to classify psychiatric drugs by their pharmacology and mode of action and

may become a more common way of discussing these treatments in the future (https://nbn2r.com/).

38: Amino acid transmitters

OVERVIEW

In this chapter we discuss the major neurotransmitters in the central nervous system (CNS), namely the excitatory transmitter, glutamate and the inhibitory transmitters, γ-aminobutyric acid (GABA) and glycine. These two transmitters work together to control the level of excitability within a brain region – the excitatory/inhibitory balance. Drugs can shift the excitatory/inhibitory balance with effects ranging from loss of consciousness to seizures. It is an area in which scientific interest has been intense in recent years. Unravelling the complexities of amino acid receptors and signalling mechanisms has thrown considerable light on their role in brain function and their likely involvement in CNS disease. Drugs that target specific receptors and transporters have been developed, but translating this knowledge into drugs for therapeutic use is proving challenging. Here, we present the pharmacological principles and include recent references for those seeking more detail.

Excitatory Amino Acids

Excitatory Amino Acids As Cns Transmitters

L-Glutamate is the principal and ubiquitous excitatory transmitter in the CNS.

The realisation of glutamate's importance came slowly (see **Watkins and Jane, 2006**). By the 1950s, work on the peripheral nervous system had highlighted the transmitter roles of acetylcholine and catecholamines and, as the brain also contained these substances, there seemed little reason to look further. The presence of **γ-aminobutyric acid** (GABA) in the brain, and its powerful inhibitory effect on neurons, was discovered in the 1950s, and its transmitter role was postulated. At the same time, work by Curtis's group in Canberra showed that glutamate and various other acidic amino acids produced a strong excitatory effect, but it seemed inconceivable that such workaday metabolites could actually be transmitters. Through the 1960s, GABA and excitatory amino acids (EAAs) were thought, even by their discoverers, to be mere pharmacological curiosities. In the 1970s, the humblest amino acid, glycine, was established as an inhibitory transmitter in the spinal cord, giving the lie to the idea that transmitters had to be exotic molecules, too beautiful for any role but to sink into the arms of a receptor. Once glycine had been accepted, the rest quickly followed. A major advance was the discovery of EAA antagonists, based on the work of Watkins in Bristol, which enabled the physiological role of glutamate to be established unequivocally, and also led to the realisation that EAA receptors are heterogeneous.

To do justice to the wealth of discovery in this field in the past 25 years is beyond the range of this book; for more detail see **Bear et al. (2020)**. Here we concentrate on pharmacological aspects. With regard to novel drug development, many promising new compounds interacting with EAAs commenced development for the treatment of a wide range of neurological and psychiatric disorders

but have failed because of lack of efficacy or adverse effects, and only a few drugs [1] have made it into clinical use. The field has yet to make a major impact on therapeutics. The major problem has been that EAA-mediated neurotransmission is ubiquitous in the brain and so agonist and antagonist drugs exert effects at many sites, giving rise not only to therapeutically beneficial effects but also to other, unwanted, harmful effects.

Metabolism And Release Of Excitatory Amino Acids

Glutamate is widely and fairly uniformly distributed in the CNS, where its concentration is much higher than in other tissues. It has an important metabolic role, the metabolic and neurotransmitter pools being linked by transaminase enzymes that catalyse the interconversion of glutamate and α-ketoglutarate (**Fig. 38.1**). Glutamate in the CNS comes mainly from either glucose, via the Krebs cycle, or glutamine, which is synthesised by glial cells and taken up by the neurons; very little comes from the periphery. The interconnection between the pathways for the synthesis of EAAs and inhibitory amino acids (GABA and glycine), shown in **Fig. 38.1**, makes it difficult to use experimental manipulations of transmitter synthesis to study the functional role of individual amino acids, because disturbance of any one step will affect both excitatory and inhibitory mediators.

Glutamate is stored in synaptic vesicles and released by Ca^{2+}-dependent exocytosis; specific transporter proteins account for its re-uptake by neurons and other cells, and for its accumulation by synaptic vesicles. Released glutamate is taken up into nerve terminals and neighbouring astrocytes (**Fig. 38.1**) by $Na^+/H^+/K^+$-

dependent transporters (cf. monoamine transporters – see Ch. **13**), and transported into synaptic vesicles, by a different transporter driven by the proton gradient across the vesicle membrane. Several EAA transporters have been cloned and characterised in detail (see **Jensen et al., 2015**). Glutamate transport can, under some circumstances (e.g. depolarisation by increased extracellular [K^+]), operate in reverse and constitute a source of glutamate release, a process that may occur under pathological conditions such as brain ischaemia (see **Ch. 40**). Glutamate taken up by astrocytes is converted to glutamine and recycled, via transporters, back to the neurons, which convert the glutamine back to glutamate (see **Fig. 38.1**). Glutamine, which lacks the pharmacological activity of glutamate, thus serves as a pool of inactive transmitter under the regulatory control of the astrocytes, which act as ball boys, returning the ammunition in harmless form in order to rearm the neurons.

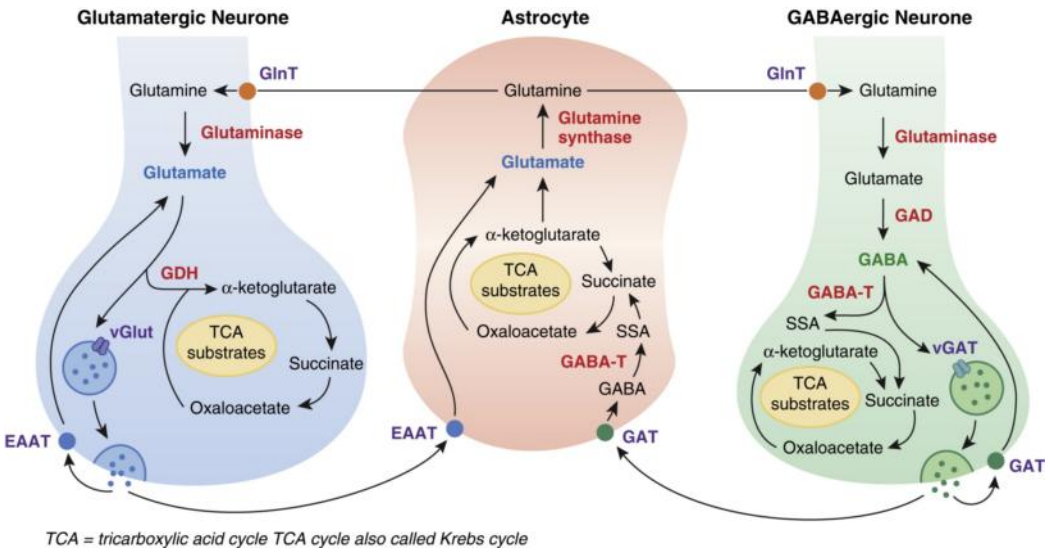

FIG. 38.1 Metabolism of transmitter amino acids in neurones and astrocytes. In this simplified illustration, a glutamatergic neurones, GABAergic interneurone and astrocyte are shown. The synthesis, storage and termination of the actions of the EAA transmitters occur across neuronal and glial cells. Synthesis of glutamate or GABA depends on the presence of key enzymes with the neurotransmitter stored into vesicles via specific vesicular transporters. Following release, neurotransmitter is taken back up into neurons and astrocytes by specific transporters. Note: although not illustrated here, the TCA takes place in the mitochondria. *AAT,* Aspartate aminotransferase; *EAAT,* excitatory amino acid transporter; *GABA,* γ-aminobutyric acid; *GABA-T,* GABA transaminase; *GAD,* glutamic acid decarboxylase; *GAT,* GABA transporter; *GDH,* glutamate dehydrogenase;

SSA, succinic semialdehyde; *TCA,* tricarboxylic acid cycle; *vGAT,* vesicular GABA transporter; *vGlut,* vesicular glutamate transporter.

Glutamate

GLUTAMATE RECEPTOR SUBTYPES

Glutamate and related EAAs, such as aspartate and homocysteate, activate both ionotropic (ligand-gated cation channels) and metabotropic (G protein–coupled) receptors (see **Ch. 3** for a general description of ionotropic and metabotropic receptors).

Ionotropic Glutamate Receptors

On the basis of studies with selective agonists and antagonists (**Fig. 38.2** and **Table 38.1**), three main subtypes of ionotropic receptors for glutamate can be distinguished: ***N*-methyl- d -aspartate (NMDA)**, (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (**AMPA)** and **kainate** [2] receptors, named originally according to their specific agonists. These ligand-gated channels comprise four subunits, each with the 'pore loop' structure shown in **Fig. 3.4** (see **Ch. 3**). There are some 16 different receptor subunits and their nomenclature has, until recently, been somewhat confusing. [3] Here, in this brief, general description, we use the International Union of Basic and Clinical Pharmacology (IUPHAR)–recommended terminology because it simplifies the subject considerably, but beware confusion when reading older papers. NMDA receptors are heteromers assembled from seven types of subunit (GluN1, GluN2A, GluN2B, GluN2C, GluN2D, GluN3A, GluN3B). The

subunits comprising AMPA receptors (GluA1–4) and kainate receptors (GluK1–5) are closely related to, but distinct from, GluN subunits. AMPA and kainite receptors can be homomeric or heteromeric. Receptors comprising different subunits have different pharmacological and physiological characteristics, e.g. AMPA receptors lacking the GluA2 subunit have much higher permeability to Ca^{2+} than the others, which has important functional consequences (see **Ch. 4**). AMPA receptor subunits are also subject to other kinds of variation, namely alternative splicing, giving rise to the engagingly named *flip* and *flop* variants, RNA editing at the single amino acid level, and associated auxiliary subunits, all of which contribute yet more functional diversity to this diverse family.

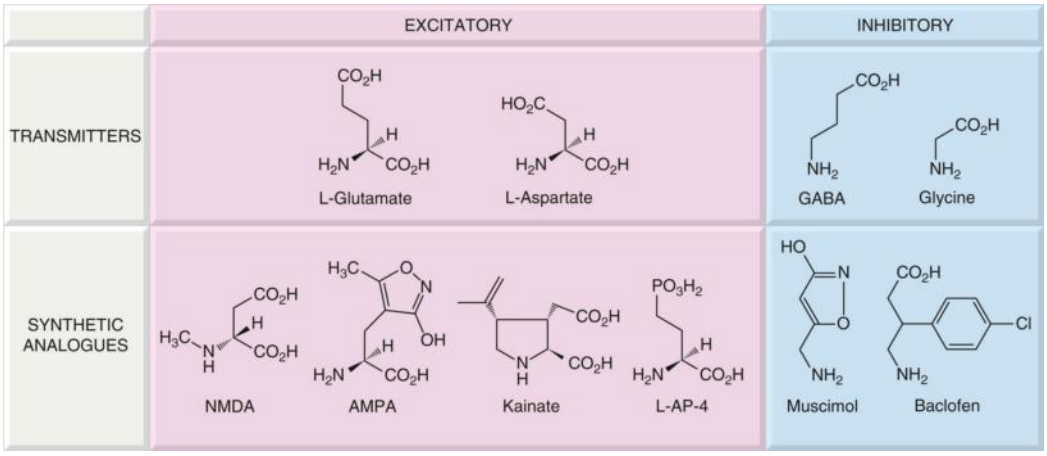

FIG. 38.2 Structures of agonists acting on glutamate, γ-aminobutyric acid **(GABA)** and glycine receptors.The receptor specificity of these compounds is shown in Tables **38.1** and **38.2**. *AMPA,* (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid; *L-AP4,* L-2-amino-4-phosphonopentanoic acid; *NMDA*, *N*-methyl-D-aspartic acid.

AMPA receptors, and in certain brain regions kainate receptors, serve to mediate fast excitatory synaptic transmission in the CNS – absolutely essential for our brains to function. NMDA receptors (which often coexist with AMPA receptors) contribute a slow component to the excitatory synaptic potential (**Fig. 38.3B**), the magnitude of which varies in different pathways. NMDA, kainate and AMPA receptors are also expressed on nerve terminals where they can enhance or reduce transmitter release. [4] AMPA receptors occur on astrocytes as well as on neurons.

Binding studies show that ionotropic glutamate receptors are most abundant in the cortex, basal ganglia and sensory pathways. NMDA and AMPA receptors are generally co-localised, but kainate

receptors have a much more restricted distribution. Expression of the many different receptor subtypes in the brain also shows distinct regional differences, but we have hardly begun to understand the significance of this extreme organisational complexity.

Special features of *N*-methyl-D-aspartate receptors

NMDA receptors and their associated channels have been studied in more detail than the other types and show special pharmacological properties, summarised in **Fig. 38.4**, and are postulated to play a role in pathophysiological mechanisms.

- They are highly permeable to Ca^{2+}, as well as to other cations, so activation of NMDA receptors is particularly effective in promoting Ca^{2+} entry.
- They are readily blocked by Mg^{2+}, and this block shows marked voltage dependence. It occurs at physiological Mg^{2+} concentrations when the cell is normally polarised, but disappears if the cell is depolarised.
- Activation of NMDA receptors requires glycine as well as glutamate (**Fig. 38.4**). The binding site for glycine is distinct from the glutamate binding site, i.e. glycine is a co-agonist that acts allosterically to permit glutamate activation of the receptor (see **Ch. 2**), and both have to be occupied for the channel to open. This discovery by Johnson and Ascher caused a stir, because glycine had hitherto been recognised as an inhibitory transmitter, so to find it facilitating excitation ran counter to the prevailing doctrine. The concentration of glycine required depends on the

subunit composition of the NMDA receptor: for some NMDA receptor subtypes, physiological variation of the glycine concentration may serve as a regulatory mechanism, whereas others are fully activated at all physiological glycine concentrations. Competitive antagonists at the glycine site (see **Table 38.1**) indirectly inhibit the action of glutamate. **D-serine**, somewhat surprisingly, [5] may also function as an endogenous activator of the glycine site on the NMDA receptor.

- Some endogenous polyamines (e.g. **spermine**, **spermidine**) act at an allosteric site distinct from that of glycine to facilitate channel opening. The experimental drugs **ifenprodil** and **eliprodil** block their action.
- Other allosteric sites have been identified on the NMDA receptor and positive and negative allosteric modulators with novel patterns of GluN2 subunit selectivity have been discovered (**Burnell et al., 2019**).

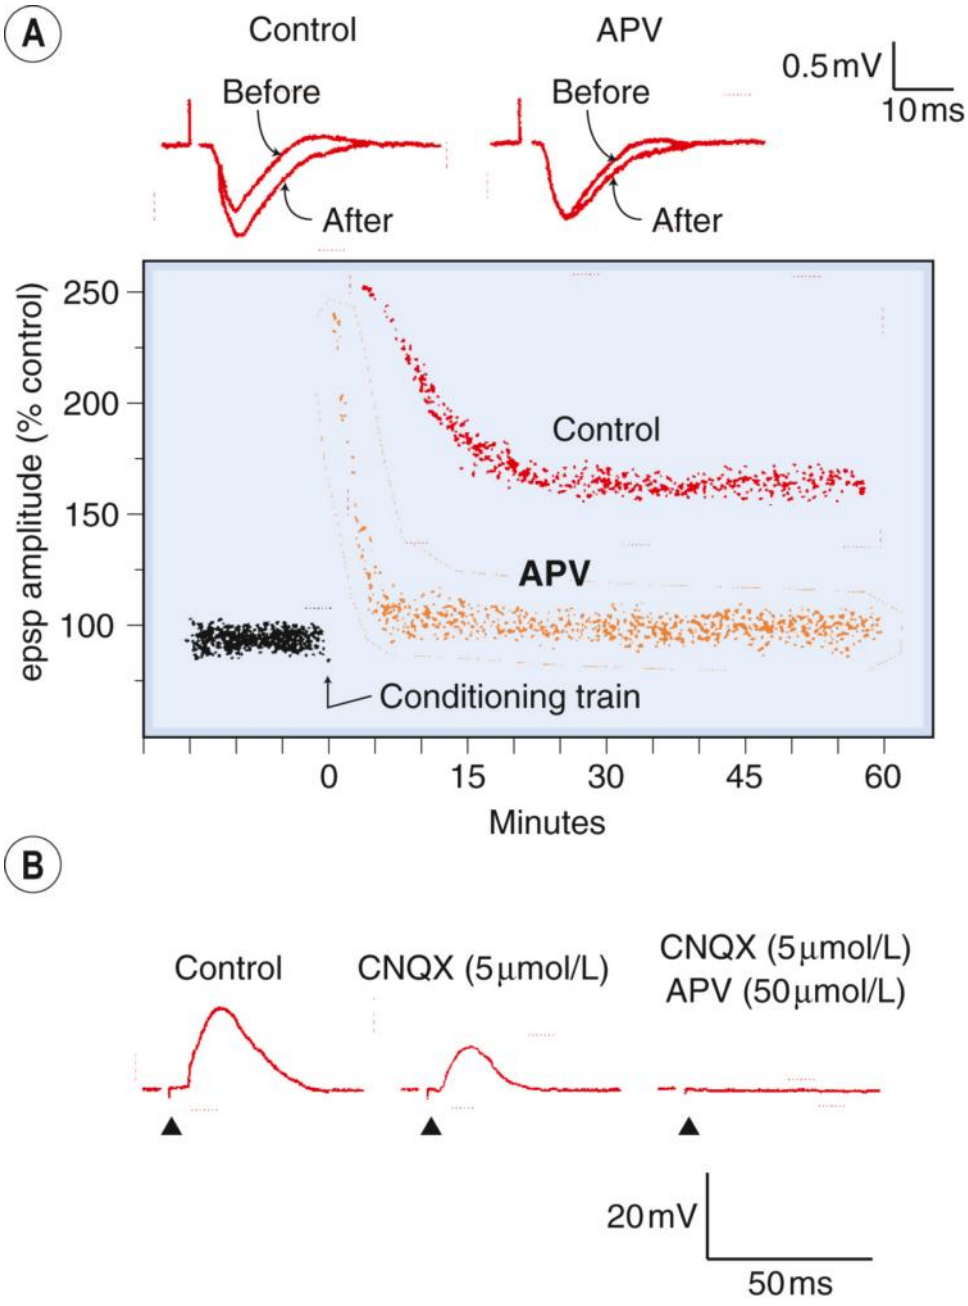

FIG. 38.3 Effects of excitatory amino acid receptor antagonists on synaptic transmission.(A) AP5 (*N*-methyl-D-aspartic acid (NMDA) antagonist) prevents long-term potentiation (LTP) in the rat hippocampus without affecting the fast

excitatory postsynaptic potential (epsp). Top records show the extracellularly recorded fast epsp *(downward deflection)* before and 50 min after a conditioning train of stimuli (100 Hz for 2 s). The presence of LTP in the control preparation is indicated by the increase in epsp amplitude. In the presence of AP5 (50 μmol/L), the normal epsp is unchanged, but LTP does not occur. Lower trace shows epsp amplitude as a function of time. The conditioning train produces a short-lasting increase in epsp amplitude, which still occurs in the presence of AP5, but the long-lasting effect is prevented. (B) Block of fast and slow components of epsp by *CNQX* (6-cyano-7-nitroquinoxaline-2,3-dione; (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor antagonist) and 2-amino-5-phosphonovaleric acid (AP5) (NMDA receptor antagonist). The epsp *(upward deflection)* in a hippocampal neuron recorded with intracellular electrode is partly blocked by CNQX (5 μmol/L), leaving behind a slow component, which is blocked by AP5 (50 μmol/L). A from Malinow, R., Madison, D., Tsien, R.W., 1988. Nature 335, 821; B from Andreasen, M., Lambert, J.D.,

Jensen, M.S., 1989. J. Physiol. 414, 317–336.

- **Aspartate** and **homocysteate** activate NMDA receptors and may be endogenous activators in certain brain regions.
- Some well-known anaesthetic and psychotomimetic agents, such as **ketamine** (see **Ch. 40**) and **phencyclidine** (see **Ch. 49**), are selective non-competitive antagonists blocking NMDA-operated channels.

Antagonists selective for the NR2B subunit have shown promise as antidepressants (**Ch. 48**) with **Traxoprodil** giving a positive result in a clinical trial but unfortunately failing to progress due to side effects. Other NR2B antagonists are under development.

Metabotropic Glutamate Receptors

There are eight different metabotropic glutamate receptors ($mGlu_{1-8}$) which are unusual in showing no sequence homology with other G protein–coupled receptors (for a broad coverage of the molecular and physiological properties of mGluRs, see **Niswender and Conn, 2010**). They function as homo- and heterodimers [6] (see **Ch. 3**) cross-linked by a disulfide bridge across the extracellular domain of each protein. They are members of class C G protein–coupled receptors, possessing a large extracellular N-terminus domain that forms a Venus fly trap–like structure into which glutamate binds. They are divided into three groups on the basis of their sequence homology, G protein coupling and pharmacology. Alternatively spliced receptor variants have been reported.

mGlu receptors are widely distributed throughout the CNS on neurons, where they regulate cell excitability and synaptic transmission, and on glia. Neuronal group 1 mGlu receptors are located postsynaptically and are largely excitatory through Gq signalling. By raising intracellular [Ca^{2+}], they modify responses through ionotropic glutamate receptors (**Fig. 38.6**). Group 2 (somatodentritic and presynaptic) and 3 mGlu (presynaptic) receptors, and their activation, tend to reduce synaptic transmission and neuronal excitability through Gi/o signalling. They can be autoreceptors, involved in reducing glutamate release or heteroreceptors, e.g. when present on GABA-containing terminals. Selective agonists and antagonists have been developed as research tools and there have been numerous clinical trials with subtype selective compounds in a range of psychiatric and neurological disorders but they have failed to deliver on efficacy and as such the therapeutic potential of mGluRs has yet to be realised.

Synaptic Plasticity And Long-Term Potentiation

As well as participating in synaptic transmission, glutamate receptors play a role in long-term adaptive and pathological changes in the brain, and are of particular interest as potential drug targets.

In this context, two aspects of glutamate receptor function are of particular pathophysiological importance, namely *synaptic plasticity*, discussed here, and *excitotoxicity* (discussed in **Ch. 40**).

Synaptic plasticity is a general term used to describe long-term changes in synaptic connectivity and efficacy, either following physiological alterations in neuronal activity (as in learning and memory) or resulting from pathological disturbances (as in

epilepsy, chronic pain or drug dependence). Synaptic plasticity underlies much of what we call 'brain function', allowing it to be influenced by past experience. Needless to say, no single mechanism is responsible; however, one significant and much-studied component is *long-term potentiation* (LTP), a phenomenon in which AMPA and NMDA receptors play a central role (**Chater and Goda, 2014**; **Lüscher and Malenka, 2012**).

LTP (see **Bear et al., 2020**) is a prolonged (hours in vitro, days or weeks in vivo) enhancement of synaptic transmission that occurs at various CNS synapses following a short (conditioning) burst of high-frequency presynaptic stimulation. Its counterpart is *long-term depression* (LTD), which is produced at some synapses by a longer train of stimuli at lower frequency (see **Connor and Wang, 2016**). These phenomena have been studied at various synapses in the CNS, most especially in the hippocampus, which plays a central role in learning and memory (see **Fig. 38.3**). It has been argued that 'learning', in the synaptic sense, can occur if synaptic strength is enhanced following simultaneous activity in both pre- and postsynaptic neurons. LTP shows this characteristic; it does not occur if presynaptic activity fails to excite the postsynaptic neuron, or if the latter is activated independently, for instance by a different presynaptic input. The mechanisms underlying both LTP and LTD differ somewhat at different synapses in the brain (see **Bear et al., 2020**). Here only a brief, generic view of the underlying events is given. LTP initiation may involve both presynaptic and postsynaptic components, and results from enhanced activation of postsynaptic AMPA receptors at glutamatergic synapses and (probably) to enhanced glutamate release (although the argument rumbles on

about whether increased transmitter release does or does not occur in LTP; see **Nicoll, 2017**). The response of postsynaptic AMPA receptors to glutamate is increased due to phosphorylation of the AMPA receptor subunits by kinases such as Ca^{2+}/calmodulin-dependent protein kinase (CaMKII) and protein kinase C (PKC), thus enhancing their conductance, as well as to increase expression and trafficking of AMPA receptors to synaptic sites. LTD, on the other hand, results from modest Ca^{2+} entry into the cell activating phosphatases that reduce AMPA receptor phosphorylation and enhance AMPA receptor internalisation (see **Connor and Wang, 2016**).

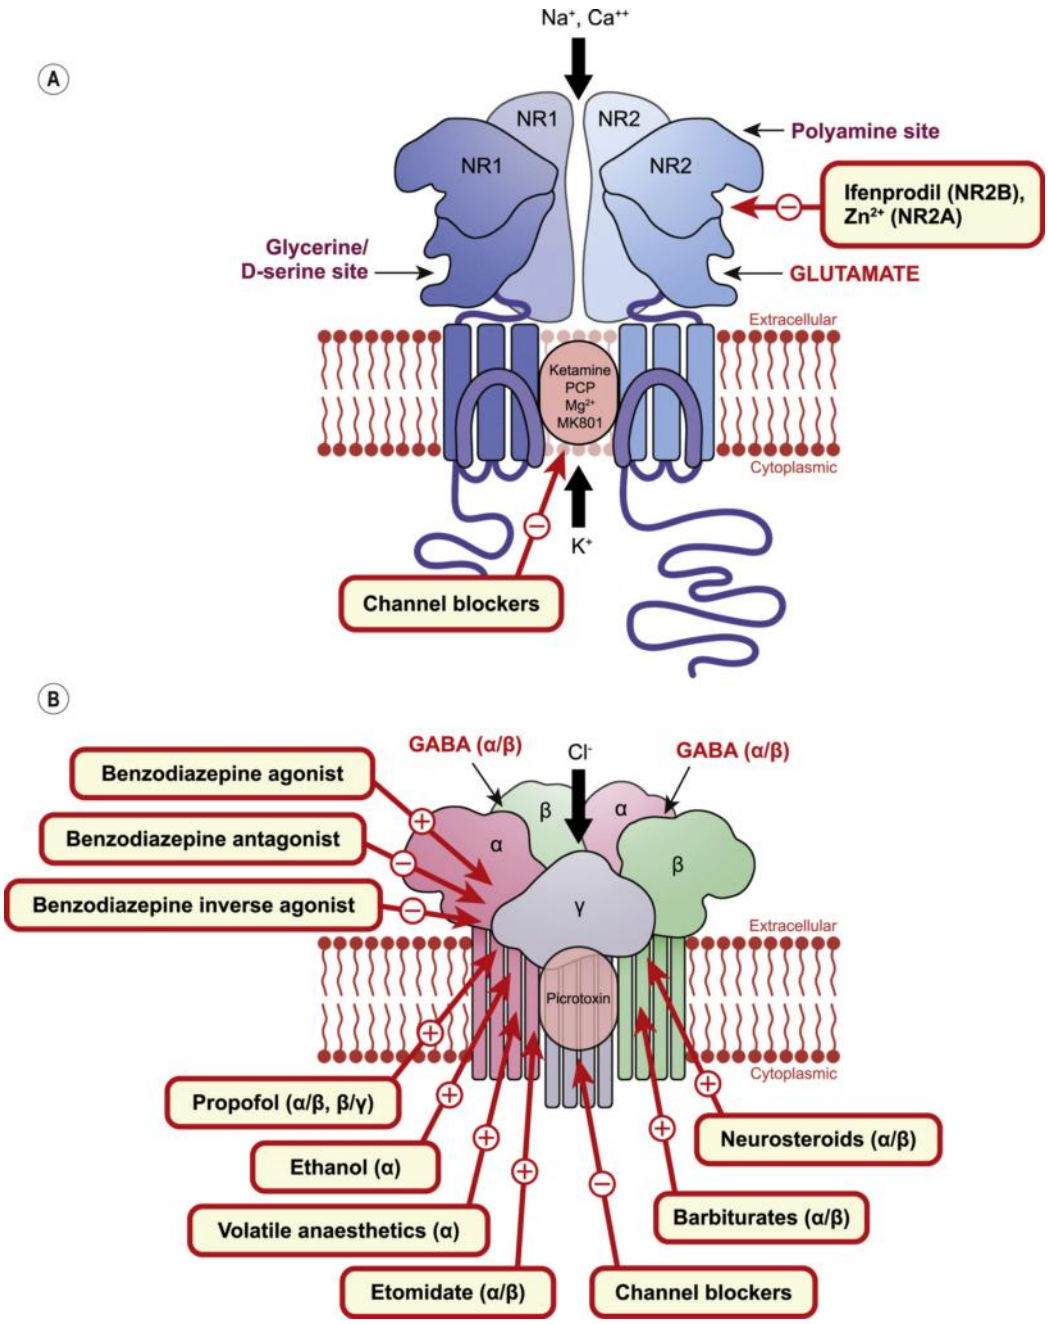

FIG. 38.4 Main sites of drug action on *N*-methyl-D-aspartic acid (NMDA) and $GABA_A$ receptors (A and B).Both receptors are multimeric ligand-gated ion channels and drugs can act as agonists or antagonists at the neurotransmitter receptor site or at modulatory

sites associated with the receptor. They can also act to block the ion channel at one or more distinct sites. In the case of the $GABA_A$ receptor, the mechanism by which 'channel modulators' (e.g. ethanol, anaesthetic agents, neurosteroids) facilitate channel opening is uncertain; they may affect both ligand-binding and channel sites. The location of the different binding sites shown in the figure is not fully understood although site-directed mutagenesis studies are revealing their specific locations. Examples of the different drug classes are given in Tables **38.1** and **38.2**. *GABA*, γ-Aminobutyric acid.

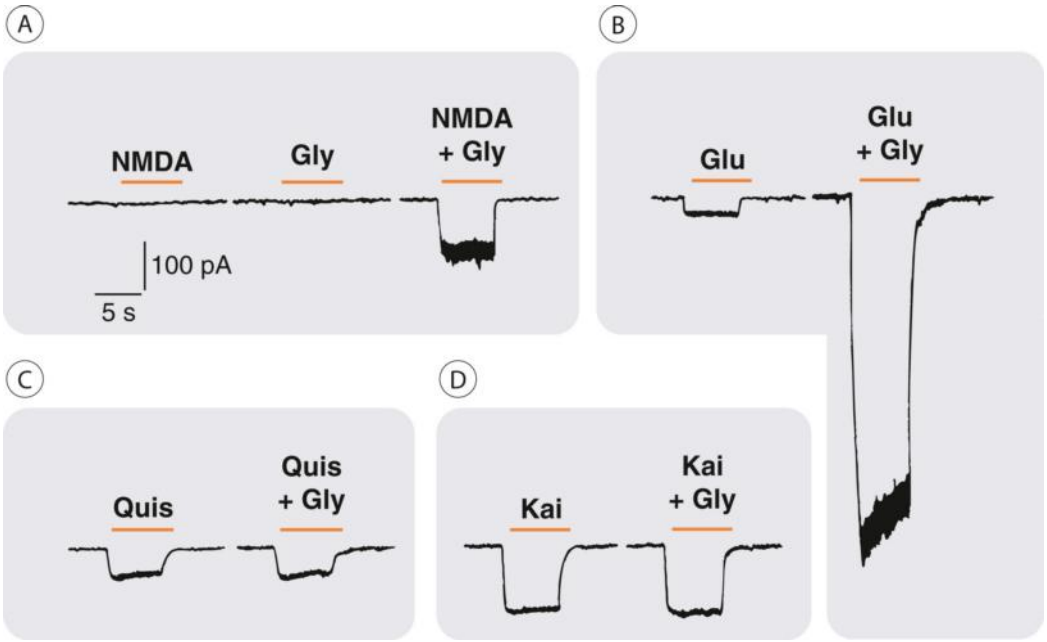

FIG. 38.5 Facilitation of *N*-methyl-D-aspartic acid **(NMDA)** by glycine.Recordings from mouse brain neurons in culture (whole-cell patch clamp technique). Downward deflections represent inward current through excitatory amino acid–activated ion channels. (A) NMDA (10 μmol/L) or glycine (1 μmol/L) applied separately had little or no effect, but together produced a response. (B) The response to glutamate (Glu; 10 μmol/L) was strongly potentiated by glycine (Gly; 1 μmol/L). (C and D) Responses of (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and kainate receptors to quisqualate (Quis) and kainate (Kai) were unaffected by glycine. From Johnson, J.W., Ascher, P., 1987. Glycine

potentiates the NMDA response in cultured mouse brain neurons. Nature 325, 529–531.

LTP is reduced by agents that block the synthesis or effects of nitric oxide or arachidonic acid. These mediators (see Chs **17** and **19**) may act as retrograde messengers through which events in the postsynaptic cell are able to influence the presynaptic nerve terminal. Endogenous cannabinoids released by the postsynaptic cell may also act as retrograde messengers to enhance glutamate release (see Chs **18** and **39**). Brain-derived neurotrophic factor (BDNF) has been shown to be released from postsynaptic neurons in response to increased glutamate release and may contribute to stabilising these changes in synaptic strength (**Gómez-Palacio-Schjetnan and Escobar, 2013**).

Two special properties of the NMDA receptor underlie its involvement in LTP, namely voltage-dependent channel block by Mg^{2+} and its high Ca^{2+} permeability. At normal membrane potentials, the NMDA channel is blocked by Mg^{2+}; a sustained postsynaptic depolarisation produced by glutamate acting repeatedly on AMPA receptors, however, removes the Mg^{2+} block, and NMDA receptor activation then allows Ca^{2+} to enter the cell. Activation of group 1 mGlu receptors also contributes to the increase in $[Ca^{2+}]_i$. This rise in $[Ca^{2+}]_i$ in the postsynaptic cell activates protein kinases, phospholipases and nitric oxide synthase, which act jointly with other cellular processes to facilitate transmission via AMPA receptors. Initially, during the induction phase of LTP, phosphorylation of AMPA receptors increases their responsiveness to glutamate. Later, during the maintenance phase, more AMPA receptors are recruited to the membrane of

postsynaptic dendritic spines as a result of altered receptor trafficking; later still, other mediators and signalling pathways including neurotrophic factors are activated, causing structural changes and leading to a permanent increase in the number of synaptic contacts.

The general descriptions of LTP and LTD given earlier are intended to provide the uninitiated reader with an overview of the topic. There are subtle differences in their forms and in the mechanisms underlying them at different synapses in the CNS. How LTP and LTD, in all of their guises, relate to different forms of memory is slowly being worked out (see **Connor and Wang, 2016**). Thus there is hope that drugs capable of modifying LTP and LTD may improve learning and memory. [7]

Table 38.1

(Other structures are shown in **Fig. 39.3**.)

[a] **Hansen et al. (2021)** provides a detailed review of the pharmacology of ionotropic glutamate receptors including experimental compounds.

[b] A neurotoxin from mussels (see **Ch. 41**).

Drugs Acting On Glutamate Receptors

Antagonists And Negative Modulators

Inotropic glutamate receptor antagonists

The main types and examples of ionotropic glutamate antagonists are shown in **Table 38.1**. They are selective for the main receptor types but generally not for specific subtypes. Many of these compounds, although very useful as experimental tools, are unable to penetrate the blood–brain barrier, so they are not effective when given systemically.

NMDA receptors, as discussed before, require glycine as well as NMDA to activate them, so blocking the glycine site is an alternative

way to produce antagonism. **Kynurenic acid** and the more potent analogue **7-chloro-kynurenic acid** act in this way.

Another site of block is the channel itself, where substances such as ketamine, phencyclidine and **memantine** act. These agents are lipid soluble and thus able to cross the blood–brain barrier. Depending on their affinity and kinetics, these channel blocking NMDA antagonists have quite different functional effects.

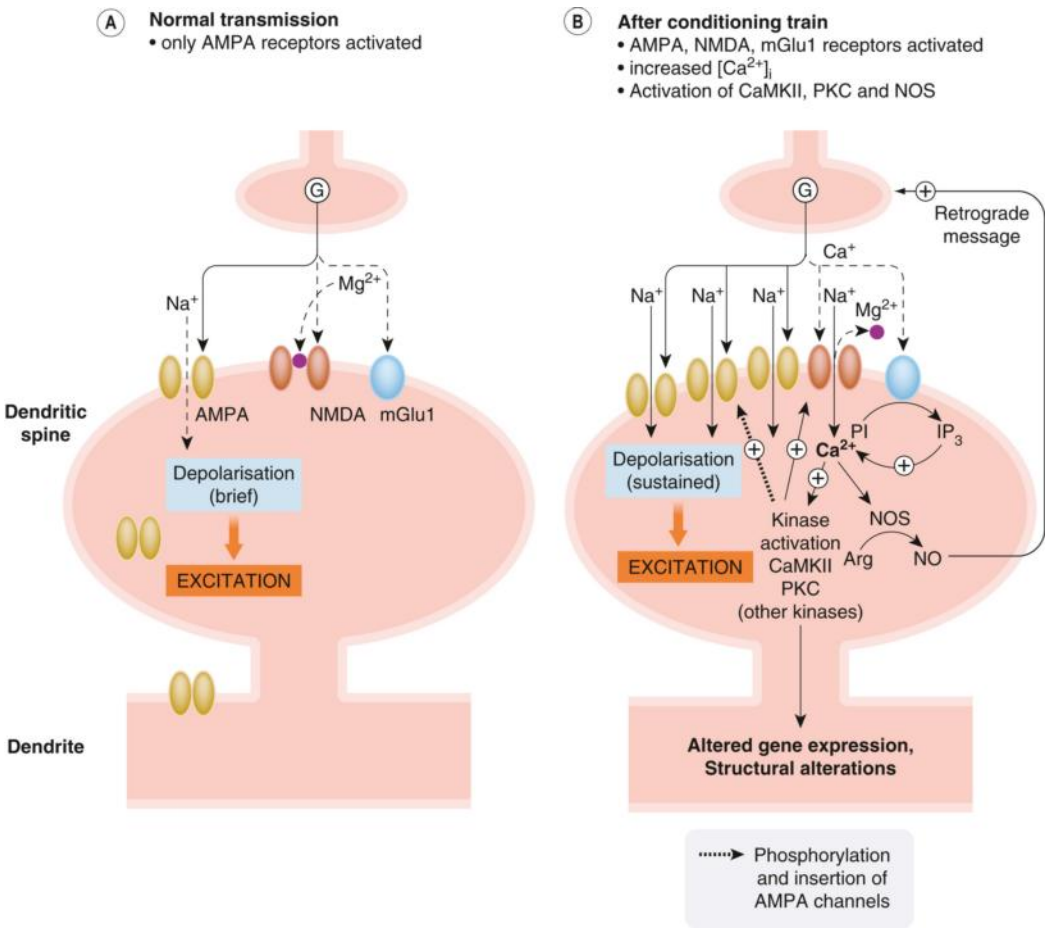

FIG. 38.6 Mechanisms of long-term potentiation.(A) With infrequent synaptic activity, glutamate (G) activates mainly (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors. There is insufficient glutamate to activate metabotropic receptors, and *N*-methyl-D-aspartic acid (NMDA) receptor channels are blocked by Mg^{2+}. (B) After a conditioning train of stimuli, enough glutamate is released to activate metabotropic receptors, and NMDA channels are unblocked by the sustained depolarisation. The resulting increase

in $[Ca^{2+}]_i$ activates various enzymes, including the following:

- Ca^{2+}/calmodulin-dependent protein kinase (CaMKII) and protein kinase C (PKC) phosphorylate various proteins, including AMPA receptors (causing them to be trafficked to areas of synaptic contact on dendritic spines and facilitation of transmitter action) and other signal transduction molecules controlling gene transcription (not shown) in the postsynaptic cell.
- Nitric oxide synthase (NOS); release of nitric oxide (NO) facilitates glutamate release (retrograde signalling, otherwise known as NO turning back).
- Phospholipase A_2 (not shown) catalyses the formation of arachidonic acid (see **Ch. 18**), a retrograde messenger that increases presynaptic glutamate release.
- A phospholipase (NAPE-PLD, not shown) that catalyses production of the endocannabinoids (see **Ch. 20**) that act as retrograde messengers to enhance glutamate release.
- Brain-derived neurotrophic factor (BDNF) released from nerve terminals and postsynaptic structures (not shown)

plays a multimodal role in the early and later stages of LTP.

Arg, Arginine; *IP_3,* inositol (1,4,5) trisphosphate; *NAPE-PLD*, N-acyl phosphatidylethanolamine-specific phospholipase D; *PI,* phosphatidylinositol.

The therapeutic potential for ionotropic glutamate receptor antagonists is diverse, including the reduction of brain damage following strokes and head injury (see **Ch. 40**), as well as in the treatment of epilepsy (see **Ch. 46**) and Alzheimer's disease (see **Ch. 40**). They have also been considered for indications such as drug dependence (see **Ch. 50**) and schizophrenia (see **Ch. 47**). Trials with NMDA antagonists and channel blockers have so far proved disappointing, and a serious drawback of these agents is their tendency to cause hallucinatory and other disturbances (also a feature of phencyclidine; see **Ch. 49**). Only two NMDA receptor antagonists, ketamine (anaesthesia, analgesia and depression; see Chs **41**, **43** and **48**) and memantine (Alzheimer's disease; see **Ch. 40**), are in clinical use. Ketamine is also used for its psychoactive properties (see **Ch. 49**) inducing relaxation and euphoria and at high doses an 'out-of-body' experience. It is possible that antagonists selective for NMDA receptors containing the GluN2B subunit, which is highly Ca^{2+} permeable, have reduced dissociative effects and may be better tolerated and several drugs of this type are in development as rapid-acting antidepressants (see **Ch. 48**).

The non-competitive AMPA receptor antagonist **perampanel** has been introduced as an antiepileptic drug (see **Ch. 48**). The

prospects for kainate receptor antagonists appear promising – antagonists for GluK1 have shown potential for the treatment of pain, migraine, epilepsy, stroke and anxiety (see **Hansen et al., 2021**).

Overall, the promise foreseen for ionotropic glutamate receptor antagonists in the clinic has been less successful than was hoped. The problem may be that glutamate is such a ubiquitous and multifunctional mediator – involved, it seems, in almost every aspect of brain function – that attempting to improve a specific malfunction by flooding the brain with a compound that affects the glutamate system in some way is just too crude a strategy. The new hope is that subunit selective negative allosteric modulators may have fewer side effects than previous generations of orthosteric antagonists.

Metabotropic glutamate receptor antagonists

While antagonists that discriminate between the different groups of mGlu receptors are available, it has proven more difficult to develop selective antagonists for the subtypes within the groups. mGlu receptors, like many G protein–coupled receptors, possess allosteric modulatory sites, which can be either inhibitory or facilitatory (see **Ch. 3**). Antagonists or negative allosteric modulators acting at group 1 mGlu receptors have potential for the treatment of fragile X syndrome, [8] various pain states, Parkinson's disease (including the control of **levodopa**-induced dyskinesias, see **Ch. 40**), neuroprotection, epilepsy and drug use disorder, whereas antagonists or negative allosteric modulators of group 2 mGlu

receptors have potential as cognition enhancers (see **Nicoletti et al., 2011**).

Agonists And Positive Modulators

Ionotropic glutamate receptors

Various agonists at ionotropic glutamate receptors that are used experimentally are shown in **Table 38.1**. From the clinical perspective, interest centres on the theory that positive AMPA receptor modulators may improve memory and cognitive performance. Early examples include **cyclothiazide**, **piracetam** [9] (approved for use in certain forms of epilepsy, see **Ch. 46**) and CX-516 (**Ampalex**). These positive allosteric modulators, known as *ampakines*, can act in subtly different ways to increase response amplitude, slow deactivation and/or attenuate desensitisation of AMPA receptor–mediated currents. They therefore increase AMPA-mediated synaptic responses and enhance LTP as well as up-regulating the production of nerve growth factors such as *brain-derived neurotrophic factor* (BDNF). Originally, ampakines were thought to have therapeutic potential as cognition enhancers (nootropics or 'smart drugs') and for the treatment of schizophrenia, depression, attention deficit hyperactivity disorder (ADHD) and Parkinson's disease (see **Kadriu et al., 2021**) but so far clinical trials have been disappointing. A more recently developed ampakine, CX1739, is in clinical trial for the treatment of drug-induced respiratory depression.

Inhibition of the glycine transporter GlyT1 leads to an elevation of extracellular glycine levels throughout the brain and, through potentiation of NMDA receptor-mediated responses, could be

beneficial in the treatment of various neurological disorders (see **Marques et al., 2020**).

Metabotropic glutamate receptors

Developing selective agonists of mGlu receptors has proven to be quite difficult but selective positive allosteric modulators have been developed (see **Nicoletti et al., 2011**). Group 2 and 3 mGlu receptors are located presynaptically on nerve terminals and agonists at these receptors decrease glutamate release. Group 2 mGlu agonists and positive allosteric modulators were therefore thought to have therapeutic potential to decrease neuronal cell death in stroke and in the treatment of epilepsy, but to date clinical trials have been disappointing. Similarly, clinical trials with agonists and positive allosteric modulators for group 2 mGlu receptors and group 3 mGlu receptor–positive allosteric modulators have also failed to deliver on efficacy in clinical trials.

Excitatory amino acids

- Glutamate is the main fast excitatory transmitter in the CNS.
- Glutamate is formed mainly from the Krebs cycle intermediate α-ketoglutarate by the action of GABA transaminase.
- There are three main ionotropic glutamate receptors and eight metabotropic receptors.
- *N*-methyl-D-aspartic acid (NMDA), (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and kainate receptors are ionotropic receptors regulating cation channels.

- The channels controlled by NMDA receptors are highly permeable to Ca^{2+} and are blocked by Mg^{2+}.
- AMPA and kainate receptors are involved in fast excitatory transmission; NMDA receptors mediate slower excitatory responses and, through their effect in controlling Ca^{2+} entry, play a more complex role in controlling synaptic plasticity (e.g. long-term potentiation).
- Competitive NMDA receptor antagonists include **AP5** (2-amino-5-phosphonopentanoic acid) and **CPP** (3-(2-carboxypirazin-4-yl)-propyl-1-phosphonic acid); the NMDA-operated ion channel is blocked by **ketamine** and **memantine** with high and low affinity, respectively.
- **NBQX** (2,3-dihydro-6-nitro-7-sulfamoyl-benzoquinoxaline) is an AMPA and kainate receptor antagonist.
- NMDA receptors require low concentrations of glycine as a co-agonist, in addition to glutamate; **7-chlorokynurenic acid** blocks this action of glycine.
- NMDA receptor activation is increased by endogenous polyamines, such as **spermine**, acting on a modulatory site that is blocked by **ifenprodil.**
- The entry of excessive amounts of Ca^{2+} produced by NMDA receptor activation can result in cell death – excitotoxicity (see **Ch. 40**).
- Metabotropic glutamate receptors ($mGlu_{1-8}$) are dimeric G protein–coupled receptors. $mGlu_1$ and $mGlu_5$ receptors couple through G_q to inositol trisphosphate formation and intracellular Ca^{2+} release. They play a part in glutamate-

mediated synaptic plasticity and excitotoxicity. The other mGlu receptors couple to G_i/G_o and inhibit neurotransmitter release, most importantly glutamate release.

- Some specific metabotropic glutamate receptor agonists and antagonists are available, as are positive and negative allosteric modulators.

γ-AMINOBUTYRIC ACID

GABA is the main inhibitory transmitter in the brain. In the spinal cord and brain stem, glycine is also important.

SYNTHESIS, STORAGE AND FUNCTION

GABA occurs in brain tissue but not in other mammalian tissues, except in trace amounts. It is particularly abundant (about 10 μmol/g tissue) in the nigrostriatal system, but occurs at lower concentrations (2–5 μmol/g) throughout the grey matter.

GABA is formed from glutamate (see **Fig. 38.1**) by the action of glutamic acid decarboxylase (GAD), an enzyme found only in GABA-synthesising neurons in the brain. [10] Immunohistochemical labelling of GAD is used to map the GABA pathways in the brain. GABAergic neurons and astrocytes take up GABA via specific transporters, thus removing GABA after it has been released. GAT1 is the predominant GABA transporter in the brain and is located primarily on GABAergic nerve terminals where it recycles GABA. GAT3 is located predominantly on astrocytes around the GABAergic synapse. GABA transport is inhibited by **tiagabine** used to treat epilepsy (see **Ch. 46**). In astrocytes GABA can be destroyed by a

transamination reaction in which the amino group is transferred to α-oxoglutaric acid (to yield glutamate), with the production of succinic semialdehyde and then succinic acid. This reaction is catalysed by GABA transaminase, an enzyme located primarily in astrocytes. It is inhibited by **vigabatrin**, another compound used to treat epilepsy (see **Ch. 46**).

GABA functions as an inhibitory transmitter in many different CNS pathways. About 20% of CNS neurons are GABAergic; most are short interneurons, but there are some long GABAergic tracts, e.g. from the striatum to the substantia nigra and globus pallidus (see **Ch. 40**). The widespread distribution of GABA – GABA serves as a transmitter at about 30% of all the synapses in the CNS – and the fact that virtually all neurons are sensitive to its inhibitory effect suggests that its function is ubiquitous in the brain. That antagonists such as **bicuculline** induce seizures illustrates the important, ongoing inhibitory role of GABA in the brain.

Gaba Receptors: Structure and Pharmacology

GABA acts on two distinct types of receptor: $GABA_A$ receptors are ligand-gated ion channels permeable to chloride whereas $GABA_B$ receptors are G protein–coupled.

$GABA_A$ Receptors

$GABA_A$ receptors [11] are members of the *cys-loop* family of receptors that also includes the glycine, nicotinic and 5-HT_3 receptors (see **Ch. 3**). The $GABA_A$ receptors are pentamers made up of different subunits.

The reader should not despair when informed that 19 $GABA_A$ receptor subunits have been cloned (α1–6, β1–3, γ1–3, δ, ε, θ, π and

ρ1–3) and that splice variants of some subunits also exist. Although the number of possible combinations is large, only a few dozen have been shown to exist. The most common are α1β2γ2 (by far the most abundant), α2β3γ2 and α3β3γ2 subunits. To make up the pentamer, each receptor contains two α, two β and one γ subunit arranged in a circle in the sequence α–β–α–β–γ around the pore when viewed from the extracellular side of the membrane. GABA binds at each of the interfaces between the α and β subunits whereas benzodiazepines (see **Ch. 45**) bind at the α/γ interface. Three different benzodiazepione binding sites have been described but their functional significance is unclear at present. Receptors containing different α and γ subunits exhibit differential sensitivity to benzodiazepines and mediate different behavioural responses to these drugs. This raises the tantalising prospect of developing new agents with greater selectivity and potentially fewer side effects. The $GABA_A$ receptor should therefore be thought of as a group of receptors exhibiting subtle differences in their physiological and pharmacological properties (**Olsen, 2018**).

$GABA_A$ receptors are primarily located postsynaptically and mediate both fast and tonic postsynaptic inhibition. The $GABA_A$ channel is selectively permeable to Cl^- and because the equilibrium membrane potential for Cl^- is usually negative to the resting potential, increasing Cl^- permeability hyperpolarises the cell as Cl^- ions enter, thereby reducing its excitability. [12] In the postsynaptic cell, $GABA_A$ receptors are located both at areas of synaptic contact and extrasynaptically (**Fig. 38.7**, and see **Farrant and Nusser, 2005**). Thus GABA produces inhibition by acting both as a fast 'point-to-point' transmitter and as an 'action-at-a-distance'

neuromodulator, as the extrasynaptic $GABA_A$ receptors can be tonically activated by GABA that has diffused away from its site of release. Extrasynaptic $GABA_A$ receptors contain α4 and α6 subunits as well as the δ subunit. They have higher affinity for GABA and show less desensitisation than synaptic receptors, and are also highly sensitive to general anaesthetic agents (see **Ch. 41**) and ethanol (see **Ch. 49**).

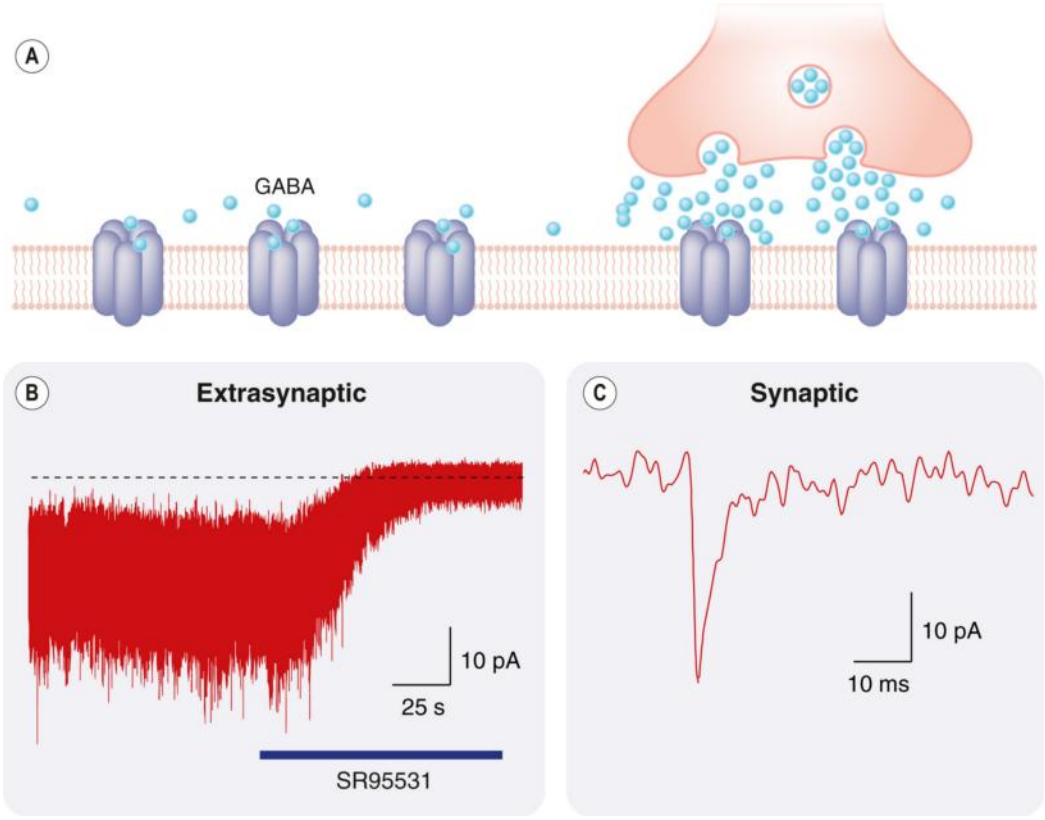

FIG. 38.7 Synaptic and extrasynaptic $GABA_A$ receptors.(A) Diagram depicting $GABA_A$ receptors at synaptic and extrasynaptic sites in the plasma membrane. The *blue dots* represent GABA molecules. (B) Tonic activation of extrasynaptic $GABA_A$ receptors gives rise to a steady-state inward current *(distance from the baseline indicated by the dashed line)* and increased 'noise' on the trace. The current is blocked on application of the $GABA_A$ receptor antagonist SR95531. (C) Phasic release of GABA from the presynaptic terminal evokes a fast synaptic current *(rapid downward deflection)*. Note the different timescales in (B) and (C).

GABA, γ-Aminobutyric acid. Figure courtesy M. Usowicz.

$GABA_B$ RECEPTORS

$GABA_B$ receptors (see **Evenseth et al., 2020**) are located pre- and postsynaptically. They are class C G protein–coupled receptors that couple through G_i/G_o to inhibit voltage-gated Ca^{2+} channels (thus reducing transmitter release), to open potassium channels (thus reducing postsynaptic excitability) and to inhibit adenylyl cyclase.

For $GABA_B$ receptors, the functional receptor is a dimer (see **Ch. 3**) consisting of two different seven-transmembrane subunits, B1 and B2, held together by a coil/coil interaction between their C-terminal tails. In the absence of B2, the B1 subunit does not traffic to the plasma membrane as it possesses an endoplasmic reticulum retention signal. Interaction of B1 with B2 masks the retention signal and facilitates trafficking to the membrane. Activation of the dimer results from GABA binding to the extracellular, 'Venus fly trap' domain of B1 (even although the B2 subunit possesses a similar domain) whereas it is the B2 subunit that interacts with and activates the G protein (**Fig. 38.8**).

Drugs Acting On Gaba Receptors

$GABA_A$ Receptors

$GABA_A$ receptors resemble NMDA receptors in that drugs may act at several different sites (see **Fig. 38.4**). These include:

- the GABA-binding site
- allosteric modulatory sites

- the ion channel pore

$GABA_A$ receptors are the target for several important centrally acting drugs, notably benzodiazepines (see **Ch. 45**), alcohol (see **Ch. 49**), barbiturates, neurosteroids (see **Table 38.2**) and many general anaesthetics (see **Ch. 41**). The main agonists, antagonists and modulatory substances that act on GABA receptors are shown in **Table 38.2**.

Muscimol, derived from a hallucinogenic mushroom, resembles GABA chemically (see **Fig. 38.2**) and is a powerful $GABA_A$ receptor agonist. A synthetic analogue, **gaboxadol,** is a partial agonist that was developed as a hypnotic drug (see **Ch. 45**) but has now been withdrawn. **Bicuculline**, a naturally occurring convulsant compound, is a specific antagonist that blocks the fast inhibitory synaptic potential in most CNS synapses. **Gabazine**, a synthetic GABA analogue, is similar. These compounds are useful experimental tools but have no therapeutic uses.

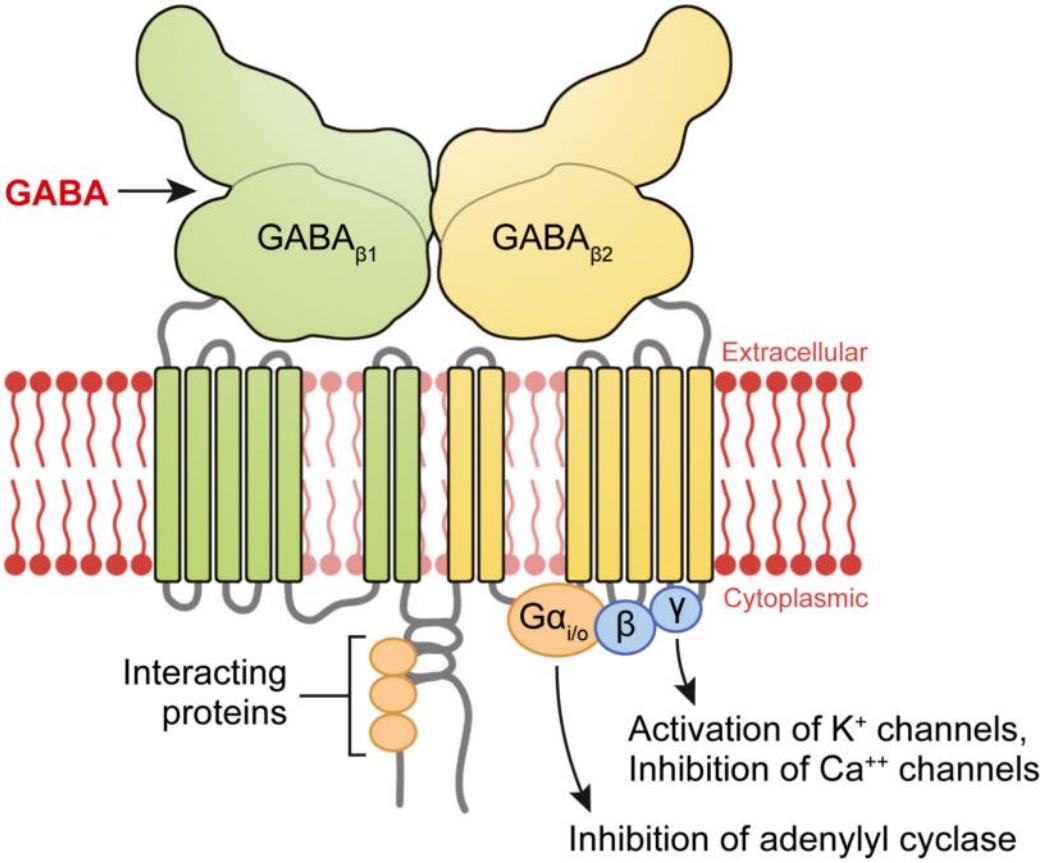

FIG. 38.8 Dimeric structure of the $GABA_B$ receptor.The receptor is made up of two seven-transmembrane domain subunits held together by a coil/coil interaction between their C-terminal tails. Activation of the receptor occurs when GABA binds to the extracellular domain of the B1 subunit (known as the Venus fly trap, because it snaps shut when GABA binds). This produces an allosteric change in the B2 subunit which is coupled to the G protein. *GABA*, γ-Aminobutyric acid.

Benzodiazepines, which have powerful sedative, anxiolytic and anticonvulsant effects (see **Ch. 45**), selectively potentiate the

effects of GABA on some $GABA_A$ receptors depending upon the subunit composition. They bind with high affinity to an accessory allosteric site on the $GABA_A$ receptor, in such a way that the binding of GABA is facilitated and its agonist effects are enhanced. Conversely, inverse agonists at the benzodiazepine site (e.g. Ro15-4513) reduce GABA binding and are anxiogenic and proconvulsant – they are unlikely to be therapeutically useful!

Modulators that also enhance the action of GABA, but whose site of action is less well defined than that of benzodiazepines (shown as 'channel modulators' in **Fig. 38.5**), include other CNS depressants such as barbiturates, anaesthetic agents (see **Ch. 41**) and neurosteroids. Neurosteroids (see **Belelli et al., 2021**) are compounds that are related to steroid hormones but that act to enhance activation of $GABA_A$ receptors – those containing δ subunits appear most sensitive. Interestingly, they include metabolites of progesterone and androgens that are formed in the nervous system and are believed to have a physiological role. Synthetic neurosteroids include **alphaxalone**, developed as an anaesthetic agent (see **Ch. 41**). In 2019, **allopregnanolone** (brexanolone) became the first treatment to be approved by the FDA for postpartum depression but requires a 60-h continuous infusion and is not without significant potential adverse effects including loss of consciousness.

Picrotoxin, a plant product, is a convulsant that acts by blocking the $GABA_A$ receptor chloride channel, thus blocking the postsynaptic inhibitory effect of GABA. It also blocks glycine receptors. It has no therapeutic uses.

$GABA_B$ RECEPTORS

When the importance of GABA as an inhibitory transmitter was recognised, it was thought that a GABA-like substance might prove to be effective in controlling epilepsy and other convulsive states; because GABA itself fails to penetrate the blood–brain barrier, more lipophilic GABA analogues were sought, one of which, **baclofen** (see **Fig. 38.2**), was introduced in 1972. Unlike GABA, its actions are not blocked by bicuculline. These findings led to the recognition of the $GABA_B$ receptor, for which baclofen is a selective agonist. Baclofen is used to treat spasticity and related motor disorders (see **Ch. 46**); it has been tested for treating alcohol and opioid dependence (see **Ch. 49**) but results so far are inconclusive.

Competitive antagonists for the $GABA_B$ receptor include a number of experimental compounds (e.g. **2-hydroxy-saclofen** and more potent compounds with improved brain penetration, such as CGP 35348). Tests in animals showed that these compounds produce only slight effects on CNS function (in contrast to the powerful convulsant effects of $GABA_A$ antagonists). The main effect observed, paradoxically, was an antiepileptic action, specifically in an animal model of absence seizures (see **Ch. 46**), together with enhanced cognitive performance. However, as in many areas of pharmacology, such preclinical promise has not resulted in the development of a new therapeutic drug.

γ-Hydroxybutyrate

γ-Hydroxybutyrate (**sodium oxybate** or GHB) occurs naturally in the brain as a side product of GABA synthesis. As a synthetic drug it can be used to treat narcolepsy and alcoholism. In addition, it has found favour with bodybuilders, based on its ability to evoke the

release of growth hormone, and with partygoers, based on its euphoric and disinhibitory effects. It is also used as an intoxicant and 'date rape' drug, but is fatal in higher doses. In common with many euphoric drugs (see **Ch. 49**), it activates 'reward pathways' in the brain, and its use is now illegal in most countries. GHB is an agonist at $GABA_A$ receptors containing α4 and δ subunits and a weak partial agonist at $GABA_B$ receptors. A specific GHB receptor has also been postulated but the evidence for its existence is not yet convincing.

Glycine

Glycine is an important inhibitory neurotransmitter in the spinal cord and brain stem. It is present in particularly high concentration (5 μmol/g) in the grey matter of the spinal cord. Applied ionophoretically to motor neurons or interneurons, it produces a hyperpolarisation that is indistinguishable from the inhibitory synaptic response. **Strychnine**, a convulsant poison that acts mainly on the spinal cord, blocks both the synaptic inhibitory response and the response to glycine. This, together with direct measurements of glycine release in response to nerve stimulation, provides strong evidence for its physiological transmitter role. **β-Alanine** has pharmacological effects and a pattern of distribution very similar to those of glycine, but its action is not blocked by strychnine.

Table 38.2

GABA, γ-Aminobutyric acid; *ipsp,* inhibitory postsynaptic potential.

[a] THIP is an abbreviation of the chemical name of gaboxadol. It is reported to have preference for δ subunit-containing extrasynaptic $GABA_A$ receptors.

[b] Picrotoxin also blocks some glycine receptors.

The inhibitory effect of glycine is quite distinct from its role in facilitating activation of NMDA receptors (see earlier in this chapter).

The glycine receptor (see **Breitinger and Breitinger, 2020**.) resembles the $GABA_A$ receptor in that it is a cys-loop, pentameric ligand-gated chloride channel. There are no specific metabotropic receptors for glycine. Five glycine receptor subunits have been cloned (α1–4, β) and it appears that in the adult brain the main form of glycine receptor is a heteromeric complex of α and β subunits, probably with a stoichiometry of 2α and 3β. Homomers formed of only α subunits can form and are sensitive to glycine and strychnine, indicating that the binding site for these drugs is on the α subunit. They are also much more sensitive to channel block by **picrotoxin** than are receptors comprised of α and β subunits.

Glycine receptors are involved in the regulation of respiratory rhythms, motor control and muscle tone as well as in the processing of pain signals. Mutations of the receptor have been identified in some inherited neurological disorders associated with muscle spasm and reflex hyperexcitability. There are as yet no therapeutic drugs that act specifically by modifying glycine receptors.

Tetanus toxin, a bacterial toxin resembling **botulinum toxin** (see **Ch. 14**), acts selectively to prevent glycine release from inhibitory interneurons in the spinal cord, causing excessive reflex hyperexcitability and violent muscle spasms (lockjaw). [13]

Glycine is removed from the extracellular space by two transporters, GlyT1 and GlyT2 (**Marques et al., 2020**). GlyT1 is located primarily on astrocytes and expressed throughout most regions of the CNS. GlyT2, on the other hand, is expressed on glycinergic neurons in the spinal cord, brain stem and cerebellum. The GlyT1 inhibitor **bitopertin** failed in phase III clinical trials for the treatment of negative symptoms of schizophrenia (see **Ch. 47**). GlyT2 inhibitors have been proposed as potential analgesics based on studies in animal models (**Vandenberg et al., 2014**).

Inhibitory amino acids: GABA and glycine

- GABA is the main inhibitory transmitter in the brain.
- It is present fairly uniformly throughout the brain; there is very little in peripheral tissues.
- GABA is formed from glutamate by the action of glutamic acid decarboxylase. Its action is terminated mainly by reuptake, but also by deamination, catalysed by GABA transaminase.
- There are two main types of GABA receptor: $GABA_A$ and $GABA_B$.
- $GABA_A$ receptors, which occur mainly postsynaptically, are directly coupled to chloride channels, the opening of which reduces membrane excitability.

- **Muscimol** is a specific $GABA_A$ agonist, and the convulsant **bicuculline** is an antagonist.
- Other drugs that interact with $GABA_A$ receptors and channels include:
  - benzodiazepines, which act at an allosteric binding site to facilitate the action of GABA;
  - convulsants such as **picrotoxin**, which block the anion channel;
  - neurosteroids, including endogenous progesterone metabolites;
  - CNS depressants, such as barbiturates and many general anaesthetic agents, which facilitate the action of GABA.
- $GABA_B$ receptors are heterodimeric G protein–coupled receptors. They cause pre- and postsynaptic inhibition by inhibiting Ca^{2+} channel opening and increasing K^+ conductance. **Baclofen** is a $GABA_B$ receptor agonist used to treat spasticity. $GABA_B$ antagonists are not in clinical use.
- Glycine is an inhibitory transmitter mainly in the spinal cord, acting on its own receptor, structurally and functionally similar to the $GABA_A$ receptor.
- The convulsant drug **strychnine** is a competitive glycine antagonist. Tetanus toxin acts mainly by interfering with glycine release.

Concluding Remarks

The study of amino acids and their receptors in the brain has been one of the most active fields of research in the past 30 years, and the amount of information available is prodigious. These signalling systems have been speculatively implicated in almost every kind of neurological and psychiatric disorder, and the pharmaceutical industry has put a great deal of effort into identifying specific ligands – agonists, antagonists, modulators, enzyme inhibitors, transport inhibitors – designed to influence them. While a large number of pharmacologically unimpeachable compounds have emerged, and many clinical trials have been undertaken, due to lack of efficacy and serious adverse effects, there have been few therapeutic breakthroughs. The optimistic view is that a better understanding of the particular functions of the many molecular subtypes of these targets, and the design of more subtype-specific ligands, will lead to future breakthroughs. Expectations have, however, undoubtedly dimmed in recent years.

QUESTIONS

QUESTION 38.1

One significant and much-studied component of synaptic plasticity which underpins learning and memory is long-term potentiation (LTP).

Which of the following is most likely to lead to an enhancement of LTP?

OPTIONS:

A. A long train of stimuli in the presynaptic neuron

B. Activation of postsynaptic receptors independent of presynaptic neurons

C. Dephosphorylation of (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors

D. A sustained postsynaptic depolarisation

E. Agents that block the synthesis or effects of nitric oxide

QUESTION 38.2

The therapeutic potential for ionotropic glutamate receptor antagonists is diverse including the reduction of brain damage following strokes and head injury, as well as in the treatment of epilepsy and Alzheimer's disease.

What is the major drawback to the therapeutic potential of ionotropic receptor antagonists?

OPTIONS:

A. An inability to penetrate the blood–brain barrier

B. The ubiquitous functions of glutamate

C. Hallucinatory side effects

D. A lack of receptor selectivity

E. A requirement to target allosteric not orthosteric sites

QUESTION 38.3

γ-Aminobutyric acid (GABA) is the main inhibitory transmitter in the brain.

Which of the following statements about GABA is correct?

OPTIONS:

A. The abundance of GABA is greatest in the grey matter.

B. GABA is formed from glutamate by the action of by the action of GABA transaminase.

C. The GAT3 transporter is responsible for the reuptake of GABA into nerve terminals.

D. $GABA_A$ receptors are primarily located postsynaptically and mediate both fast and tonic postsynaptic inhibition.

E. Benzodiazepines bind at the α/β interface of the GABA channel.

ANSWERS

ANSWER 38.1

RATIONALE:

A. LTP occurs following a short (conditioning) burst of high-frequency presynaptic stimulation. Long-term depression (LTD) is produced at some synapses by a longer train of stimuli at lower frequency.

B. 'Learning' can occur if synaptic strength is enhanced following simultaneous activity in both pre- and postsynaptic neurons. It does not occur if presynaptic activity fails to excite the postsynaptic neuron, or if the latter is activated independently, for instance by a different presynaptic input.

C. The response of postsynaptic AMPA receptors to glutamate is increased following phosphorylation of the AMPA receptor subunits by kinases such as Ca^{2+}/calmodulin-dependent protein kinase (CaMKII) and protein kinase C (PKC), thus enhancing their conductance.

D.

E. Nitric oxide may act as a retrograde messenger to reduce activation of the presynaptic nerve terminal.

CORRECT ANSWER WITH EXPLANATION:

D. A sustained postsynaptic depolarisation

At normal membrane potentials, the *N*-methyl-D-aspartate (NMDA) channel is blocked by Mg^{2+}. A sustained postsynaptic depolarisation produced by glutamate acting repeatedly on AMPA

receptors, removes the Mg^{2+} block, and NMDA receptor activation then allows Ca^{2+} to enter the cell.

ANSWER 38.2

RATIONALE:

A. Agents such as memantine which are lipid soluble are able to cross the blood–brain barrier.

B. The clinical success of these agents has been less than expected potentially due to the ubiquitous and multifunctional effects of glutamate.

C.

D. The main types and examples of ionotropic glutamate antagonists show selectivity for the main receptor types but generally not for specific subtypes.

E. The development of subunit selective negative allosteric modulators may be more effective and have fewer side effects than previous generations of orthosteric antagonists.

CORRECT ANSWER WITH EXPLANATION:

C. Hallucinatory side effects

Trials with NMDA antagonists and channel blockers have so far proved disappointing, and a serious drawback of these agents is their tendency to cause hallucinatory and other disturbances.

ANSWER 38.3

RATIONALE:

A. GABA is particularly abundant (about 10 μmol/g tissue) in the nigrostriatal system, but occurs at lower concentrations (2–5 μmol/g) throughout the grey matter.

B. GABA is formed from glutamate by the action of glutamic acid decarboxylase (GAD), an enzyme found only in GABA-synthesising neurons in the brain.

C. GAT1 is the predominant GABA transporter in the brain and is located primarily on GABAergic nerve terminals where it recycles GABA. GAT3 is located predominantly on astrocytes around the GABAergic synapse.

D.

E. GABA binds at each of the interfaces between the α and β subunits whereas benzodiazepines bind at the α/γ interface.

CORRECT ANSWER WITH EXPLANATION:

D. $GABA_A$ receptors mediate both fast and tonic postsynaptic inhibition.

The $GABA_A$ channel is selectively permeable to Cl^- and because the equilibrium membrane potential for Cl^- is usually negative to the resting potential, increasing Cl^- permeability hyperpolarises the cell as Cl^- ions enter, thereby reducing its excitability.

[1] Perampanel, a non-competitive AMPA receptor antagonist, has been approved for the treatment of epilepsy (**Ch. 45**). Memantine, an NMDA antagonist, licensed for the treatment of moderate to severe Alzheimer's disease (**Ch. 40**), has been used for some time, as has the dissociative anaesthetic ketamine, an NMDA channel blocker (**Ch. 41**). Ketamine has also been found to have rapid-acting antidepressant effects (**Ch. 37**).

[2] In the past, AMPA and kainate receptors were often lumped together as AMPA/kainate or non-NMDA receptors, but molecular studies revealed distinct subunit compositions and they should not

be grouped together (see Collingridge and Abraham, 2022, for a recent review and discussion of the role of key scientists in this field).

[3] An international committee has sought to bring order to the area but, despite the logic of their recommendations, how generally accepted they will be remains to be seen (see Bettler et al., 2019, and www.guidetopharmacology.org). Scientists can get very stuck in their ways.

[4] In the CNS, presynaptic ligand-gated ion channels such as kainate and NMDA receptors as well as nicotinic and P2X receptors (see Ch. 39) modulate neurotransmitter release. An explanation of how this control can be either facilitatory or inhibitory is given in Schicker et al. (2008).

[5] Surprising, because it is the 'wrong' enantiomer for amino acids of higher organisms. Nevertheless, vertebrates possess specific enzymes and transporters for this D-amino acid, which is abundant in the brain.

[6] It has been suggested that mGlu receptors may form heterodimers with non mGlu receptors such as the 5-HT_{2A} receptor (**González-Maeso et al., 2008**).

[7] In 2016, Bliss, Collingridge and Morris won the 'Brain Prize' for their seminal work on understanding memory including the role of LTP. See Bliss and Collingridge (2019) for a description of their research into LTP and the growing evidence that LTP is impaired in numerous neurological and psychiatric disorders.

[8] Fragile X syndrome is caused by mutation of a single gene on the X chromosome. It affects about 1:4000 children of either sex, causing intellectual disability, autism and motor disturbances.

[9] Piracetam is an uncontrolled substance sold in the United States as a dietary supplement with a growing market developing for nootropic supplements and more potent ampakines for 'holistic brain hacking'.

[10] It has been suggested that GABA can also be synthesised in the brain from putrescine by the action of diamine oxidase and aldehyde dehydrogenase.

[11] The IUPHAR Nomenclature Committee has recommended (see Belelli et al., 2019) that the receptors previously referred to as '$GABA_C$' receptors, because they were insensitive to bicuculline, benzodiazepines and baclofen, should be subtypes of the $GABA_A$ receptor family as they are pentameric Cl^--permeable ligand-gated channels comprising homo- or heteromeric assemblies of ? subunits. They are referred to as $GABA_A$-rho or $GABA_A$-? receptors. Their pharmacology and functional significance is slowly being worked out (see Naffaa et al., 2017).

[12] During early brain development (in which GABA plays an important role), and also in some regions of the adult brain, GABA has an excitatory rather than an inhibitory effect, because the intracellular Cl^-concentration is relatively high, so that the equilibrium potential is positive to the resting membrane potential.

[13] Botulinum toxin (also known as botox), then tetanus toxin, hold the prize for the two deadliest substances, with LD_{50}s of ~1 and 3 ng/kg. That means 1 g of each is enough to kill over 8 million

people, or 975 g could potentially wipe out the entire global population!!

39: Other transmitters and modulators

OVERVIEW

The principal ‘amine’ transmitters in the central nervous system (CNS), namely noradrenaline, dopamine, 5-hydroxytryptamine (5-HT, serotonin) and acetylcholine (ACh), are described in this chapter, with briefer coverage of other mediators, including histamine, melatonin and purines. The monoamines were the first CNS transmitters to be identified, and during the 1960s a combination of neurochemistry and neuropharmacology led to many important discoveries about their role, and about the ability of drugs to influence these systems. Amine mediators differ from the amino acid transmitters discussed in **Chapter 38** in being localised to small populations of neurons with cell bodies in localised nuclei, which project diffusely both rostrally to cortical and other areas and in some cases caudally to the spinal cord. These amine-containing neurons are broadly associated with modulation of the primary excitatory or inhibitory signal rather than with localised synaptic excitation or inhibition. [1] More recently, ‘gaseotransmitters’ – such as nitric oxide (NO), carbon dioxide and hydrogen sulfide (see **Ch. 19**) – and endocannabinoids (see **Ch. 18**) have come on the scene, and they are discussed at the end of the chapter. The other major class of CNS mediators, the neuropeptides (e.g. endorphins,

neurokinins and orexins), appear in later chapters in this section.

Introduction

Although we know much about the many different mediators, their cognate receptors and signalling mechanisms at the cellular level, when describing their effects on brain function and behaviour, we fall back on relatively crude terms – psychopharmacologists will be at our throats for so under-rating the sophistication of their measurements – such as 'motor coordination', 'arousal', 'cognitive impairment' and 'exploratory behaviour'. The gap between these two levels of understanding still frustrates the best efforts to link drug action at the molecular level to drug action at the therapeutic level. Modern approaches, such as the use of genetically altered animal technologies (see **Ch. 8**) and non-invasive imaging techniques, are helping to forge links, but there is still a long way to go.

More detail on the content of this chapter can be found in **Iversen et al. (2009)** and **Nestler et al. (2020)**.

Noradrenaline

The basic processes responsible for the synthesis, storage and release of noradrenaline are the same in the CNS as in the periphery (see **Ch. 15**). In the CNS, inactivation of released noradrenaline is by neuronal reuptake or by metabolism, largely through the *monoamine oxidase*, *aldehyde reductase* and *catechol*-O-*methyl*

transferase mediated pathway to 3-hydroxy-4-methoxyphenylglycol (MHPG) (see **Fig. 15.3**).

Noradrenergic Pathways in the Cns

Although the transmitter role of noradrenaline in the brain was suspected in the 1950s, detailed analysis of its neuronal distribution became possible only when a technique, based on the formation of fluorescent catecholamine derivatives when tissues are exposed to formaldehyde, was devised by Falck and Hillarp. Detailed maps of the pathway of noradrenergic, dopaminergic and serotonergic neurons in laboratory animals were produced and later confirmed in human brains. The cell bodies of noradrenergic neurons occur in small clusters in the *pons* and *medulla*, and they send extensively branching axons to many other parts of the brain and spinal cord (**Fig. 39.1**). The most prominent cluster is the locus coeruleus (LC), located in the pons. Although it contains only about 10,000 neurons in humans, the axons, running in a discrete *medial forebrain bundle*, give rise to many millions of noradrenergic nerve terminals throughout the cortex, hippocampus, thalamus, hypothalamus and cerebellum (**Robertson et al., 2013**). These nerve terminals do not form distinct synaptic contacts but appear to release transmitter somewhat diffusely. The LC also projects to the spinal cord and is involved in the descending control of pain (see **Ch. 43**).

Other noradrenergic neurons lie close to the LC in the pons and project to the amygdala, hypothalamus, hippocampus and other parts of the forebrain, as well as to the spinal cord. A small cluster of adrenergic neurons, which release adrenaline rather than

noradrenaline, lies more ventrally in the brain stem. These cells contain phenylethanolamine *N*-methyl transferase, the enzyme that converts noradrenaline to adrenaline (see **Ch. 15**), and project mainly to the pons, medulla and hypothalamus. Rather little is known about them, but they are believed to be important in cardiovascular control.

Functional Aspects

Noradrenergic innervation occurs in most brain regions particularly cortical, hippocampal and hypothalamic areas and modulates a diverse range of functions from homeostasis e.g. food intake, thermogenesis, to cognitive and emotional behaviours. With the exception of the β_3 adrenoceptor, all of the adrenoceptors (α_{1A}, α_{1B}, α_{1D}, α_{2A}, α_{2B}, α_{2C}, β_1 and β_2) [2] are expressed in the CNS (see **Waterhouse and Navarra, 2019**).). They are G protein–coupled receptors that interact with a variety of effector mechanisms (see **Table 15.1**). The role of α_1 receptors in the CNS is poorly understood. They are widely distributed, located both on postsynaptic neurons and on glial cells, and may be involved in motor control, cognition and fear. α_2 Adrenoceptors are located on noradrenergic neurons (in both somatodendritic and nerve terminal regions where they function as inhibitory autoreceptors activated by locally released noradrenaline), as well as on postsynaptic non-noradrenergic neurons. They are involved in blood pressure control (see later), sedation (α_2 agonists such as **medetomidine** are used as anaesthetics in veterinary practice) and analgesia. β_1 Receptors are found in the cortex, striatum and hippocampus whereas β_2 receptors are largely found in the cerebellum. They have been

implicated in the long-term effects of antidepressant drugs but quite how remains a mystery (see **Ch. 48**).

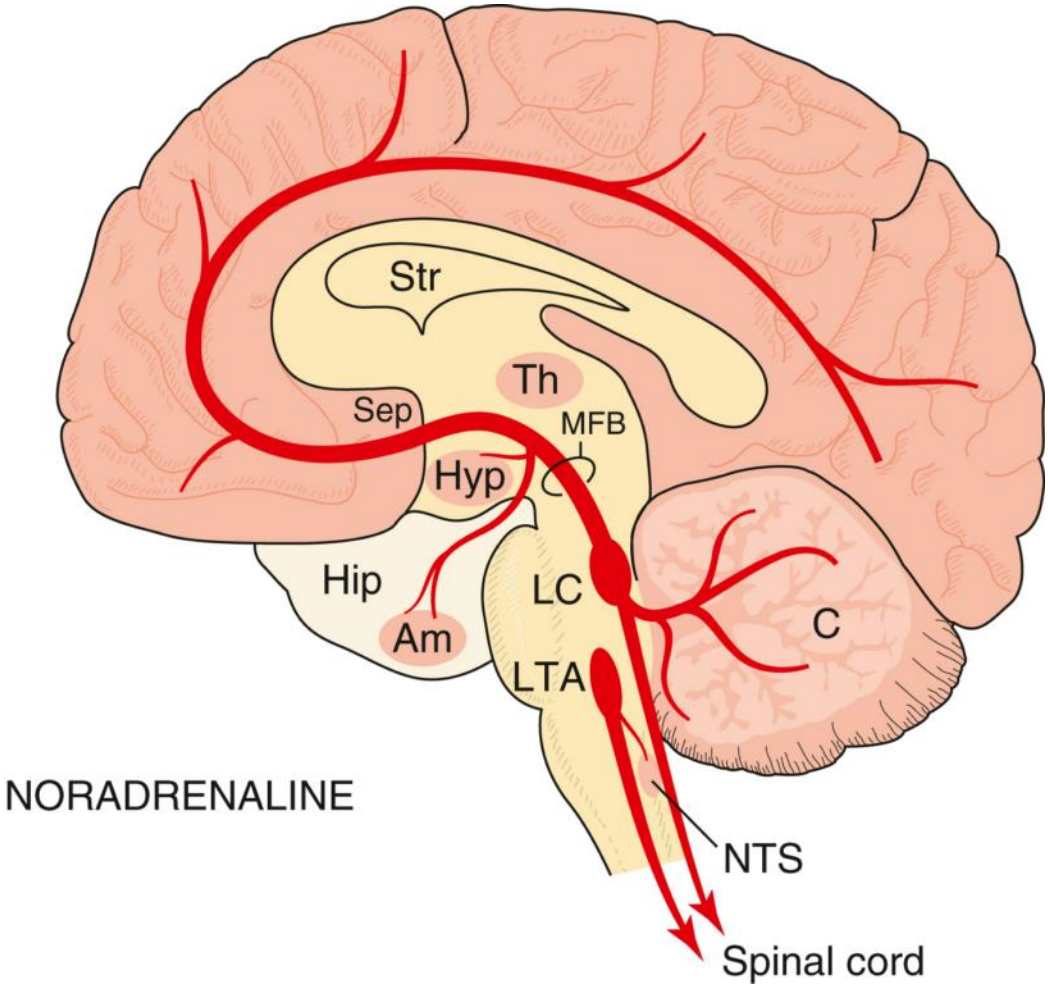

FIG. 39.1 Simplified diagram of the noradrenaline pathways in the brain.The location of the main groups of cell bodies and fibre tracts is in *solid colour*. *Light-shaded areas* show the location of noradrenergic terminals. *Am,* Amygdaloid nucleus; *C,* cerebellum; *Hip,* hippocampus; *Hyp,* hypothalamus; *LC,* locus coeruleus; *LTA,* lateral tegmental area, part of the reticular formation; *MFB,* medial forebrain bundle; *NTS,* nucleus of the tractus solitarius (vagal sensory nucleus); *Sep,* septum; *Str,* corpus striatum; *Th,* thalamus.

Arousal and mood

Attention has focused mainly on the LC, which is the source of most of the noradrenaline released in the brain, and from which neuronal activity can be measured by implanted electrodes. LC neurons are silent during sleep, and their activity increases with behavioural arousal. 'Wake-up' stimuli of an unfamiliar or threatening kind excite these neurons much more effectively than familiar stimuli. Amphetamine-like drugs, which release catecholamines in the brain, increase wakefulness, alertness and exploratory activity (although, in this case, firing of LC neurons is actually reduced by feedback mechanisms; see **Ch. 48**). In contrast, activation of somatodentritic α_2 autoreceptors in the LC leads to sedation.

There is a close relationship between mood and state of arousal, and the ability of noradrenaline to directly alter 5-HT activαity (via α_1-adrenoceptors in the raphe) means that any treatment which alters noradrenaline levels will also impact on 5-HT (**Ch. 48**). The role of noradrenaline and dopamine in attentional processes is also thought to be important in the efficacy of treatments for attention deficit hyperactivity disorder (ADHD) (**Ch. 49**).

Blood pressure regulation

The role of central, as well as peripheral, noradrenergic synapses in blood pressure control is shown by the action of hypotensive drugs such as **clonidine** and **methyldopa** (see Chs **15** and **21**), which decrease the discharge of sympathetic nerves emerging from the CNS. They cause hypotension when injected locally into the medulla or fourth ventricle, in much smaller amounts than are required

when the drugs are given systemically. Noradrenaline and other α_2-adrenoceptor agonists have the same effect when injected locally. Noradrenergic synapses in the medulla probably form part of the baroreceptor reflex pathway, because stimulation or antagonism of α_2 adrenoceptors in this part of the brain has a powerful effect on the activity of baroreceptor reflexes.

Ascending noradrenergic fibres run to the hypothalamus, and descending fibres run to the lateral horn region of the spinal cord, acting to increase sympathetic discharge in the periphery. It has been suggested that these regulatory neurons may release adrenaline rather than noradrenaline as inhibition of phenylethanolamine *N*-methyl transferase, the enzyme that converts noradrenaline to adrenaline, interferes with the baroreceptor reflex.

Noradrenaline in the central nervous system

- The mechanisms for synthesis, storage, release and reuptake of noradrenaline in the central nervous system (CNS) are essentially the same as in the periphery, as are the receptors (see **Ch. 15**).
- Noradrenergic cell bodies occur in discrete clusters, mainly in the pons and medulla, one important such cell group being the LC.
- Noradrenergic pathways, running mainly in the medial forebrain bundle and descending spinal tracts, terminate

diffusely in the cortex, hippocampus, hypothalamus, cerebellum and spinal cord.

- The actions of noradrenaline are mediated through α_1, α_2, β_1 and β_2 adrenoceptors.
- Noradrenergic transmission is believed to be important in:
  - the 'arousal' system, controlling wakefulness and alertness;
  - blood pressure regulation;
  - control of mood and cognition (functional deficiency contributing to depression).
- Psychotropic drugs that act partly or mainly on noradrenergic transmission in the CNS include antidepressants and **amphetamine.** Some antihypertensive drugs (e.g. **clonidine**, **methyldopa**) act mainly on noradrenergic transmission in the CNS.

Dopamine

Drugs which modulate dopamine transmission are important in the treatment of several common disorders of brain function, notably Parkinson's disease, schizophrenia and attention deficit disorder, as well as in drug dependence and certain endocrine disorders.

The distribution of dopamine in the brain is more restricted than that of noradrenaline. Dopamine is most abundant in the *corpus striatum*, a part of the extrapyramidal motor system concerned with the coordination of movement (see **Ch. 40**), and high concentrations also occur in certain parts of the frontal cortex,

limbic system and hypothalamus (where its release into the pituitary blood supply inhibits secretion of prolactin; see **Ch. 33**).

The synthesis of dopamine follows the same route as that of noradrenaline (see **Fig. 15.1**), namely conversion of tyrosine to dopa (the rate-limiting step), followed by decarboxylation to form dopamine. Dopaminergic neurons do not express dopamine β-hydroxylase, and thus do not convert dopamine to noradrenaline.

Dopamine is largely recaptured, following its release from nerve terminals, by a specific dopamine transporter, one of the large family of monoamine transporters (see **Ch. 15**). It is metabolised by monoamine oxidase and catechol-*O*-methyl transferase (**Fig. 39.2**), the main products being *dihydroxyphenylacetic acid* (DOPAC) and *homovanillic acid* (HVA), the methoxy derivative of DOPAC. The brain content of HVA is often used in animal experiments as an index of dopamine turnover. Drugs that cause the release of dopamine increase HVA, often without changing the content of dopamine. DOPAC and HVA, and their sulfate conjugates, are excreted in the urine, which provides an index of dopamine release in human subjects.

6-Hydroxydopamine, which selectively destroys dopaminergic nerve terminals, is used as a research tool. It is taken up by the dopamine transporter and converted to a reactive metabolite that causes oxidative cytotoxicity.

Dopaminergic Pathways in the CNS

There are four main dopaminergic pathways in the brain (**Fig. 39.3**):

1. The **nigrostriatal pathway**, accounting for about 75% of the dopamine in the brain, consists of cell bodies largely in the substantia nigra whose axons terminate in the corpus striatum. These fibres run in the medial forebrain bundle along with other monoamine-containing fibres. The abundance of dopamine-containing neurons in the human striatum can be appreciated from the image shown in **Fig. 39.4**, which was obtained by injecting a dopa derivative containing radioactive fluorine, and scanning for radioactivity 3 h later by positron emission tomography (PET) scanning.
2. The **mesolimbic pathway**, whose cell bodies occur in the midbrain ventral tegmental area (VTA), adjacent to the substantia nigra, and whose fibres project via the medial forebrain bundle to parts of the limbic system, especially the *nucleus accumbens* and the *amygdaloid nucleus*.

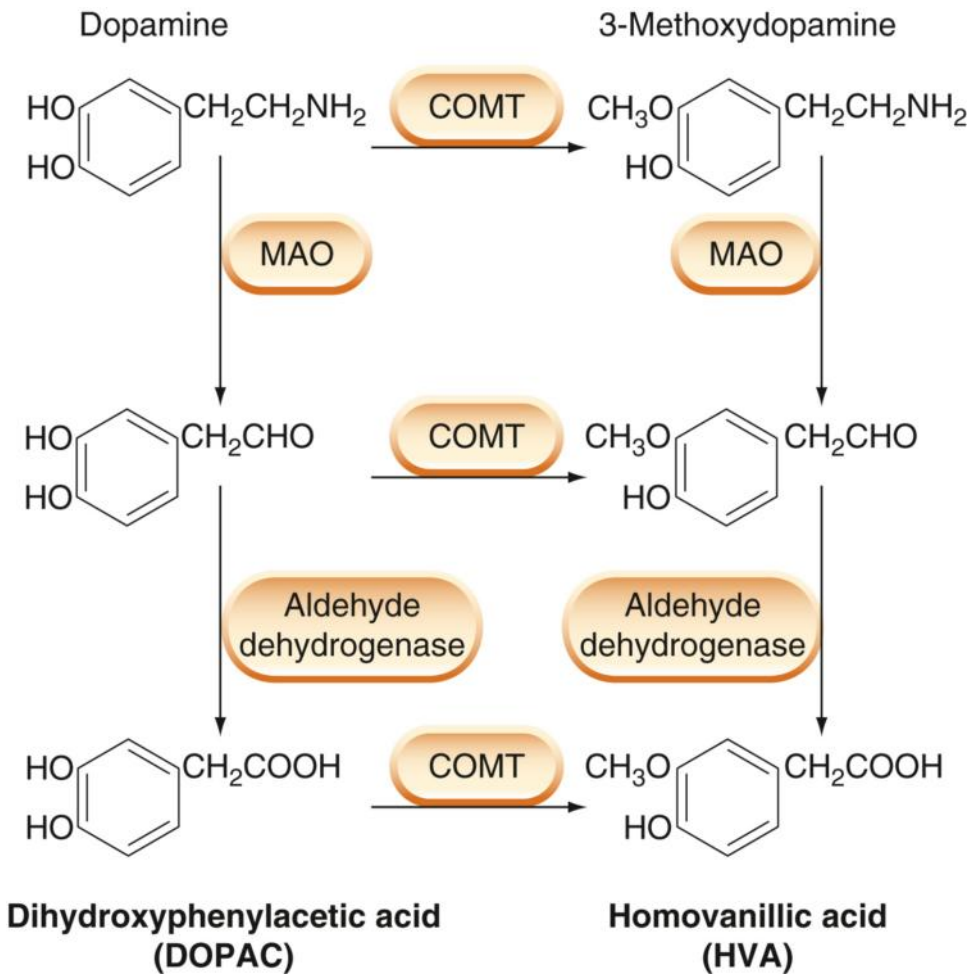

FIG. 39.2 The main pathways for dopamine metabolism in the brain. *COMT,* Catechol-*O*-methyl transferase; *MAO,* monoamine oxidase.

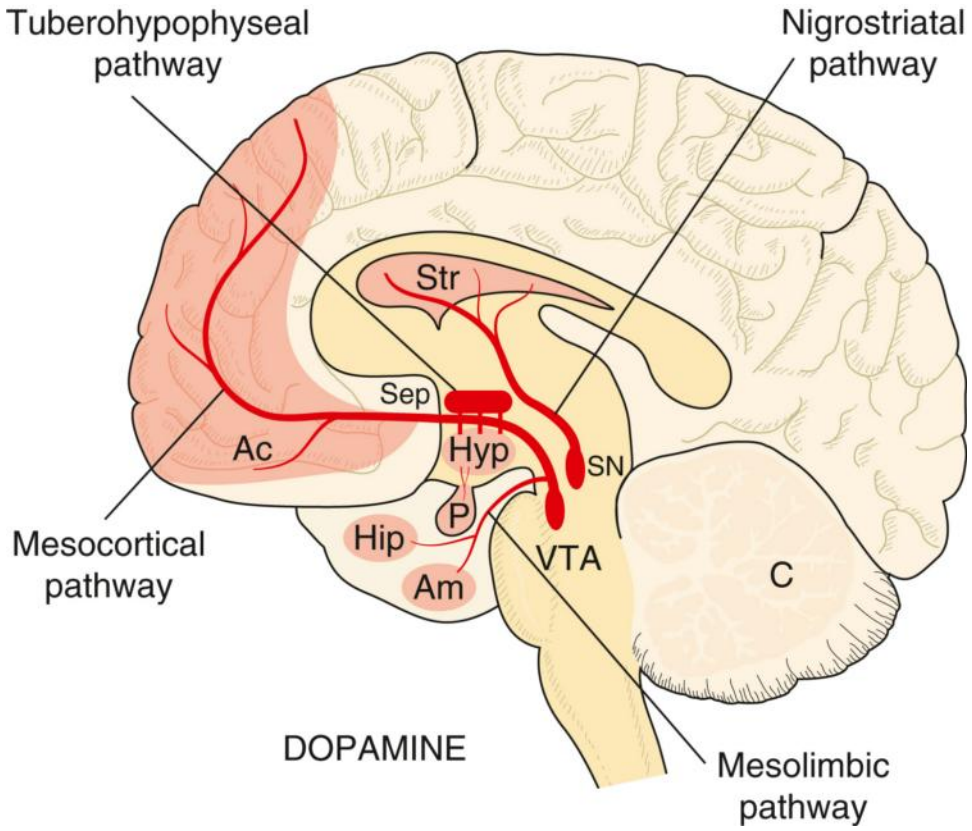

FIG. 39.3 Simplified diagram of the dopamine pathways in the brain, drawn as in Fig. 39.1.The pituitary gland (P) is shown, innervated with dopaminergic fibres from the hypothalamus. *Ac,* Nucleus accumbens; *SN,* substantia nigra; *VTA,* ventral tegmental area; other abbreviations as in Fig. 39.1.

3. The **mesocortical pathway**, whose cell bodies also lie in the VTA and which project via the medial forebrain bundle to the frontal cortex.
4. The **tuberohypophyseal** (or **tuberoinfundibular**) system is a group of short neurons running from the ventral

hypothalamus to the median eminence and pituitary gland, the secretions of which they regulate.

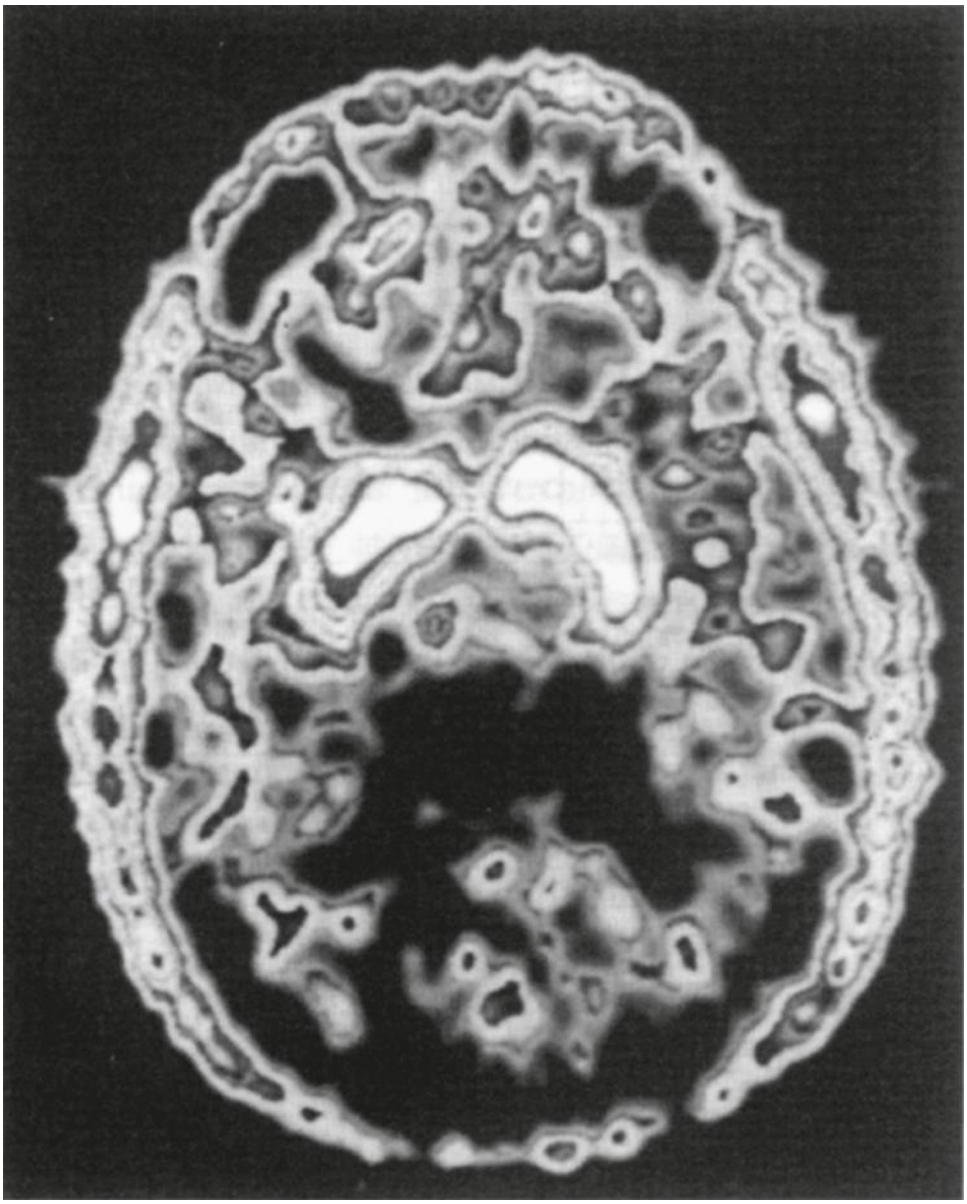

FIG. 39.4 Dopamine in the basal ganglia of a human subject.The subject was injected with 5-fluoro-dopa labelled with the positron-emitting isotope ^{18}F, which was localised 3 h later by the technique of positron emission tomography. The isotope is accumulated *(white areas)* by the dopa uptake system of the neurons of the basal

ganglia, and to a smaller extent in the frontal cortex. It is also seen in the scalp and temporalis muscles. From Garnett, E.S., Firnau, G., Nahmias, C., 1983. Dopamine visualized in the basal ganglia of living man. Nature 305, 137–138.

There are also dopaminergic neurons in other brain regions and in the retina. For a more complete description, see **Björklund and Dunnett (2007)**. The functions of the main dopaminergic pathways are discussed later.

Dopamine Receptors

Two types of receptors, D_1 and D_2, were originally distinguished on pharmacological and biochemical grounds. Gene cloning revealed further subgroups, D_1 to D_5. The original D_1 family now includes D_1 and D_5, while the D_2 family consists of D_2, D_3 and D_4 (**Table 39.1**). Splice variants, leading to long and short forms of D_2, and genetic polymorphisms, particularly of D_4, have subsequently been identified (see **Beaulieu and Gainetdinov, 2011**).

All belong to the family of G protein–coupled transmembrane receptors described in **Chapter 3**. D_1 and D_5 receptors link through G_s to stimulate adenylyl cyclase and activate protein kinase A (PKA). PKA mediates many of the effects of D_1 and D_5 receptors by phosphorylating a wide array of proteins, including voltage-activated sodium, potassium and calcium channels, as well as ionotropic glutamate and GABA receptors. D_2, D_3, and D_4 receptors link through G_i/G_o and activate potassium channels as well as

inhibiting calcium channels and adenylyl cyclase, and can also affect other cellular second messenger cascades (see **Ch. 3**). When intracellular cAMP is increased through activation of D_1 receptors, activating PKA, DARPP-32 (a *cAMP-regulated phosphoprotein* also known as *protein phosphatase 1 regulatory subunit 1B*) is phosphorylated. Phosphorylated DARPP-32 inhibits protein phosphatase-1, thus acting in concert with protein kinases as an amplifying mechanism favouring protein phosphorylation. In general, activation of D_2 receptors opposes the effects of D_1 receptor activation.

Dopamine receptors are expressed in the brain in distinct but overlapping areas. D_1 receptors are the most abundant and widespread in areas receiving a dopaminergic innervation (namely the striatum, limbic system, thalamus and hypothalamus; see **Fig. 39.3**), as are D_2 receptors, which also occur in the pituitary gland. D_2 receptors are found not only on dopaminergic neurons (on the soma, dendrites and nerve terminals), where they function as inhibitory autoreceptors activated by locally released dopamine, but also on glutamatergic, GABAergic and cholinergic nerve terminals (see **De Mei et al., 2009**). D_3 receptors occur in the limbic system but not in the striatum. The D_4 receptor is much more weakly expressed, mainly in the cortex and limbic systems.

Dopamine receptors also mediate various effects in the periphery (mediated by D_1 receptors), notably renal vasodilatation and increased myocardial contractility (dopamine itself has been used clinically in the treatment of circulatory shock; see **Ch. 23**).

Functional Aspects

The functions of dopaminergic pathways divide broadly into:

- motor control (nigrostriatal system)
- behavioural and cognitive effects (mesolimbic and mesocortical systems)
- endocrine control (tuberohypophyseal system)

Dopamine and motor systems

Ungerstedt showed, in 1968, that bilateral ablation of the substantia nigra in rats, which destroys the nigrostriatal neurons, causes profound catalepsy, the animals becoming so inactive that they die of starvation unless artificially fed. Parkinson's disease (see **Ch. 40**) is a disorder of motor control, associated with a deficiency of dopamine in the nigrostriatal pathway.

In treating CNS disorders, it is often desired that a certain receptor type be activated or inhibited only in one part of the brain, but the problem is that drugs are rarely brain-region selective and will affect a given receptor type throughout the brain. For example, many antipsychotic drugs (see **Ch. 47**) are D_2 receptor antagonists, exerting a beneficial effect by blocking D_2 receptors in the mesolimbic pathway. However, their D_2 antagonist property also gives rise to their major side effect, which is to cause movement disorders, by simultaneously blocking D_2 receptors in the nigrostriatal pathway.

Behavioural effects

Administration of **amphetamine** to rats, which releases both dopamine and noradrenaline, causes a cessation of normal 'ratty' behaviour (exploration and grooming), and the appearance of

repeated ‘stereotyped’ behaviour (rearing, gnawing and so on) unrelated to external stimuli. These amphetamine-induced motor disturbances in rats probably reflect hyperactivity in the nigrostriatal dopaminergic system, and are prevented by dopamine antagonists and by destruction of dopamine-containing cell bodies in the midbrain, but not by drugs that inhibit the noradrenergic system.

Table 39.1

Ant, Antagonist; *FA,* full agonist; *PA,* partial agonist.

[a] Agonists generally exhibit lower potency at D_1 and D_5 receptors compared with D_2, D_3 and D_4 receptors.

Data based on that contained in the IUPHAR/BPS Guide to Pharmacology database **www.guidetopharmacology.org**.

Amphetamine and **cocaine** have direct effects on mesolimbic dopamine due to their inhibition of the dopamine transporter but other drugs of abuse (see Chs **49** and **50**) have also been shown to indirectly activate mesolimbic dopaminergic ‘reward’ pathways to produce feelings of euphoria in humans, e.g. disinhibition of GABAergic interneurons in the VTA by mu-opioid receptor agonists. The main receptor involved appears to be D_1, and genetically altered mice lacking D_1 receptors behave as though generally demotivated, with reduced food intake and insensitivity to amphetamine and cocaine.

Neuroendocrine function

The tuberohypophyseal dopaminergic pathway (see **Fig. 39.3**) inhibits prolactin secretion via dopamine release. This system is of clinical importance. Many antipsychotic drugs (see **Ch. 47**), by blocking D_2 receptors, increase prolactin secretion and can cause breast development and lactation, even in males. **Bromocriptine**, a dopamine-receptor agonist derived from ergot, is used clinically to suppress prolactin secretion by tumours of the pituitary gland.

Growth hormone production is increased in normal subjects by dopamine, but bromocriptine paradoxically inhibits the excessive secretion responsible for acromegaly (probably because it desensitises dopamine receptors, in contrast to the physiological release of dopamine, which is pulsatile) and has a useful therapeutic effect, provided it is given before excessive growth has taken place. It is now rarely used, as other agents are more effective (see **Ch. 33**). Bromocriptine and other dopamine agonists, such as **cabergoline**, enhance libido and sexual performance.

Vomiting

Pharmacological evidence strongly suggests that dopaminergic neurons have a role in the production of nausea and vomiting. Thus nearly all dopamine-receptor agonists (e.g. bromocriptine) and **levodopa** (see **Ch. 40**) cause nausea and vomiting as side effects, while many dopamine antagonists (e.g. phenothiazines, **metoclopramide**; see **Ch. 30**) have antiemetic activity. D_2 receptors occur in the area of the medulla (the chemoreceptor trigger zone) associated with the initiation of vomiting (see **Ch. 30**) and are assumed to mediate this effect.

Dopamine in the central nervous system

- Dopamine is a neurotransmitter as well as being the precursor for noradrenaline. It is degraded in a similar fashion to noradrenaline, giving rise mainly to DOPAC and HVA, which are excreted in the urine.
- There are four main dopaminergic pathways:
  - nigrostriatal pathway, important in motor control;
  - mesolimbic pathway, running from groups of cells in the midbrain to parts of the limbic system, especially the nucleus accumbens, involved in emotion and drug-induced reward;
  - mesocortical pathway, running from the midbrain to the cortex, involved in emotion;
  - tuberohypophyseal neurons, running from the hypothalamus to the pituitary gland, whose secretions they regulate.
- There are five dopamine-receptor subtypes. D_1 and D_5 receptors are linked to stimulation of adenylyl cyclase. D_2, D_3 and D_4 receptors are linked to activation of K^+ channels and inhibition of Ca^{2+} channels as well as to inhibition of adenylyl cyclase.
- D_2 receptor antagonism has been implicated in treating the positive symptoms of schizophrenia.
- Parkinson's disease is associated with a loss of nigrostriatal dopaminergic neurons.

- Hormone release from the anterior pituitary gland is regulated by dopamine, especially prolactin release (inhibited) and growth hormone release (stimulated).
- Dopamine acts on the chemoreceptor trigger zone to cause nausea and vomiting.

5-Hydroxytryptamine

The occurrence and functions of 5-HT (serotonin) in the periphery are described in **Chapter 16**. Interest in 5-HT as a possible CNS transmitter dates from 1953, when Gaddum found that **lysergic acid diethylamide** (LSD), a powerful hallucinogen (see **Ch. 49**), acted as a 5-HT antagonist on peripheral tissues, [3] and suggested that its central effects might also be related to this action. The presence of 5-HT in the brain was demonstrated a few years later. Even though brain 5-HT accounts for only about 1% of the total body content, 5-HT is an important CNS transmitter (see **Iversen et al., 2009**). 5-HT is involved in various physiological processes, including sleep, appetite, thermoregulation and pain perception as well as in disorders such as migraine, depression, mania, anxiety, obsessive–compulsive disorders, schizophrenia, autism and drug abuse.

In its formation, storage and release, 5-HT resembles noradrenaline. Its precursor is tryptophan, an amino acid derived from dietary protein, the plasma content of which varies considerably according to food intake and time of day. 5-HT does not cross the blood–brain barrier and is synthesised in the CNS. Tryptophan is actively taken up into neurons, converted by

tryptophan hydroxylase to 5-hydroxytryptophan (see **Fig. 16.1**), and then decarboxylated by a non-specific amino acid decarboxylase to form 5-HT. Tryptophan hydroxylase can be selectively and irreversibly inhibited by ***p*-chlorophenylalanine** (PCPA). Availability of tryptophan and the activity of tryptophan hydroxylase are thought to be the main factors that regulate 5-HT synthesis. The decarboxylase is very similar, if not identical, to dopa decarboxylase, and does not play any role in regulating 5-HT synthesis. Following release, 5-HT is largely recovered by neuronal uptake, through a specific transporter (see **Ch. 3**) similar to, but not identical with, those that take up noradrenaline and dopamine. 5-HT reuptake is specifically inhibited by *selective serotonin reuptake inhibitors* (SSRIs) such as **fluoxetine** and, less specifically, by many of the drugs that inhibit catecholamine uptake (e.g. *tricyclic antidepressants*). SSRIs (see Chs **45** and **48**) constitute an important group of antidepressant and anxiolytic drugs. 5-HT is degraded almost entirely by monoamine oxidase (**Fig. 16.1**), which converts it to 5-hydroxyindole acetaldehyde, most of which is then dehydrogenated to form 5-hydroxyindole acetic acid (5-HIAA) and excreted in the urine.

5-HT Pathways in the CNS

The distribution of 5-HT-containing neurons (**Fig. 39.5**) resembles that of noradrenergic neurons. The cell bodies are grouped in the pons and upper medulla, close to the midline (raphe), and are often referred to as raphe nuclei. The rostrally situated nuclei project, via the medial forebrain bundle, to many parts of the cortex, hippocampus, basal ganglia, limbic system and hypothalamus. The

caudally situated cells project more to the cerebellum, medulla and spinal cord.

5-HT Receptors in the CNS

The main 5-HT receptor types are shown in **Table 16.1**. All are G protein–coupled receptors except for 5-HT_3, which is a ligand-gated cation channel (see later). All are expressed in the CNS, and their functional roles have been extensively analysed. With some 14 identified subtypes plus numerous splice variants, and a large number of pharmacological tools of relatively low specificity, assigning clear-cut functions to 5-HT receptors is not simple. Our present state of knowledge is described by **Sharp and Barnes (2020)**.

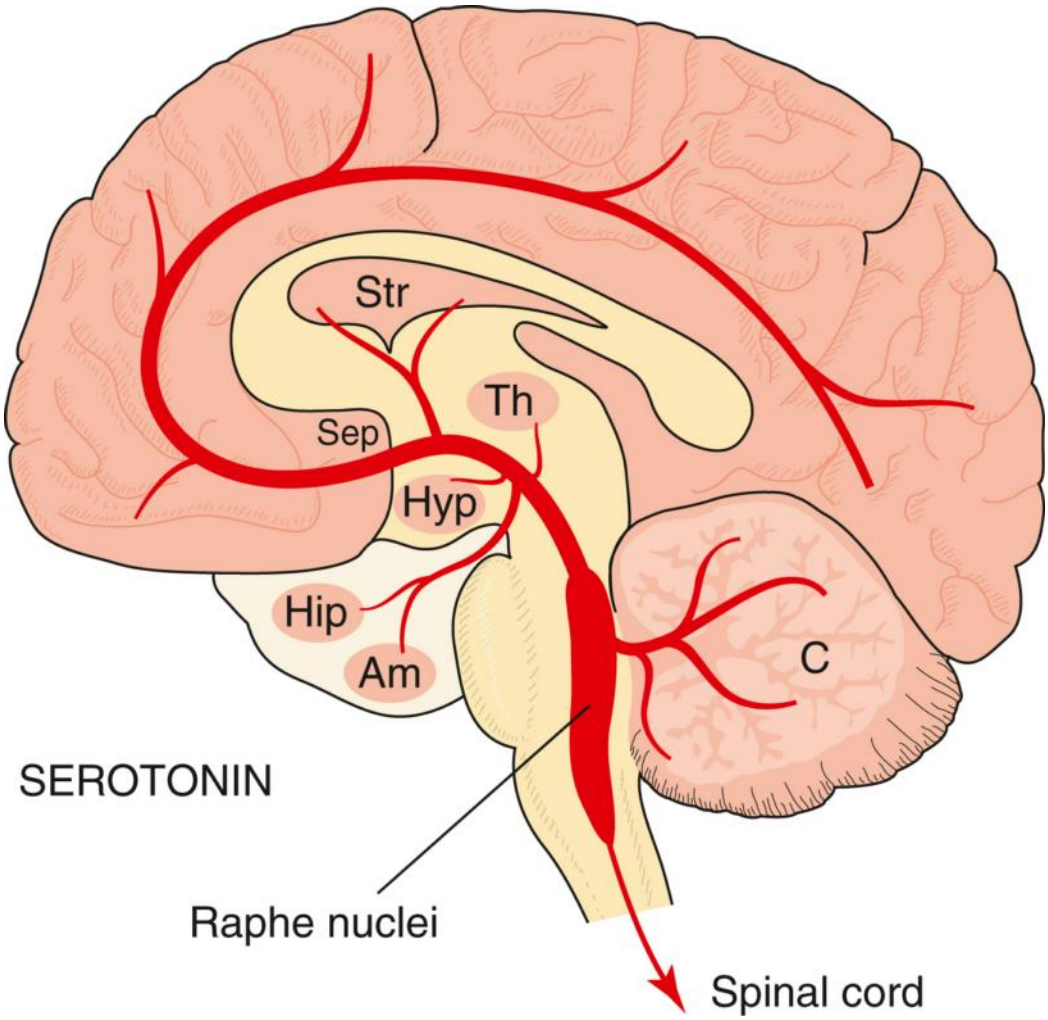

FIG. 39.5 Simplified diagram of the 5-hydroxytryptamine pathways in the brain, drawn as in Fig. 39.1.Abbreviations as in Fig. 39.1.

Certain generalisations can be made:

- 5-HT_1 receptors (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, 5-HT_{1F}) [3] are predominantly inhibitory in their effects. 5-HT_{1A} receptors are expressed on the soma and dendrites of 5-HT neurons in the raphe nuclei and are activated by locally released 5-HT. This inhibitory effect tends to limit the rate of firing of these cells. They are also widely distributed post-

synaptically in the limbic system and are believed to mediate the therapeutic effects of drugs used to treat anxiety and depression (see Chs **45** and **48**).

- 5-HT_{1B} and 5-HT_{1D} receptors are found mainly as presynaptic inhibitory receptors on both 5-HT-containing and other nerve terminals in the basal ganglia and cortex. Agonists acting on 5-HT_{1B} and 5-HT_{1D} receptors such as **sumatriptan** are used to treat migraine (see **Ch. 16**).
- 5-HT_2 receptors (5-HT_{2A}, 5-HT_{2B} and 5-HT_{2C}) are abundant in the cortex and limbic system, where they are located at both pre- and postsynaptic sites. They can exert excitatory or inhibitory effects by enhancing the release of glutamate and GABA. They are the target of some antidepressants (see **Ch. 48**) and antipsychotic drugs (see **Ch. 47**) as well as various hallucinogenic drugs (see **Ch. 49**). **Lorcaserin**, a 5-HT_{2C} agonist is an anti-obesity drug (see **Ch. 32**). The use of 5-HT_2 receptor antagonists such as **methysergide** in treating migraine is discussed in **Chapter 42**.
- 5-HT_3 receptors are pentameric ligand-gated cation channels that can be either homomeric or heteromeric complexes of different 5-HT_3 receptor subunits (see **Peters et al., 2005**). While 5-HT_{3A} and 5-HT_{3B} subunits are the most extensively studied, the roles of other subunits remain to be fully investigated (see **Jensen et al., 2008**). In the brain, 5-HT_3 receptors are found in the *area postrema* (a region of the medulla involved in vomiting; see **Ch. 30**) and other parts of the brain stem, extending to the dorsal horn of the spinal cord. They are also present in certain parts of the

cortex, as well as in the peripheral nervous system. They are excitatory ionotropic receptors, and specific antagonists (e.g. **granisetron** and **ondansetron**; see Chs **16** and **30**) are used to treat nausea and vomiting.

- 5-HT_4 receptors are important in the gastrointestinal (GI) tract (see Chs **16** and **31**), and are also expressed in the brain, particularly in the limbic system, basal ganglia, hippocampus and substantia nigra. They are located at both pre- and postsynaptic sites. They exert a presynaptic facilitatory effect, particularly on ACh release, thus enhancing cognitive performance (see Chs **40** and **49**). Activation of medullary 5-HT_4 receptors opposes the respiratory depressant actions of opioids (see **Ch. 43**).
- There are two 5-HT_5 receptors, 5-HT_{5A} and 5-HT_{5B}. In the human, only 5-HT_{5A} is functional. Antagonists may have anxiolytic, antidepressant and antipsychotic activity in animal models.
- 5-HT_6 receptors occur primarily in the CNS, particularly in the hippocampus, cortex and limbic system. Blockade of 5-HT_6 receptors increases glutamate and ACh release and $5HT_6$-antagonists are considered potential drugs to improve cognition or relieve symptoms of schizophrenia.
- 5-HT_7 receptors occur in the hippocampus, cortex, amygdala, thalamus and hypothalamus. They are found on the soma and axon terminals of GABAergic neurons. They are also expressed in blood vessels and the GI tract. Likely CNS functions include thermoregulation and endocrine regulation, as well as suspected involvement in mood,

cognitive function and sleep. The antipsychotic drug, **lurasidon**e (see **Ch. 47**), has slightly higher affinity for 5-HT_7 receptors than for D_2 receptors. Selective antagonists are being developed for clinical use in a variety of potential indications.

Functional Aspects

The precise localisation of 5-HT neurons in the brain stem has allowed their electrical activity to be studied in detail and correlated with direct neurochemical measures and behavioural and other effects produced by drugs thought to affect 5-HT-mediated transmission. 5-HT cells show an unusual, highly regular, slow discharge pattern, and are strongly inhibited by 5-HT_1 receptor agonists, suggesting a local inhibitory feedback mechanism.

In vertebrates, certain physiological and behavioural functions relate particularly to 5-HT pathways, namely:

- hallucinations and behavioural changes
- sleep, wakefulness and mood
- feeding behaviour
- control of sensory transmission (especially pain pathways; see **Ch. 43**)

Hallucinatory effects

Many hallucinogenic drugs (e.g. LSD; see **Ch. 49**) are agonists or partial agonists at 5-HT_{2A} receptors. It is suggested that a loss of cortical inhibition underlies the hallucinogenic effect. Many antipsychotic drugs (see **Ch. 47**) are antagonists at 5-HT_{2A} receptors in addition to blocking dopamine D_2 receptors. The

psychostimulant properties of **MDMA** (3,4-methylenedioxymethamphetamine, see **Ch. 49**) are due partly to its ability to release 5-HT. MDMA is taken up by the serotonin transporter, and displaces 5-HT from storage vesicles – a mechanism analogous to the action of amphetamine on noradrenergic nerve terminals (see **Ch. 15**).

Sleep, wakefulness and mood

Lesions of the raphe nuclei, or depletion of 5-HT by PCPA administration, abolish sleep in experimental animals, whereas microinjection of 5-HT at specific points in the brain stem induces sleep. 5-HT_7 receptor antagonists inhibit 'rapid-eye-movement' (REM) sleep and increase the latency to onset of REM sleep. Attempts to cure insomnia in humans by giving 5-HT precursors (tryptophan or 5-hydroxytryptophan) have, however, proved unsuccessful. There is strong evidence that 5-HT, as well as noradrenaline, may be involved in the control of mood (see **Ch. 48**), and the use of tryptophan to enhance 5-HT synthesis has been tried in depression, with equivocal results.

Feeding and appetite

In experimental animals, 5-HT_{1A} agonists such as 8-hydroxy-2-(di-n-propylamino)-tetralin (8-OH-DPAT) cause hyperphagia, leading to obesity. Antagonists acting on 5-HT_{2C} receptors, including several antipsychotic drugs used clinically, also increase appetite and cause weight gain. However, antidepressant drugs that inhibit 5-HT uptake (see **Ch. 48**) cause loss of appetite, as does the 5-HT_{2C} receptor agonist **lorcaserin**.

Sensory transmission

After lesions of the raphe nuclei or administration of PCPA, animals show exaggerated responses to many forms of sensory stimulus. They are startled much more easily, and also quickly develop avoidance responses to stimuli that would not normally bother them. It appears that the normal ability to disregard irrelevant forms of sensory input requires intact 5-HT pathways. The 'sensory enhancement' produced by hallucinogenic drugs may be partly due to loss of this gatekeeper function of 5-HT. 5-HT also exerts an inhibitory effect on transmission in the pain pathway, both in the spinal cord and in the brain, and there is a synergistic effect between 5-HT and analgesics such as **morphine** (see **Ch. 43**). Thus depletion of 5-HT by PCPA, or selective lesions to the descending 5-HT-containing neurons that run to the dorsal horn, antagonise the analgesic effect of morphine, while inhibitors of 5-HT uptake have the opposite effect.

Other roles

Other roles of 5-HT include various autonomic and endocrine functions, such as the regulation of body temperature, blood pressure and sexual function. Further information can be found in **Iversen et al. (2009)**.

Clinically Used Drugs

Several classes of drugs used clinically influence 5-HT-mediated transmission. They include:

- 5-HT reuptake inhibitors, such as fluoxetine, used as antidepressants (see **Ch. 48**) and anxiolytic agents (see **Ch.**

45)

- 5-HT_{1D} receptor agonists, such as sumatriptan, used to treat migraine (see **Ch. 42**)
- 5-HT_2 antagonists, such as **pizotifen**, used to treat migraine (see **Ch. 42**)
- 5-HT_{1A} receptor agonists have antidepressant and anxiolytic effects (see Chs **45** and **48**)
- 5-HT_3 receptor antagonists, such as ondansetron, used as antiemetic agents (see **Ch. 30**)
- antipsychotic drugs (e.g. clozapine, see **Ch. 47**), which owe their efficacy at least partly to an action on 5-HT_2 receptors

Acetylcholine

There are numerous cholinergic neurons in the CNS, and the basic processes by which ACh is synthesised, stored and released are the same as in the periphery (see **Ch. 14**). Various biochemical markers have been used to locate cholinergic neurons in the brain, the most useful being choline acetyltransferase, the enzyme responsible for ACh synthesis, and the transporters that capture choline and package ACh, which can be labelled by immunofluorescence. Biochemical studies on ACh precursors and metabolites are generally more difficult than corresponding studies on other amine transmitters, because the relevant substances, choline and acetate, are involved in many processes other than ACh metabolism.

Cholinergic Pathways in the CNS

ACh is very widely distributed in the brain, occurring in all parts of the forebrain (including the cortex), midbrain and brain stem,

although there is little in the cerebellum. Cholinergic neurons in the forebrain and brain stem send diffuse projections to many parts of the brain (**Fig. 39.6**). Cholinergic neurons in the forebrain lie in a discrete area, forming the magnocellular forebrain nuclei (so called because the cell bodies are conspicuously large). Degeneration of one of these, the *nucleus basalis of Meynert*, which projects mainly to the cortex, is associated with Alzheimer's disease (see **Ch. 40**). Another cluster, the *septohippocampal nucleus*, provides the main cholinergic input to the hippocampus, and is also involved in memory. In addition, there are – in contrast to noradrenaline, dopamine and 5-HT-containing pathways – many local cholinergic interneurons, particularly in the corpus striatum, these being important in relation to Parkinson's disease and Huntington's chorea (see **Ch. 40**).

Acetylcholine Receptors

ACh acts on both muscarinic (G protein–coupled) and nicotinic (ionotropic) receptors in the CNS (see **Ch. 14**).

The muscarinic ACh receptors (mAChRs) in the brain are predominantly of the G_q-coupled M_1 class (i.e. M_1, M_3 and M_5 subtypes; see **Ch. 14**). Activation of these receptors can result in excitation through blockade of M-type (KCNQ/Kv7) K^+ channels (see **Delmas and Brown, 2005**). G_i/G_o-coupled M_2 and M_4 receptors, however, are inhibitory through activation of inwardly rectifying K^+ channels and

5-Hydroxytryptamine in the central nervous system

- The processes of synthesis, storage, release, reuptake and degradation of 5-HT in the brain are very similar to events in the periphery (see **Ch. 16**).
- Activity of the rate limiting enzyme, tryptophan hydroxylase is the main factor regulating synthesis. As the precursor, tryptophan can only be obtained from the diet, there has been some suggestion that the availability of tryptophan may also be a factor and hence why some people use dietary supplements although evidence is limited.
- Urinary excretion of 5-hydroxyindole acetic acid provides a measure of 5-HT turnover.
- 5-HT neurons are concentrated in the midline raphe nuclei in the brain stem projecting diffusely to the cortex, limbic system, hypothalamus and spinal cord, similar to the noradrenergic projections.
- Functions associated with 5-HT pathways include:
  - various behavioural responses (e.g. hallucinatory behaviour, impulsivity)
  - feeding behaviour
  - control of mood and emotion
  - control of sleep/wakefulness
  - control of sensory pathways, including nociception
  - control of body temperature
  - vomiting
- 5-HT can exert inhibitory or excitatory effects on individual neurons, acting either presynaptically or postsynaptically and, through these receptors, interacts with many other

transmitter systems (**De Deurwaerdere and Di Giovanni, 2021**).

- The main receptor subtypes (see **Table 16.1**) in the CNS are 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{2A}, 5-HT_{2C} and 5-HT_3. Associations of behavioural and physiological functions with these receptors have been partly worked out. Other receptor types (5-$HT_{4–7}$) also occur in the CNS, but less is known about their function.
- Drugs acting selectively on 5-HT receptors or transporters include:
  - **buspirone**, a 5-HT_{1A} receptor partial agonist used to treat anxiety (see **Ch. 45**);
  - 'triptans' (e.g. **sumatriptan**), 5-HT_{1D} agonists used to treat migraine (see **Ch. 16**);
  - 5-HT_2 antagonists (e.g. **pizotifen**) used for migraine prophylaxis (see **Ch. 16**);
  - selective serotonin uptake inhibitors (e.g. **fluoxetine**) used to treat depression (see **Ch. 48**);
  - **ondansetron**, a 5-HT_3 antagonist, used to treat chemotherapy-induced emesis (see Chs **16** and **31**);
  - **MDMA** (ecstasy), a substrate for the 5-HT transporter. It then displaces 5-HT from nerve terminals onto 5-HT receptors to produce its mood-altering effects (see **Ch. 49**).

inhibition of voltage-sensitive Ca^{2+} channels. mAChRs on cholinergic terminals function to inhibit ACh release, and

muscarinic antagonists, by blocking this inhibition, markedly increase ACh release. Many of the behavioural effects associated with cholinergic pathways seem to be produced by ACh acting on mAChRs. Positive allosteric modulators (see **Ch. 2**) selective for different muscarinic receptors are under development.

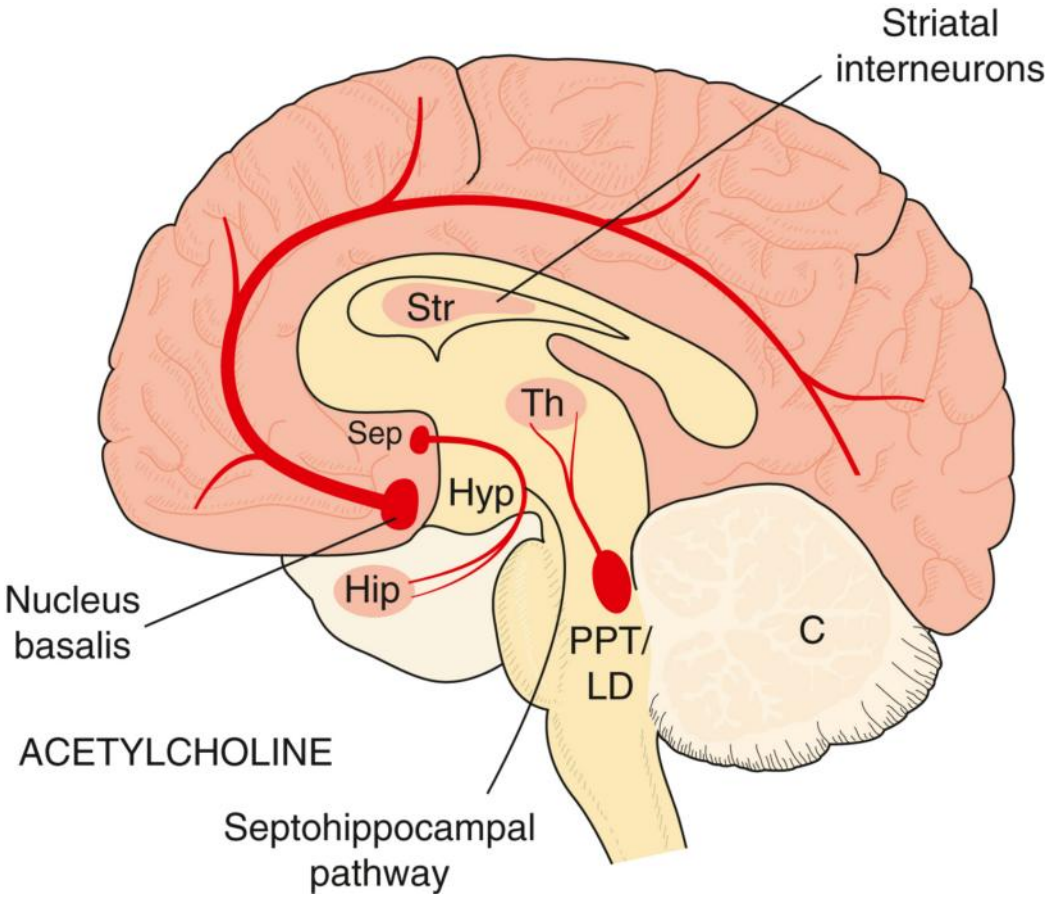

FIG. 39.6 Simplified diagram of the acetylcholine pathways in the brain, drawn as in Fig. 39.1. *PPT/LD,* Pedunculopontine and laterodorsal tegmental nuclei; other abbreviations as in Fig. 39.1.

Nicotinic ACh receptors (nAChRs) are ligand-gated cation channels permeable to Na^+, K^+ and Ca^{2+} ions (see Chs **3** and **14**). They are pentamers and can be formed as homomeric or heteromeric combinations of α (α2–7) and β (β2–4) subunits (see **Ch. 3**; see **Gotti et al., 2008**) distributed widely throughout the brain (**Table 39.2**). Nicotine (see **Ch. 49**) exerts its central effects by agonist action on nAChRs. The heteromeric α4β2 and the homomeric α7 subtypes are the most extensively characterised. Subtype-specific agonists and positive allosteric modulators have been developed but initial results from clinical trials for cognitive enhancement have so far not lived up to expectation.

nAChRs are located both pre- and postsynaptically. Presynaptic nAChRs act usually to facilitate the release of other transmitters such as glutamate, dopamine and GABA. [4] Postsynaptic nAChRs mediate fast excitatory transmission, as in the periphery (see **Ch. 14**).

Many of the drugs that block nAChRs (e.g. **tubocurarine**; see **Ch. 14**) do not cross the blood–brain barrier, and even those that do (e.g. **mecamylamine**) produce only modest CNS effects. Varenicline is a high-affinity partial agonist for the α4β2 nAChR subtype which regulates dopamine release in the mesolimbic pathway and is used to reduce craving in smoking cessation.

Functional Aspects

The main functions ascribed to cholinergic pathways are related to arousal, reward, learning and memory and motor control. The cholinergic projection from the ventral forebrain to the cortex is thought to mediate arousal, whereas the septohippocampal pathway

is involved in learning and short-term memory (see **Hasselmo, 2006**). Cholinergic interneurons in the striatum are involved in motor control (see **Ch. 40**).

Table 39.2

α7 may also form heteromeric receptors with β2 subunits. nAChRs comprising α2β2 and α3β3β4 are found in some other areas of the brain.

Data taken from Gotti, C., Zoli, M., Clementi, F., 2008. Brain nicotinic acetylcholine receptors: native subtypes and their relevance. Trends Pharmacol. Sci. 27, 482–491.

Muscarinic agonists have been shown to partially restore learning and memory deficits induced in experimental animals by lesions of the septohippocampal cholinergic pathway. **Hyoscine**, a muscarinic antagonist, impairs memory in human subjects and causes amnesia when used as preanaesthetic medication. Preliminary clinical studies suggest that another muscarinic antagonist, scopolamine, has rapid-acting antidepressant effects, possibly related to its amnesic effects (see **Ch. 48**).

Nicotine increases alertness and also enhances learning and memory, as do various synthetic agonists at neuronal nAChRs. Conversely, CNS-active nAChR antagonists such as mecamylamine cause detectable, although slight, impairment of learning and memory. In the dopaminergic VTA to accumbens ‘reward’ pathway, nicotine affects neuronal firing at the level of the cell soma in the VTA and modulates dopamine release from terminals in the nucleus

accumbens to modify dopamine release in this reward pathway (see **Ch. 50**).

The importance of cholinergic neurons in neurodegenerative conditions such as dementia and Parkinson's disease is discussed in **Chapter 40**. The role of nAChRs in addiction to nicotine is described in **Chapter 50** and their role in modulating pain transmission in the CNS is described in **Chapter 43**.

Acetylcholine in the central nervous system

- Synthesis, storage and release of ACh in the CNS are essentially the same as in the periphery (see **Ch. 14**).
- ACh is widely distributed in the CNS, important pathways being:
  - basal forebrain (magnocellular) nuclei, which send a diffuse projection to most forebrain structures, including the cortex;
  - septohippocampal projection;
  - short interneurons in the striatum and nucleus accumbens.
- Certain neurodegenerative diseases, especially dementia and Parkinson's disease (see **Ch. 41**), are associated with abnormalities in cholinergic pathways.
- Both nicotinic and muscarinic (predominantly M_1) ACh receptors occur in the CNS. The former mediate the central effects of nicotine. Nicotinic receptors are mainly located presynaptically; there are few examples of transmission mediated by postsynaptic nicotinic receptors.

- Muscarinic receptors appear to mediate the main behavioural effects associated with ACh, namely effects on arousal, and on learning and short-term memory.
- Muscarinic antagonists (e.g. **hyoscine**) cause amnesia.

In conclusion, both nAChRs and mAChRs may play a role in learning and memory, while nAChRs also mediate behavioural arousal. Genetically altered mice lacking expression of different cholinergic receptors show very limited impairments suggesting that alternative mechanisms may be able to compensate for the loss of ACh receptor signalling.

Purines

Both adenosine and ATP act as transmitters and/or modulators in the CNS (for review, see **Tozaki-Saitoh et al., 2011**; **Burnstock, 2018**) as they do in the periphery (see **Ch. 16**). Mapping the pathways is difficult, because purinergic neurons are not easily identifiable histochemically. It is likely that adenosine and ATP serve as neuromodulators.

Adenosine is produced intracellularly from ATP. It is not packaged into vesicles but is released mainly by carrier-mediated transport. Because the intracellular concentration of ATP (several mmol/L) greatly exceeds that of adenosine, conversion of a small proportion of ATP results in a large increase in adenosine. ATP is packaged into vesicles and released by exocytosis as a conventional transmitter but can also leak out of cells in large amounts under conditions of tissue damage. In high concentrations, ATP can act as

an excitotoxin (like glutamate; see **Ch. 40**) and cause further neuronal damage but it is also quickly converted to adenosine, which exerts a protective effect. These special characteristics of purine metabolism suggest that adenosine serves mainly as a safety mechanism, protecting the neurons from damage when their viability is threatened, for example by ischaemia or seizure activity. It has been suggested that adenosine deficiency may underlie a number of CNS disorders such as some epilepsies as well as Alzheimer's and Parkinson's diseases (**Boison and Aronica, 2015**).

Adenosine produces its effects through G protein–coupled adenosine A receptors (see **Ch. 16**). There are four adenosine receptors – A_1, A_{2A}, A_{2B} and A_3 – distributed throughout the CNS. The overall effect of adenosine, or of various adenosine receptor agonists, is inhibitory, leading to effects such as drowsiness and sedation, motor incoordination, analgesia and anticonvulsant activity. Xanthines, such as **caffeine** (see **Ch. 49**), which are antagonists at A_2 receptors, produce arousal and alertness.

For ATP there are two forms of receptor – P2X and P2Y receptors (see **Ch. 16** also). P2X receptor subunits (P2X1-7) are trimeric ligand-gated cation channels that can be homomeric or heteromeric in composition. The evidence in favour of ATP acting on postsynaptic P2X receptors mediating fast synaptic transmission in the brain remains weak. P2X receptors are located on the postsynaptic cell membrane away from sites of synaptic contact, on nerve terminals and on astrocytes. Like ACh at nicotinic receptors, ATP acting on nerve terminal P2X receptors appears to play a

neuromodulatory role. There are eight P2Y receptors [5] ; all are G protein coupled (see **Table 16.1**).

While there is little doubt that purinergic signalling plays a significant role in CNS function, our understanding is still very limited (**Burnstock, 2016**).

Histamine

Histamine is present in the brain in much smaller amounts than in other tissues, such as skin and lung, but undoubtedly serves a neurotransmitter role (see **Brown et al., 2001**). The cell bodies of histaminergic neurons, which also synthesise and release a variety of other transmitters, are restricted to a small part of the hypothalamus, and their axons run to virtually all parts of the brain. Unusually, no uptake mechanism for histamine is present, its action being terminated instead by enzymic methylation. Histamine's prolonged extracellular presence may explain its involvement in homeostatic process such as the sleep/wake cycle, food and water intake and temperature regulation.

Histamine acts on four types of receptors (H_{1-4}; see **Ch. 17**) in the brain. H_1–H_3 occur in most brain regions, H_4 has a more restricted distribution. All are G protein coupled – H_1 receptors to G_q, H_2 to G_s and H_3 and H_4 to G_i/G_o. H_3 receptors are inhibitory receptors on histamine-releasing neurons as well as on terminals releasing other neurotransmitters.

Like other monoamine transmitters, histamine is involved in many different CNS functions. Histamine release follows a distinct circadian pattern, the neurons being active by day and silent by night. H_1 receptors in the cortex and reticular activating system

contribute to arousal and wakefulness, and H_1 receptor antagonists that access the CNS produce sedation (see **Ch. 45**). Antihistamines are widely used to control nausea and vomiting, for example, in motion sickness and middle ear disorders, as well as to induce sleep. Recent pharmaceutical industry activity has centred on the development of selective H_3 receptor antagonists, as they may have potential for the treatment of cognitive impairment associated with Alzheimer's disease (see **Ch. 40**), schizophrenia (see **Ch. 47**), ADHD (see **Ch. 49**) and Parkinson's disease (see **Ch. 40**) as well as for the treatment of narcolepsy, obesity and pain states (**Hu and Chen, 2017**).

Other CNS Mediators

We now move from the familiar neuropharmacological territory of the 'classic' monoamines to some of the odder agents which challenge many of our preconceived ideas of how neurotransmission functions. Useful drugs interacting with some of these mediators are starting to be approved for clinical use.

Melatonin

Melatonin (*N*-acetyl-5-methoxytryptamine) (reviewed by **Dubocovich et al., 2010**) is synthesised exclusively in the pineal, an endocrine gland that plays a role in establishing circadian rhythms. The gland contains two enzymes, not found elsewhere, which convert 5-HT by acetylation and *O*-methylation to melatonin, its hormonal product.

There are two well-defined melatonin receptors (MT_1 and MT_2) which are G protein–coupled receptors – both coupling to G_i/G_o –

found mainly in the brain and retina but also in peripheral tissues (see **Jockers et al., 2016**). Another type (termed MT_3) has been suggested to be the enzyme quinone reductase 2 (QR2). The function of the interaction between melatonin and QR2 is unclear.

Melatonin secretion (in all animals studied, whether diurnal or nocturnal in their habits) is high at night and low by day. This rhythm is controlled by input from the retina via a noradrenergic retinohypothalamic tract that terminates in the suprachiasmatic nucleus (SCN) in the hypothalamus, a structure often termed the biological clock, which generates the circadian rhythm. Activation of MT_1 receptors inhibits neuronal firing in the SCN and prolactin secretion from the pituitary. Activation of MT_2 receptors phase shifts circadian rhythms generated within the SCN. Melatonin has antioxidant properties and may be neuroprotective in Alzheimer's disease and Parkinson's disease (see **Ch. 40**).

Given orally, melatonin is well absorbed but quickly metabolised, its plasma half-life being a few minutes. Based on its ability to reset the circadian clock, melatonin supplements has been promoted for various uses, such as controlling jet lag, improving the performance of night-shift workers, treating insomnia in the elderly and controlling sleep disorders in children with autism or as a consequence of psychostimulant use for ADHD. **Ramelteon**, an agonist at MT_1 and MT_2 receptors, is used to treat insomnia (see **Ch. 45**) and **agomelatine**, which also has agonist actions at MT_1 and MT_2 receptors as well as antagonist actions at $5\text{-}HT_{2C}$ receptors, is a novel antidepressant drug (see **Ch. 48**).

Nitric Oxide

NO as a peripheral mediator is discussed in **Chapter 19**. Its significance as an important chemical mediator in the nervous system has demanded a considerable readjustment of our views about neurotransmission and neuromodulation (for review, see **Chachlaki et al., 2017**). The main defining criteria for transmitter substances – namely that neurons should possess machinery for synthesising and storing the substance, that it should be released from neurons by exocytosis, that it should interact with specific membrane receptors and that there should be mechanisms for its inactivation – do not apply to NO. Moreover, it is an inorganic gas, not at all like the kind of molecule pharmacologists are used to. The mediator function of NO is now well established (**Zhou and Zhu, 2009**). NO diffuses rapidly through cell membranes, and its action is not highly localised. Its half-life depends greatly on the chemical environment, ranging from seconds in blood to several minutes in normal tissues. The rate of inactivation of NO (see **Ch. 19**) increases disproportionately with NO concentration, so low levels of NO are relatively stable. The presence of superoxide, with which NO reacts (see later), shortens its half-life considerably.

NO in the nervous system is produced mainly by the constitutive neuronal form of *NO synthase* (nNOS; see **Ch. 19**), which can be detected either histochemically or by immunolabelling. This enzyme is present in roughly 2% of neurons, both short interneurons and long-tract neurons, in virtually all brain areas, with particular concentrations in the cerebellum and hippocampus. It occurs in cell bodies and dendrites, as well as in axon terminals, suggesting that NO may be produced both pre- and postsynaptically. nNOS is calmodulin dependent and is activated by a rise in

intracellular Ca^{2+} concentration, which can occur by many mechanisms (see **Ch. 4**), including action potential conduction and neurotransmitter action, especially by glutamate activation of *N*-methyl-D-aspartate (NMDA) receptors. NO is not stored but released as it is made. Many studies have shown that NO production is increased by activation of synaptic pathways, or by other events, such as brain ischaemia (see **Ch. 40**).

NO exerts pre- and postsynaptic actions on neurons as well as acting on glial cells (**Garthwaite, 2008**). It produces its effects in two main ways:

1. By activation of soluble guanylyl cyclase, leading to the production of cGMP, which itself or through activation of protein kinase G can affect membrane ion channels (**Steinert et al., 2010**). This 'physiological' control mechanism operates at low NO concentrations of about 0.1 µmol/L.
2. By reacting with the superoxide free radical to generate peroxynitrite, a highly toxic anion that acts by oxidising various intracellular proteins. This requires concentrations of 1–10 µmol/L, which are achieved in brain ischaemia.

There is good evidence that NO plays a role in synaptic plasticity (see **Ch. 38**), because long-term potentiation and depression are reduced or prevented by NOS inhibitors and are absent in transgenic mice in which the *nNOS* gene has been disrupted.

Based on the same kind of evidence, NO is also believed to play an important part in the mechanisms by which ischaemia causes neuronal death (see **Ch. 40**). There is also evidence that it may be

involved in other processes, including neurodegeneration in Parkinson's disease, senile dementia and amyotrophic lateral sclerosis, and the local control of blood flow linked to neuronal activity.

Other 'gaseotransmitters'. These include carbon monoxide, hydrogen sulfide and, more recently, ammonia (see **Ch. 19** and **Wang, 2014**). While evidence is accumulating for their roles in CNS disorders, their pharmacology is still at a very preliminary stage.

Carbon monoxide (CO) is best known as a poisonous gas present in vehicle exhaust, which binds strongly to haemoglobin, causing tissue anoxia. However, it is also formed endogenously and has many features in common with NO. Neurons and other cells contain a CO-generating enzyme, haem oxygenase, and CO, like NO, activates guanylyl cyclase. There is some evidence that CO plays a role in memory mechanisms in the hippocampus (see **Cutajar and Edwards, 2007**).

Hydrogen sulfide (H_2S) has been postulated to be involved in learning, memory and pain perception but then again so has almost every other neurotransmitter or neuromodulator! It has been suggested that brain H_2S concentrations are lowered in Alzheimer's and Parkinson's diseases but the relevance of such observations still needs to be worked out.

Lipid Mediators

The formation of arachidonic acid, and its conversion to eicosanoids (mainly prostaglandins, leukotrienes and hydroxyeicosatetraenoic acids (HETEs) – see **Ch. 17**) and to endocannabinoids, anandamide

and 2-arachidonoylglycerol (see **Ch. 18**), also takes place in the CNS.

Phospholipid cleavage, leading to arachidonic acid production, occurs in neurons in response to receptor activation by many different mediators, including neurotransmitters. The arachidonic acid so formed can act directly as an intracellular messenger, controlling both ion channels and various parts of the protein kinase cascade (see **Ch. 3**), producing both rapid and delayed effects on neuronal function. Both arachidonic acid itself and its products escape readily from the cell of origin and can affect neighbouring structures, including presynaptic terminals (retrograde signalling) and adjacent cells (paracrine signalling), by acting on receptors or by acting directly as intracellular messengers. **Fig. 39.7** shows a schematic view of the variety of different roles these agents can play at the synapse.

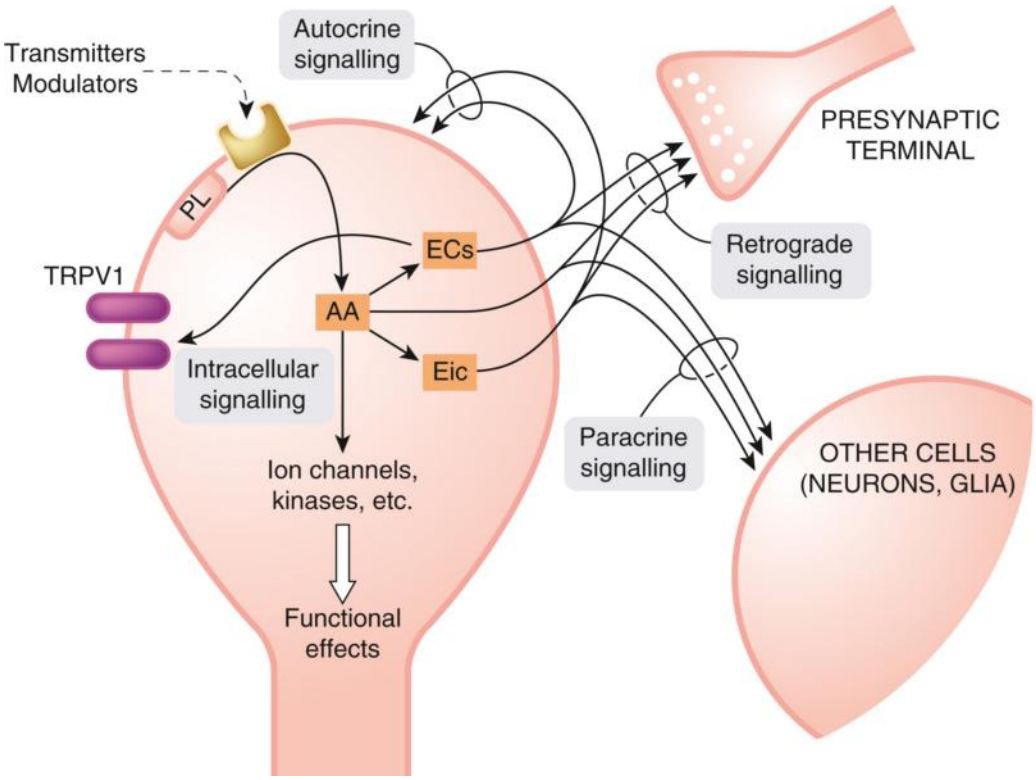

FIG. 39.7 Postulated modes of signalling by lipid mediators.Arachidonic acid (AA) is formed by receptor-mediated cleavage of membrane phospholipid. It can act directly as an intracellular messenger on ion channels or components of different kinase cascades, producing various long- and short-term effects. It can also be converted to eicosanoids (prostaglandins, leukotrienes or hydroxyeicosatetraenoic acids (HETEs)) or to the endocannabinoids (ECs), anandamide and 2-arachidonoylglycerol. ECs can also act as intracellular messengers to activate TRPV1 channels. HETEs can also act directly as intracellular messengers. All these mediators

also diffuse out of the cell, and exert effects on presynaptic terminals and neighbouring cells, acting either on extracellular receptors or intracellularly. There are examples of most of these modes of signalling, but only limited information about their functional significance in the nervous system. *Eic,* Eicosanoids; *PL,* membrane phospholipid.

Arachidonic acid can be metabolised to eicosanoids, some of which (principally the HETEs) can also act as intracellular messengers acting in the same cell. Eicosanoids can also exert an autocrine effect via membrane receptors expressed by the cell (see **Ch. 17**). The eicosanoids play important roles in neural function including pain, temperature regulation, sleep induction, synaptic plasticity and spatial learning.

It is now generally accepted that endocannabinoids, such as anandamide and 2-arachidonylglycerol, act as retrograde synaptic messengers in the CNS (see **Pertwee, 2015**, and **Ch. 18**). They are synthesised and secreted in response to a rise in intracellular Ca^{2+} and activate presynaptic CB_1 receptors inhibiting the release of neurotransmitters such as glutamate and GABA. CB_1 receptors are widely distributed in the brain and spinal cord, not only on neurons but also on astrocytes and microglia, whereas CB_2 receptor expression is much less but may be up-regulated under pathological conditions. Agonists at CB_1 receptors have therapeutic potential for the treatment of vomiting, pain (CB_2 receptor agonists may also be effective in some pain states), muscle spasms as occur in conditions such as multiple sclerosis and anxiety, as well as in other brain

disorders including Alzheimer's disease and tardive dyskinesias. Endocannabinoids released into the extracellular space are removed into cells by facilitated transport, for which inhibitors have been developed, and then metabolised (**Cascio and Marini, 2015**). Anandamide is metabolised by fatty acid amide hydrolase (FAAH; see **Ch. 18**). Inhibitors of FAAH potentiate the effects of endocannabinoids and were shown to be effective analgesics in animal models of pain (**Roques et al., 2012**). [6] The CB_1-receptor antagonist **rimonabant** was introduced as an anti-obesity agent but subsequently had to be withdrawn because of negative effects on mood (see **Ch. 18**). Endocannabinoids, besides being agonists at cannabinoid receptors, also interact with a variety of ion channels including TRPV1 channels (see **Ch. 43**), 5-HT3 receptors, calcium channels and potassium channels (**Pertwee, 2015**)

Lysophosphatidic acid and sphingosine 1-phosphate are phospholipids with important signalling functions in the brain and elsewhere throughout the body. Their effects are mediated by multiple G protein–coupled receptors (LPA1-6 and S1P1-5). Agonists at S1P1 receptors are in phase III clinical trials for the treatment of multiple sclerosis (see **Ch. 40**).

Other transmitters and modulators

Purines

- ATP functions as a neurotransmitter, being stored in vesicles and released by exocytosis. It acts via ionotropic P2X receptors and metabotropic P2Y receptors.

- Cytosolic ATP is present at a relatively high concentration and can be released directly if neuronal viability is compromised (e.g. in stroke). Excessive release may be neurotoxic.
- Released ATP is rapidly converted to ADP, AMP and adenosine.
- Adenosine is not stored in vesicles but is released by carrier mechanisms or generated from released ATP, mainly under pathological conditions.
- Adenosine exerts mainly inhibitory effects, through A_1 and A_2 receptors, resulting in sedative, anticonvulsant and neuroprotective effects, and acting as a safety mechanism.
- Methylxanthines (e.g. **caffeine**) are antagonists at A_2 receptors and increase wakefulness.

Histamine

- Histamine fulfils the criteria for a neurotransmitter. Histaminergic neurons originate in a small area of the hypothalamus and have a widespread distribution.
- H_1, H_2 and H_3 receptors are widespread in the brain.
- The functions of histamine are not well understood, the main clues being that histaminergic neurons are active during waking hours, and H_1 receptor antagonists are strongly sedative.
- H_1 receptor antagonists are antiemetic.

Melatonin

- Melatonin is synthesised from 5-HT, mainly in the pineal gland, from which it is released as a circulating hormone.
- Secretion is controlled by light intensity, being low by day and high by night. Fibres from the retina run to the SCN ('biological clock'), which controls the pineal gland via its sympathetic innervation.
- Melatonin acts on MT_1 and MT_2 receptors in the brain.
- Agonists at melatonin receptors induce sleep and have antidepressant properties.

Other mediators

Nitric oxide

- nNOS is present in many CNS neurons, and NO production is increased by mechanisms (e.g. transmitter action) that raise intracellular Ca^{2+}.
- NO affects neuronal function by increasing cGMP formation, producing both inhibitory and excitatory effects on neurons.
- In larger amounts, NO forms peroxynitrite, which contributes to neurotoxicity.
- Inhibition of nNOS reduces long-term potentiation and long-term depression, probably because NO functions as a retrograde messenger. Inhibition of nNOS also protects against ischaemic brain damage in animal models.
- Carbon monoxide and hydrogen sulfide may also be neural mediators.

Lipid mediators

- Arachidonic acid is produced in neurons by receptor-mediated hydrolysis of phospholipid. It is converted to various eicosanoids and endocannabinoids.
- Arachidonic acid itself, as well as its active products, can produce rapid and slow effects by regulation of ion channels and protein kinase cascades. Such effects can occur in the donor cell or in adjacent cells and nerve terminals.
- Anandamide and 2-arachidonoylglycerol are endogenous activators of cannabinoid CB_1 and CB_2 receptors (see **Ch. 18**) and also of the TRPV1 receptor (see **Ch. 43**).

A Final Message

In the last two chapters we have taken a long and tortuous tour through the brain and its chemistry, with two questions at the back of our minds. What mediators and what receptors play a key role in what brain functions? How does the information relate to existing and future drugs that aim to correct malfunctions? Through the efforts of a huge army of researchers deploying an arsenal of powerful modern techniques, the answers to these questions are slowly being produced. The array of potential CNS targets – comprising multiple receptor subtypes, many with the added complexity of heteromeric assemblies, splice variants, etc., along with regulatory mechanisms that control their expression and localisation – continues to grow in complexity. The view that specific malfunctions in a particular system give rise to specific CNS

disorders is becoming less of a reality particularly in relation to cognitive and emotional disorders. The interactions between transmitter systems and capacity within the CNS to rapidly adapt in response to drug treatments add to this complexity. In the ensuing chapters in this section we shall find that most of the therapeutic successes have come from chance discoveries that were followed up empirically; few have followed a logical, mechanism-based route to success. The optimistic view is that this is changing, and that future therapeutic discoveries will depend less on luck and more on molecular logic. But the revolution is slow in coming. One of the key problems, perhaps, is that the brain puts cells, organelles and molecules exactly where they are needed, and uses the same molecules to perform different functions in different locations. Drug discovery scientists are getting quite good at devising molecule-specific ligands (see **Ch. 60**), but we lack delivery systems able to target them anatomically even to macroscopic brain regions, let alone to specific cells and subcellular structures.

QUESTIONS

QUESTION 39.1

Amine transmitters have diverse functional roles in the CNS, including blood pressure control and effects on arousal, cognition and emotions.

Which of the following statements about the physiological roles of the amine transmitters is correct?

OPTIONS:

A. The baroreceptor reflex is mediated by noradrenaline released from the medulla.

B. Adenosine produces sedation through activation of purinergic A_2 receptors.

C. The dopaminergic nigrostriatal pathway is involved in emotion and drug-induced reward.

D. The psychostimulant properties of 3,4-methylenedioxymethamphetamine (MDMA) are due partly to its ability to displace noradrenaline.

E. Cholinergic projections from the ventral forebrain to the cortex are involved in learning and short-term memory.

QUESTION 39.2

Dysregulation of amine transmitter levels has been implicated in a number of disease states warranting the use of therapeutic agents

to redress the balance.

Which agent would not be suitable for the indicated condition?

OPTIONS:

A. Sumatriptan for migraine prophylaxis

B. Clonidine for hypertension

C. Bromocriptine for tumours of the pituitary gland

D. Metoclopramide for vomiting

E. Selective H_3 receptor antagonists for Alzheimer's disease

ANSWERS

ANSWER 39.1

RATIONALE:

A. It is thought the main regulatory neurons may release adrenaline rather than noradrenaline as the baroreceptor reflex is dependent upon the activity of phenylethanolamine *N*-methyl transferase, the enzyme that converts noradrenaline to adrenaline.

B.

C. The nigrostriatal pathway is important in motor control whereas the mesolimbic pathway is involved in emotion and drug-induced reward.

D. The psychostimulant properties of MDMA are due partly to its ability to release 5-HT by competition for reuptake and displacement of 5-HT from vesicles.

E. Acetylcholine released from neurons in the septohippocampal pathway is involved in learning and short-term memory. Cholinergic projection from the ventral forebrain to the cortex is thought to mediate arousal.

CORRECT ANSWER WITH EXPLANATION:

B. Adenosine produces sedation through activation of purinergic A_2 receptors.

The overall effect of adenosine is inhibitory, leading to effects such as drowsiness and sedation. Xanthines, such as caffeine, which are antagonists at A_2 receptors, produce arousal and alertness.

ANSWER 39.2

RATIONALE:

A.

B. Some antihypertensive drugs (e.g. clonidine, methyldopa) act mainly on noradrenergic transmission in the CNS.

C. Bromocriptine, a dopamine-receptor agonist derived from ergot, is used clinically to suppress prolactin secretion by tumours of the pituitary gland.

D. Many dopamine antagonists (e.g. metoclopramide) have antiemetic activity by inhibition of D_2 receptors in the chemoreceptor trigger zone associated with the initiation of vomiting.

E. Selective H_3 receptor antagonists may have potential for the treatment of cognitive impairment associated with Alzheimer's disease, schizophrenia, attention deficit hyperactivity disorder and Parkinson's disease as well as for the treatment of narcolepsy, obesity and pain states.

CORRECT ANSWER WITH EXPLANATION:

A. Sumatriptan for migraine prophylaxis

5-HT_{1D} agonists (e.g. sumatriptan) are used to treat migraine whereas 5-HT_2 antagonists (e.g. pizotifen) are more often used for migraine prophylaxis.

[2] The a_{1C} receptor was subsequently found to be identical to a_{1A} receptor.

[3] LSD has subsequently been shown to act centrally as a 5-HT2A agonist.

[3] There is no 5-HT_{1C} receptor. The original 5-HT_{1C} receptor has been reclassified as 5-HT_{2C}.

[4] See Schicker et al. (2008) for a description of how presynaptic cation-selective ligand-gated channels can, under different circumstances, facilitate or enhance neurotransmitter release.

[5] Unfortunately the nomenclature for P2Y receptors has developed in a rather haphazard manner. There is compelling evidence for the existence of $P2Y_{1,\ 2,\ 4,\ 6,\ 11,\ 12,\ 13\ and\ 14}$ receptors, but not for others.

[6] Readers may recall the tragic phase I clinical trial of one FAAH inhibitor, BIA 10-2474, that caused sudden, severe CNS damage and resulted in one subject being brain dead and four others having permanent brain damage. In this instance the adverse effects were due to actions of the drug on other lipases.

40: Neurodegenerative diseases

OVERVIEW

Despite ongoing neural plasticity, dead neurons in the adult central nervous system (CNS) are not as a rule replaced, [1] nor can their terminals regenerate when their axons are interrupted. Therefore any pathological process causing neuronal death generally has irreversible consequences. At first sight, this appears to be very unpromising territory for pharmacological intervention, and indeed drug therapy is currently very limited, except in the case of Parkinson's disease (PD). Nevertheless, the incidence and social impact of neurodegenerative brain disorders in ageing populations have resulted in a massive research effort in recent years. To date there has been more success in developing drugs that treat the symptoms arising from neuronal cell loss than in developing ones that attempt to halt or reverse the degenerative processes.

In this chapter, a number of neurodegenerative conditions are described: ischaemic brain damage (stroke), dementias – Alzheimer's disease (AD), dementia associated with Lewy bodies (DLB) and vascular dementia – PD, essential tremor (ET), Huntington's disease (HD), amyotrophic lateral sclerosis (ALS), spinal muscular atrophy (SMA) and multiple sclerosis (MS).

The main topics discussed in this chapter are:

- mechanisms responsible for neuronal death, focusing on genetic defects, protein aggregation (e.g. amyloidosis), excitotoxicity, oxidative stress and apoptosis;
- pharmacological approaches to neuroprotection, based on the earlier mechanisms; and
- pharmacological approaches to compensation for neuronal loss (applicable mainly to AD and PD).

Protein Misfolding and Aggregation in Chronic Neurodegenerative Diseases

Protein misfolding and aggregation is considered to be the first step in many neurodegenerative diseases (see **Peden and Ironside, 2012**). Misfolding means the adoption of abnormal conformations, by certain normally expressed proteins, such that they tend to form large insoluble aggregates (**Fig. 40.1**). The conversion of the linear amino acid chain produced by the ribosome into a functional protein requires it to be folded correctly into a compact conformation with specific amino acids correctly located on its surface. This complicated stepwise sequence can easily go wrong and lead to misfolded variants that are unable to find a way back to the correct 'native' conformation. The misfolded molecules lack the normal function of the protein but can nonetheless make mischief within the cell. The misfolding often means that hydrophobic residues that would normally be buried in the core of the protein are exposed on its surface, which gives the molecules a strong tendency to stick to cell membranes and aggregate, initially as

oligomers and then as insoluble microscopic aggregates (see **Fig. 40.1**), leading to the death of neurons. The tendency to adopt such conformations may be favoured by specific mutations of the protein in question, or by infection with prions. [2]

Misfolded conformations can be generated spontaneously at a low rate throughout life, so that aggregates accumulate gradually with age. In the nervous system, the aggregates often form distinct structures, generally known as *amyloid deposits*, that are visible under the microscope and are characteristic of neurodegenerative disease. Although the mechanisms are not clear, such aggregates, or the misfolded protein precursors, lead to neuronal death. Examples of neurodegenerative diseases that are caused by such protein misfolding and aggregation are shown in **Table 40.1**.

The brain possesses a variety of protective mechanisms that limit the accumulation of such protein aggregates. The main ones involve the production of 'chaperone' proteins, which bind to newly synthesised or misfolded proteins and encourage them to fold correctly, and the 'ubiquitination' reaction, which prepares proteins for destruction within the cell. Accumulation of protein deposits occurs when these protective mechanisms are unable to cope.

Protein misfolding

- Many chronic neurodegenerative diseases involve the misfolding of normal or mutated forms of physiological proteins. Examples include Alzheimer's disease, dementia associated with Lewy bodies, Parkinson's disease,

amyotrophic lateral sclerosis and many less common diseases.

- Misfolded proteins are normally removed by intracellular degradation pathways, which may be altered in neurodegenerative disorders.
- Misfolded proteins tend to aggregate, initially as soluble oligomers, later as large insoluble aggregates that accumulate intracellularly or extracellularly as microscopic deposits, which are stable and resistant to proteolysis.
- Misfolded proteins often present hydrophobic surface residues that promote aggregation and association with membranes.
- The mechanisms responsible for neuronal death are unclear, but there is evidence that both the soluble aggregates and the microscopic deposits may be neurotoxic.

Mechanisms of Neuronal Death

Acute injury to cells causes them to undergo *necrosis*, recognised pathologically by cell swelling, vacuolisation and lysis and associated with Ca^{2+} overload of the cells and membrane damage. Necrotic cells typically spill their contents into the surrounding tissue, evoking an inflammatory response. Chronic inflammation is a feature of most neurodegenerative disorders (see **Schwab and McGeer, 2008**), and a possible target for therapeutic intervention.

Cells can also die by *apoptosis* (programmed cell death, see **Ch. 6**), a mechanism that is essential for many processes throughout life, including development, immune regulation and tissue

remodelling. Apoptosis, as well as necrosis, occurs in both acute neurodegenerative disorders (such as stroke and head injury) and chronic ones (such as AD and PD). The distinction between necrosis and apoptosis as processes leading to neurodegeneration is not absolute, for challenges such as excitotoxicity and oxidative stress may be enough to kill cells directly by necrosis or, if less intense, may induce them to undergo apoptosis. Both processes therefore represent possible targets for putative neuroprotective drug therapy. Pharmacological interference with the apoptotic pathway may become possible in the future, but for the present most efforts are directed at the processes involved in cell necrosis, and at compensating pharmacologically for the neuronal loss.

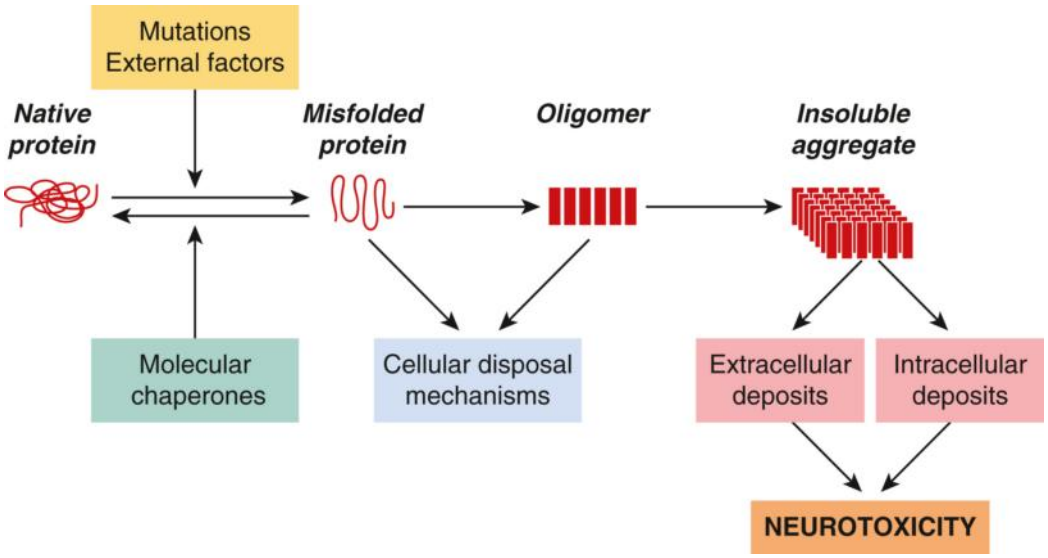

FIG. 40.1 Protein misfolding: a process involved in many chronic neurodegenerative diseases.

Table 40.1

[a] Protein aggregation disorders are often collectively known as amyloidoses and commonly affect organs other than the brain.

Excitotoxicity

Despite its ubiquitous role as a neurotransmitter, **glutamate** is highly toxic to neurons, a phenomenon dubbed *excitotoxicity* (see **Ch. 38**). A low concentration of glutamate applied to neurons in culture kills the cells, and the finding in the 1970s that glutamate given orally produces neurodegeneration in vivo caused considerable alarm because of the widespread use of glutamate as a 'taste-enhancing' food additive. The Chinese restaurant syndrome - an acute attack of neck stiffness and chest pain is well known, but so far, the possibility of more serious neurotoxicity is only hypothetical.

Local injection of the glutamate receptor agonist *kainic acid* is used experimentally to produce neurotoxic lesions. It acts by excitation of local glutamate-releasing neurons, and the release of glutamate, acting on *N*-methyl-D-aspartate (NMDA) receptors, and also metabotropic receptors (see **Ch. 38**), leads to neuronal death.

Calcium overload is the essential factor in excitotoxicity. The mechanisms by which this occurs and leads to cell death are as follows (see also **Fig. 40.2**):

- Glutamate activates NMDA, (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and metabotropic glutamate receptors (sites 1, 2 and 3 in **Fig. 40.2**). Activation of AMPA receptors depolarises the cell, which

removes the Mg^{2+} block of NMDA channels (see **Ch. 38**), permitting Ca^{2+} entry. Depolarisation also opens voltage-dependent calcium channels (site 4). Metabotropic receptors cause the release of intracellular Ca^{2+} from the endoplasmic reticulum. Na^{+} entry further contributes to Ca^{2+} entry by stimulating Ca^{2+}/Na^{+} exchange (site 5). Depolarisation inhibits or reverses glutamate uptake (site 6), thus increasing the extracellular glutamate concentration.

- The mechanisms that normally operate to counteract the rise in cytosolic free Ca^{2+} concentration, $[Ca^{2+}]_i$, include the Ca^{2+} efflux pump (site 7) and, indirectly, the Na^{+} pump (site 8).
- The mitochondria and endoplasmic reticulum act as capacious sinks for Ca^{2+} and normally keep $[Ca^{2+}]_i$ under control. Loading of the mitochondrial stores beyond a certain point, however, disrupts mitochondrial function, reducing ATP synthesis, thus reducing the energy available for the membrane pumps and for Ca^{2+} accumulation by the endoplasmic reticulum. Formation of reactive oxygen species (ROS) is also enhanced. This represents the danger point at which positive feedback exaggerates the process.
- Raised $[Ca^{2+}]_i$ affects many processes, the chief ones relevant to neurotoxicity being:
  - increased glutamate release from nerve terminals;
  - activation of proteases (calpains) and lipases, causing membrane damage;

– activation of nitric oxide synthase; while low concentrations of nitric oxide are neuroprotective, high concentrations in the presence of ROS generate peroxynitrite and hydroxyl free radicals, which damage many important biomolecules, including membrane lipids, proteins and DNA;
– increased arachidonic acid release, which increases free radical and inflammatory mediator production and also inhibits glutamate uptake (site 6).

Glutamate and Ca^{2+} are arguably the two most ubiquitous chemical signals, extracellular and intracellular, respectively, underlying brain function, so it is disconcerting that such cytotoxic mayhem can be unleashed when they get out of control. Both are stored in dangerous amounts in subcellular organelles, like hand grenades in an ammunition store. Defence against excitotoxicity is clearly essential if our brains are to have any chance of staying alive. Mitochondrial energy metabolism provides one line of defence, and impaired mitochondrial function, by rendering neurons vulnerable to excitotoxic damage, may be a factor in various neurodegenerative conditions, including PD. Furthermore, impaired mitochondrial function can cause release of cytochrome C, which is an important initiator of apoptosis.

The role of excitotoxicity in ischaemic brain damage is well established, and it is also believed to be a factor in other neurodegenerative diseases, such as those discussed here.

There are several examples of neurodegenerative conditions caused by environmental toxins acting as agonists on glutamate receptors. *Domoic acid* is a glutamate analogue produced by

mussels, which was identified as the cause of an epidemic of severe mental and neurological deterioration in a group of Newfoundlanders in 1987. On the island of Guam, a syndrome combining the features of dementia, paralysis and PD was traced to an excitotoxic amino acid, β-methylamino-alanine, in the seeds of a local plant. Discouraging the consumption of these seeds has largely eliminated the disease.

Disappointingly, intense effort, based on the mechanisms described earlier, to find effective drugs for a range of neurodegenerative disorders in which excitotoxicity is believed to play a part has had very limited success. **Riluzole** retards to some degree the deterioration of patients with ALS. Its precise mechanism of action is unclear. **Memantine** is a weak NMDA-receptor antagonist that produces slight improvement in moderate-to-severe cases of AD.

Apoptosis

Apoptosis can be initiated by various cell surface signals (see **Ch. 6**). The cell is systematically dismantled, and the shrunken remnants are removed by macrophages without causing inflammation. Apoptotic cells can be identified by a staining technique that detects the characteristic DNA breaks. Many different signalling pathways can result in apoptosis, but in all cases the final pathway resulting in cell death is the activation of a family of proteases (caspases), which inactivate various intracellular proteins. Neural survival is regulated by neuronal growth factors, including *nerve growth factor* and *brain-derived neurotrophic factor*, secreted proteins that are required for the survival of

different populations of neurons in the CNS. These growth factors regulate the expression of the two gene products, Bax and Bcl-2, Bax being proapoptotic and Bcl-2 being antiapoptotic (see **Ch. 6**). Neurons also have significant expression of anti-apoptotic family member Bcl-x, but the balance of Bax and Bcl-2 are the key determinants to neuronal survival. Blocking apoptosis by interfering at specific points on these pathways represents an attractive strategy for developing neuroprotective drugs, but one that has yet to bear fruit.

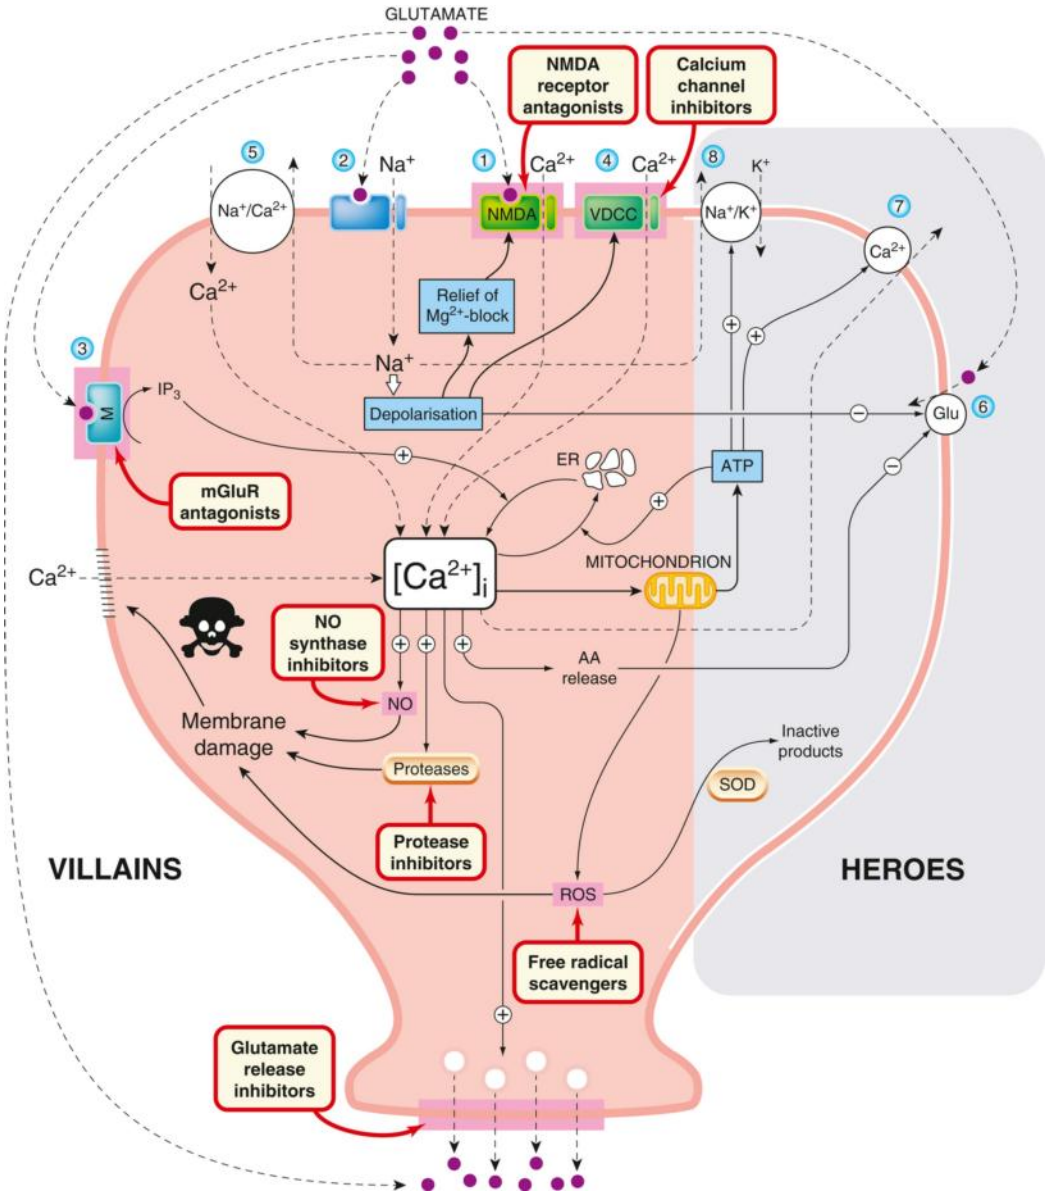

FIG. 40.2 Mechanisms of excitotoxicity.Membrane receptors, ion channels and transporters, identified by numbers 1–8, are discussed in the text. Possible sites of action of neuroprotective drugs (not yet of proven clinical value) are *highlighted*. Mechanisms on the *left* (villains) are those that favour cell death, while those on the *right* (heroes) are protective. See

text for details. *AA,* Arachidonic acid; *ER,* endoplasmic reticulum; *Glu,* glutamate uptake; IP_3, inositol trisphosphate; *M, mGluR,* metabotropic glutamate receptor; *NMDA*, *N*-methyl-D-aspartate; *NO,* nitric oxide; *ROS*, reactive oxygen species; *SOD,* superoxide dismutase; *VDCC,* voltage-dependent calcium channel.

Oxidative Stress

The brain has high energy needs, which are met almost entirely by mitochondrial oxidative phosphorylation, generating ATP at the same time as reducing molecular O_2 to H_2O. Under certain conditions, highly ROS, for example, oxygen and hydroxyl free radicals and H_2O_2, may be generated as side products of this process (see **Barnham et al., 2004**). Oxidative stress is the result of excessive production of these reactive species. They can also be produced as a byproduct of other biochemical pathways, including nitric oxide synthesis and arachidonic acid metabolism (which are implicated in excitotoxicity), as well as the P450 mono-oxygenase system (see **Ch. 10**). Unchecked, reactive oxygen radicals attack many key molecules, including enzymes, membrane lipids and DNA. During periods of tissue reperfusion following ischaemia (e.g. in stroke), delinquent leukocytes may exacerbate this problem by releasing their own cytotoxic oxygen products. Not surprisingly, defence mechanisms are provided, in the form of enzymes such as *superoxide dismutase* (SOD) and *catalase*, as well as antioxidants such as ascorbic acid, glutathione and α-tocopherol (vitamin E),

which normally keep these reactive species in check. Some cytokines, especially tumour necrosis factor (TNF)-α, which is produced in conditions of brain ischaemia or inflammation (see **Ch. 17**), exert a protective effect, partly by increasing the expression of SOD. Transgenic animals lacking TNF receptors show enhanced susceptibility to brain ischaemia. Mutations of the gene encoding SOD (see **Fig. 40.2**) are associated with ALS, a fatal, paralytic disease resulting from progressive degeneration of motor neurons, and transgenic mice expressing mutated SOD develop a similar condition. [3] Accumulation of aggregates of misfolded mutated SOD may also contribute to neurodegeneration.

Mitochondria play a central role in energy metabolism, failure of which leads to oxidative stress. Damage to mitochondria, leading to the release of cytochrome C into the cytosol, also initiates apoptosis. Mitochondrial integrity is therefore essential for neuronal survival, and mitochondrial dysfunction is seen as a major factor in many neurodegenerative disorders (see **Itoh et al., 2013**). It is possible that accumulated or inherited mutations in enzymes such as those of the mitochondrial respiratory chain lead to a congenital or age-related increase in susceptibility to oxidative stress, which is manifest in different kinds of inherited neurodegenerative disorders (such as HD), and in age-related neurodegeneration.

Oxidative stress is both a cause and a consequence of inflammation (see **Ch. 7**), which is a general feature of neurodegenerative disease and is thought to contribute to neuronal damage (see **Schwab and McGeer, 2008**).

Several possible targets for therapeutic intervention with neuroprotective drugs are shown in **Fig. 40.2**.

Excitotoxicity and oxidative stress

- Excitatory amino acids, especially glutamate, can cause neuronal death.
- Excitotoxicity is associated mainly with activation of NMDA receptors, but other types of excitatory amino acid receptors also contribute.
- Excitotoxicity results from a sustained rise in intracellular Ca^{2+} concentration (Ca^{2+} overload).
- Excitotoxicity can occur under pathological conditions (e.g. cerebral ischaemia, epilepsy) in which excessive glutamate release occurs. It can also occur when chemicals such as **kainic acid** are administered.
- Raised intracellular Ca^{2+} causes cell death by various mechanisms, including activation of proteases, formation of free radicals and lipid peroxidation. Formation of nitric oxide and arachidonic acid is also involved.
- Various mechanisms act normally to protect neurons against excitotoxicity, the main ones being Ca^{2+} transport systems, mitochondrial function and the production of free radical scavengers.
- Oxidative stress refers to conditions (e.g. hypoxia) in which the protective mechanisms are compromised, ROS accumulate and neurons become more susceptible to excitotoxic damage.
- Excitotoxicity due to environmental chemicals may contribute to some neurodegenerative disorders.

- Measures designed to reduce excitotoxicity include the use of glutamate antagonists, calcium channel-blocking drugs and free radical scavengers; none is yet proven for clinical use.
- Mitochondrial dysfunction, associated with ageing, environmental toxins and genetic abnormalities, leads to oxidative stress and is a common feature of neurodegenerative diseases.

Ischaemic Brain Damage

After heart disease and cancer, strokes are the commonest cause of death in Europe and North America, and the 70% that are non-fatal are the commonest cause of disability. Approximately 85% of strokes are *ischaemic*, usually due to cerebral arterial occlusion caused by local thrombus formation or by a circulating embolus lodging at a narrowing of the vessel. Ischaemic stroke may be preceded by transient ischaemic attacks (TIAs), or 'mini-strokes', resulting from brief episodes of inadequate blood flow. TIAs produce symptoms such as sudden limb or facial muscle weakness, inability to talk, double vision and dizziness. These symptoms usually resolve within 24 h but serve as a warning that a full stroke may occur in the near future. Measures such as taking **aspirin** or **ticagrelor** (see **Ch. 23**) should be taken to prevent further atherothrombotic events. The other type of stroke is *haemorrhagic*, due to rupture of a cerebral artery.

Pathophysiology

Prolonged interruption of blood supply to the brain initiates the cascade of neuronal events shown in **Fig. 40.2**, which lead in turn to later consequences, including cerebral oedema and inflammation, which can also contribute to brain damage. Further damage can occur following reperfusion, [4] because of the production of ROS when the oxygenation is restored. Reperfusion injury may be an important component in stroke patients. These secondary processes often take hours to develop, providing a window of opportunity for therapeutic intervention. The lesion produced by occlusion of a major cerebral artery consists of a central core in which the neurons quickly undergo irreversible necrosis, surrounded by a penumbra of compromised tissue in which inflammation and apoptotic cell death develop over a period of several hours. It is assumed that neuroprotective therapies, given within a few hours, might inhibit this secondary penumbral damage.

Glutamate excitotoxicity plays a critical role in brain ischaemia. Ischaemia causes depolarisation of neurons, and the release of large amounts of glutamate. Ca^{2+} accumulation occurs, partly as a result of glutamate acting on NMDA receptors, as both Ca^{2+} entry and cell death following cerebral ischaemia are inhibited by drugs that block NMDA receptors or channels (see **Ch. 38**). Nitric oxide is also produced in amounts much greater than result from normal neuronal activity (i.e. to levels that are toxic rather than modulatory).

Therapeutic Approaches

The only drug currently approved for treating ischaemic strokes is a recombinant tissue plasminogen activator, **alteplase**, given

intravenously, which helps to restore blood flow by dispersing the thrombus (see **Ch. 23**). Clinical trials have found that it did not reduce mortality but gave significant functional benefit to patients who survive. To be effective, it must be given within about 4.5 h of the thrombotic episode. Also, it must not be given in the 15% of cases where the cause is haemorrhage rather than thrombosis, so preliminary computerised tomography (CT) scanning is essential. These stringent requirements seriously limit the use of fibrinolytic agents for treating stroke, except where specialised rapid response facilities are available. The use of intra-arterial clot retrieval devices (mechanical thrombectomy), in combination with alteplase, has yielded greater benefits and this technology is available in specialised acute stroke treatment centres.

An alternative approach would be to use neuroprotective agents aimed at rescuing cells in the penumbral region of the lesion, which are otherwise likely to die. In animal models involving cerebral artery occlusion, many drugs targeted at the mechanisms shown in **Fig. 40.2** (not to mention many others that have been tested on the basis of more far-flung theories) act in this way to reduce the size of the infarct. These include glutamate antagonists, calcium and sodium-channel inhibitors, free radical scavengers, anti-inflammatory drugs, protease inhibitors and others (see **Green, 2008**). It seems that almost anything works in these animal models. However, of the many drugs that have been tested in over 100 clinical trials, none was effective. The dispiriting list of failures includes calcium- and sodium-channel blockers (e.g. **nimodipine**, **fosphenytoin**), NMDA-receptor antagonists (**selfotel**, **eliprodil**, **dextromethorphan**), drugs that inhibit glutamate release

(adenosine analogues, **lubeluzole**), drugs that enhance GABA effects (e.g. **chlormethiazole**), 5-hydroxytryptamine (5-HT) antagonists, metal chelators and various free radical scavengers (e.g. **tirilazad**). There was hope that mGlu1-receptor antagonists or negative allosteric modulators might be effective in the treatment of ischaemic brain damage but things have gone quiet on that front recently.

Controlled clinical trials on stroke patients are problematic and very expensive, partly because of the large variability of outcome in terms of functional recovery, which means that large groups of patients (typically thousands) need to be observed for several months. The need to start therapy within hours of the attack is an additional problem.

Stroke treatment is certainly not – so far at least – one of pharmacology's success stories, and medical hopes rest more on prevention (e.g. by controlling blood pressure, taking **aspirin**, **statins** or **ticagrelor** to prevent atherosclerosis [see **Ch. 23**]) than on treatment. [5]

One area of promise is the use of subanaesthetic doses of **xenon**, which has NMDA-receptor antagonist properties (see **Ch. 41**), in combination with hypothermia to treat hypoxia-induced brain damage in neonates (**Esencan et al., 2013**).

Stroke

- Associated with intracerebral thrombosis or haemorrhage (less common), resulting in rapid death of neurons by necrosis in the centre of the lesion, followed by more gradual

(hours) degeneration of cells in the penumbra due to excitotoxicity and inflammation.

- Spontaneous functional recovery occurs to a highly variable degree.
- Although many types of drug that interfere with excitotoxicity are able to reduce infarct size in experimental animals, none of these has so far proved efficacious in humans.
- Recombinant tissue plasminogen activator (**alteplase**), which disperses blood clots, is beneficial if it is given within 4.5 h; haemorrhagic stroke must be excluded by imaging before its administration.

Dementia

Dementia is a general term describing problems with mental abilities caused by gradual changes and damage in the brain. AD is the most common type of dementia; other common types are dementia with Lewy bodies (DLB) and vascular dementia.

AD was originally defined as presenile dementia, but it now appears that the same pathology underlies the dementia irrespective of the age of onset. AD refers to dementia of gradual onset in adulthood, which may follow earlier brain injury, but often has no known antecedent cause. Its prevalence rises sharply with age, from about 2% in those aged 65–69 to 20% in those aged 85–89. Common symptoms of AD are difficulty remembering names and recent events, loss of executive functioning, apathy and depression. Studies have revealed specific genetic and molecular mechanisms underlying AD (see **Frigero and De Strooper, 2016**; **Sims**

et al., 2020). These advances raised hopes of more effective treatments, but success has proved elusive, in part because multiple factors rather than a single cause contribute to the disease and because the symptoms of the disease become obvious only after the underlying pathology has progressed.

The symptoms of DLB include hallucinations, cognitive difficulties – although memory may be less affected in people with DLB than AD – confusion or sleepiness, impaired movement and tremors, disturbed sleep, fainting spells, unsteadiness and falls. DLB has a different aetiology from AD (see later) and in around 90% of cases occurs primarily in people with no family history of the condition.

Vascular dementia results from reduced blood flow to regions of the brain as may occur with multiple minor strokes or cardiovascular disease. Factors that increase the risk of heart disease and stroke – diabetes, high blood pressure, high cholesterol and smoking – raise the risk of vascular dementia. Symptoms include confusion, slow thinking and changes in mood or behaviour.

Pathogenesis of Alzheimer's Disease

AD is associated with brain shrinkage and loss of neurons in many brain regions, but especially in the hippocampus and basal forebrain. The loss of cholinergic neurons in the hippocampus and frontal cortex is a feature of the disease, and is thought to underlie the cognitive deficit and loss of short-term memory that occur. Two microscopic features are characteristic of the disease, namely extracellular *amyloid plaques*, consisting of amorphous extracellular deposits of β-amyloid protein (known as Aβ), and

intraneuronal *neurofibrillary tangles*, comprising filaments of a phosphorylated form of a microtubule-associated protein (Tau). Both of these deposits are protein aggregates that result from misfolding of native proteins, as discussed previously. They appear also in normal brains, although in smaller numbers. The early appearance of amyloid deposits presages the development of AD, although symptoms may not develop for many years. Altered processing of amyloid protein from its precursor (*amyloid precursor protein* [APP]) has been implicated in the pathogenesis of AD. This is based on several lines of evidence, particularly the genetic analysis of certain, relatively rare, types of familial AD, in which mutations of the APP gene, or of other genes (e.g. for *presenilins* and *sortilin-related receptor 1*) that control amyloid processing, have been discovered. [6]

Amyloid deposits consist of aggregates of Aβ (**Fig. 40.3**), a 40- or 42-residue segment of APP, generated by the action of specific proteases (*secretases*). Aβ40 is produced normally in small amounts, whereas Aβ42 is overproduced as a result of the genetic mutations mentioned earlier. Both proteins aggregate to form *amyloid plaques*, but Aβ42 shows a stronger tendency than Aβ40 to do so, and appears to be the main culprit in amyloid formation. APP is a 770–amino acid membrane protein normally expressed by many cells, including CNS neurons. Cleavage by α-secretase releases the large extracellular domain as *soluble* APP, which is believed to serve a physiological trophic function. Formation of Aβ involves cleavage at two different points, including one in the intramembrane domain of APP, by β- and γ-secretases (see **Fig. 40.3**). γ-Secretase is a clumsy enzyme – actually a large intramembrane complex of

several proteins – that lacks precision and cuts APP at different points in the transmembrane domain, generating Aβ fragments of different lengths, including Aβ40 and 42. Mutations in this region of the APP gene affect the preferred cleavage point, tending to favour formation of Aβ42. Mutations of the unrelated presenilin genes result in increased activity of γ-secretase, because the presenilin proteins form part of the γ-secretase complex. These different AD-related mutations increase the ratio of Aβ42:Aβ40, which can be detected in plasma, serving as a marker for familial AD. Mutations in another gene, that for the lipid transport protein ApoE4, also predispose to AD. It was originally thought that this was because mutated ApoE4 proteins are less effective in the clearance of Aβ oligomer. However, more recently the focus on ApoE4 has moved to other potential causes of AD such as tau neurofibrillary tangles (see later), microglia and astrocyte responses and blood–brain barrier disruption (**Husain et al., 2021**).

It is uncertain exactly how Aβ accumulation would cause neurodegeneration, and whether the damage is done by soluble Aβ monomers or oligomers or by amyloid plaques. There is evidence that the cells die by apoptosis, although an inflammatory response is also evident. Expression of Alzheimer's mutations in transgenic animals (see **Götz and Ittner, 2008**) causes plaque formation and neurodegeneration, and also increases the susceptibility of CNS neurons to other challenges, such as ischaemia, excitotoxicity and oxidative stress, and this increased vulnerability may be the cause of the progressive neurodegeneration in AD. However, the fact that several novel potential therapies designed to reduce Aβ production have so far proven to be ineffective in clinical trials on AD patients

has led some to question the importance of amyloid plaque formation in AD (see **Herrup, 2015** , for a critical view).

The other main player on the biochemical stage is *Tau*, the protein of which the neurofibrillary tangles are composed (see **Fig. 40.3**). Its role in neurodegeneration is unclear, although similar 'tauopathies' occur in many neurodegenerative conditions (see **Brunden et al., 2009**; **Hanger et al., 2009**). Tau is a normal constituent of neurons, being associated with the intracellular microtubules that serve as tracks for transporting materials along nerve axons. In AD and other tauopathies, Tau is abnormally phosphorylated by the action of various kinases, including glycogen synthase kinase-3β (GSK-3β) and cyclin-dependent kinase 5 (CDK5), and dissociates from microtubules to be deposited intracellularly as *paired helical filaments* with a characteristic microscopic appearance. When the cells die, these filaments aggregate as extracellular *neurofibrillary tangles*. Tau phosphorylation is enhanced by the presence of Aβ, possibly by activation of kinases. Conversely, hyperphosphorylated Tau favours the formation of amyloid deposits. Whether hyperphosphorylation and intracellular deposition of Tau directly harms the cell is not certain, although it is known that it impairs fast axonal transport, a process that depends on microtubules. It remains to be seen whether these pathologies drive the symptoms of the disease or arise as a consequences of other causal factors.

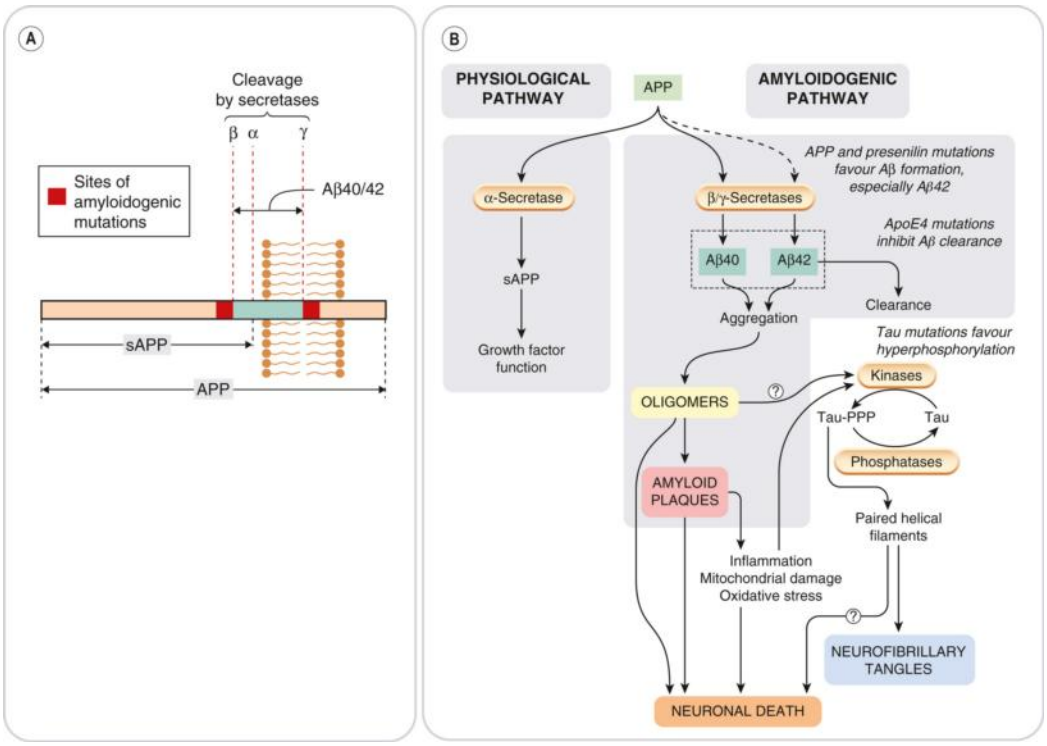

FIG. 40.3 Pathogenesis of Alzheimer's disease.(A) Structure of amyloid precursor protein (APP), showing origin of secreted APP (sAPP) and Aβ amyloid protein. The regions involved in amyloidogenic mutations discovered in some cases of familial Alzheimer's disease are shown flanking the Aβ sequence. APP cleavage involves three proteases: secretases α, β and γ. α-Secretase produces soluble APP, whereas β- and γ-secretases generate Aβ amyloid protein. γ-Secretase can cut at different points, generating Aβ peptides of varying lengths, including Aβ40 and Aβ42, the latter having a high tendency to aggregate as amyloid plaques. (B) Processing of APP. The main 'physiological' pathway gives rise to sAPP, which exerts a number of trophic

functions. Cleavage of APP at different sites gives rise to Aβ, the predominant form normally being Aβ40, which is weakly amyloidogenic. Mutations in APP or presenilins increase the proportion of APP, which is degraded via the amyloidogenic pathway, and also increase the proportion converted to the much more strongly amyloidogenic form Aβ42. Hyperphosphorylated Tau results in dissociation of Tau from microtubules, misfolding and aggregation to form paired helical filaments, which enhance Aβ toxicity.

Loss of cholinergic neurons

Although changes in many transmitter systems have been observed, mainly from measurements on postmortem AD brain tissue, a relatively selective loss of cholinergic neurons in the basal forebrain nuclei (see **Ch. 39**) is characteristic. This discovery, made in 1976, implied that pharmacological approaches to restoring cholinergic function might be feasible, leading to the use of cholinesterase inhibitors to treat AD (see later).

Choline acetyl transferase activity, acetylcholine (ACh) content and acetylcholinesterase and choline transport in the cortex and hippocampus are all reduced considerably in AD but not in other disorders, such as depression or schizophrenia. Muscarinic receptor density, determined by binding studies, is not affected, but nicotinic receptors, particularly in the cortex, are reduced. The reason for the

selective loss of cholinergic neurons resulting from Aβ formation is not known.

Alzheimer's disease

- Alzheimer's disease (AD) is a common age-related dementia, distinct from vascular dementia associated with brain infarction.
- The main pathological features of AD comprise amyloid plaques, neurofibrillary tangles and a loss of neurons (particularly cholinergic neurons of the basal forebrain).
- Amyloid plaques consist of aggregates of the Aβ fragment of amyloid precursor protein (APP), a normal neuronal membrane protein, produced by the action of β- and γ-secretases. AD is associated with excessive Aβ formation, resulting in neurotoxicity.
- Familial AD (rare) results from mutations in the APP gene, or in presenilin genes (involved in γ-secretase function), both of which cause increased Aβ formation.
- Mutations in the lipoprotein ApoE4 increase the risk of developing AD, possibly by interfering with Aβ clearance or tau-mediated neurodegeneration.
- Neurofibrillary tangles comprise intracellular aggregates of a highly phosphorylated form of a normal neuronal protein (Tau). Hyperphosphorylated Tau and Aβ act synergistically to cause neurodegeneration.

- Loss of cholinergic neurons is believed to account for much of the learning and memory deficit in AD.

Pathogenesis of Dementia with Lewy Bodies

DLB is associated with the development of intracellular protein aggregates known as Lewy bodies in various parts of the brain. Mutations in SNCA, SNCB, GBA and ApoE genes have been implicated in DLB. Lewy bodies consist largely of α-synuclein, a synaptic protein, present in large amounts in normal brains. There is evidence that α-synuclein may act as a prion-like protein (**Olanow and Brundin, 2013**). α-Synuclein normally exists in an α-helical conformation. However, under certain circumstances, such as genetic duplication or triplication or genetic mutation, it can undergo a conformational change to a β-sheet-rich structure that polymerises to form toxic aggregates and amyloid plaques. It is believed that misfolding and aggregation render the protein resistant to degradation within cells, causing it to pile up in Lewy bodies.

Brain regions involved in DLB include the cerebral cortex, which controls information processing, perception, thought and language; the limbic cortex, which plays a major role in emotions and behaviour; the hippocampus, which is involved in memory processing; the midbrain and basal ganglia, involved in movement; the brain stem, which is important in regulating sleep and maintaining alertness; and olfactory pathways. Dopaminergic neurons seem to be particularly vulnerable to Lewy bodies (see Parkinson's Disease section later).

Therapeutic Approaches to Dementia

Currently, cholinesterase inhibitors (see **Ch. 14**) and **memantine** are the main drugs available for treating AD and DLB.

Cholinesterase Inhibitors

Tacrine was the first drug approved for treating AD but because of its hepatotoxicity and the subsequent availability of other anticholinesterase agents, use of tacrine has been discontinued. Later compounds used to treat both AD and DLB include **donepezil**, **rivastigmine** and **galantamine** (**Table 40.2**). Clinical trials have demonstrated modest improvements in tests of memory and cognition but no sustained effect on disease progression or improvement in other behavioural and psychological measures that affect quality of life.

Other drugs aimed at improving cholinergic function that are being investigated include other cholinesterase inhibitors and a variety of muscarinic and nicotinic receptor agonists. To date, the lack of selectivity of muscarinic orthosteric agonists has hindered their use to treat CNS disorders due to the incidence of side effects, but the hope is that positive allosteric modulators (see **Ch. 3**) that are selective (e.g. for the M_1 receptor) will be developed.

Memantine

The other drug currently used in the treatment of AD and DLB is **memantine**, an orally active weak antagonist at NMDA receptors. It was originally introduced as an antiviral drug and resurrected as a potential inhibitor of excitotoxicity. It produces – surprisingly – a modest cognitive improvement but does not appear to be

neuroprotective. It may work by selectively inhibiting excessive, pathological NMDA-receptor activation while preserving more physiological activation. It has a long plasma half-life, and its adverse effects include headache, dizziness, drowsiness, constipation, shortness of breath and hypertension as well as a raft of less common problems.

ANTI Aβ ANTIBODIES

Aducanumab was the first new treatment for AD introduced since 2003. It is a monoclonal antibody that binds to Aβ aggregates but does not target Aβ monomers. Microglia bind to the Fc region of the antibody resulting in the phagocytosis of amyloid plaques. In initial clinical trials the therapeutic benefits of aducanumab were at best modest. Its approval by the Federal Drug Administration in the United States has been controversial (**Alexander et al., 2021**; **Walsh et al., 2021**). More recently **lecanemab**, another monoclonal antibody that binds with high affinity to Aβ aggregates has shown greater promise in an initial clinical trial (**van Dyck et al., 2023**).

Treatment of vascular dementia focuses largely on reducing blood pressure (see **Ch. 21**), atherosclerosis and thrombosis (see Chs **22** and **23**). Donepezil, galantamine, rivastigmine and memantine are not used to treat vascular dementia, but may be used in people who have a combination of vascular dementia and AD.

Clinical use of drugs in dementia

- Acetylcholinesterase inhibitors and NMDA antagonists detectably improve cognitive impairment in clinical trials but have significant adverse effects and are of limited use clinically. They have not been shown to retard neurodegeneration.
- Efficacy is monitored periodically in individual patients, and administration continued only if the drugs are believed to be working and their effect in slowing functional and cognitive deterioration is judged to outweigh adverse effects.

Acetylcholinesterase inhibitors

- **Donepezil**, **galantamine**, **rivastigmine.** Unwanted cholinergic effects may be troublesome.
- Used in mild to moderate Alzheimer's disease and dementia with Lewy bodies.

NMDA-receptor antagonists

- For example, **memantine** (see **Ch. 38**).
- Used in moderate-to-severe Alzheimer's disease and dementia with Lewy bodies.

Table 40.2

AChE, Acetylcholinesterase; *BuChE,* butyryl cholinesterase; *CNS,* central nervous system.

[a] Similar level of limited clinical benefit for all drugs. No clinical evidence for retardation of disease process, although animal tests suggest diminution of Aβ and plaque formation by a mechanism not related to cholinesterase inhibition.

Future drug development

Despite intensive research into the underlying causes of AD and DLB and the huge investment in drug development there have been few successes to date. Unravelling the mechanisms of neurodegeneration in AD and DLB has yet to result in therapies able to retard them and, with some spectacular failures having occurred in expensive clinical trials of new drugs (e.g. *verubecestat*, a β-secretase 1 [BACE1] inhibitor, and *solanezumab*, a monoclonal antibody against Aβ peptide). Fingers are crossed that aducanemab and lecanemab will be effective treatments. Descriptions of other potential therapies for AD that are still in various stages of development are provided by **Cummings et al. (2017)** and **Yiannopoulou and Papageorgiou (2020)**.

For most of the disorders discussed in this chapter, including dementia, the Holy Grail, which so far eludes us, would be a drug that retards neurodegeneration. Until more is understood about the causes of the neurodegeneration, treatments may remain elusive.

Cognitive deficits occur in a number of CNS disorders including dementia, PD, schizophrenia and depression. The development of

cognition-enhancing drugs that may be useful across these disorders is described in **Chapter 49**.

Parkinson's Disease

Features of Parkinson's Disease

PD is primarily a progressive disorder of movement that occurs mainly in the elderly. It was first described in 1817 by James Parkinson. **Przedborski (2017)** describes in detail how understanding of the disorder and its treatment have evolved over the subsequent 200 years.

The chief symptoms are:

- suppression of voluntary movements (*bradykinesia*), due partly to muscle rigidity and partly to an inherent inertia of the motor system, which means that motor activity is difficult to stop as well as to initiate;
- tremor at rest, usually starting in the hands ('pill-rolling' tremor), which tends to diminish during voluntary activity;
- muscle rigidity, detectable as an increased resistance in passive limb movement;
- cognitive and behavioural impairments.

Parkinsonian patients walk with a characteristic shuffling gait. They find it hard to start, and once in progress they cannot quickly stop or change direction. PD is commonly associated with dementia, depression, hallucinations, sleep disturbances and autonomic dysfunction, because the degenerative process is not confined to the basal ganglia but also affects other parts of the brain. Non-motor

symptoms may appear before motor symptoms and often predominate in the later stages of the disease.

PD often occurs with no obvious underlying cause, but it may be the result of cerebral ischaemia, viral encephalitis, head injury or other types of pathological damage. The symptoms can also be drug induced, the main drugs involved being those that block dopamine receptors (e.g. antiemetic and antipsychotic drugs such as **chlorpromazine**; see Chs **30** and **47**). There are rare instances of familial early-onset PD, and several gene mutations have been identified, including those encoding *synuclein* and *parkin*. Mutations in the gene encoding leucine-rich repeat kinase 2 (LRRK2) have also been associated with PD. Study of gene mutations has given some clues about the mechanism underlying the neurodegenerative process.

Neurochemical changes

PD affects the basal ganglia, and its neurochemical origin was discovered in 1960 by Hornykiewicz, who showed that the dopamine content of the substantia nigra and corpus striatum (see **Ch. 39**) in postmortem brains of PD patients was extremely low (usually less than 10% of normal), associated with a loss of dopaminergic neurons in the substantia nigra and degeneration of nerve terminals in the striatum. [7] Neurons containing other monoamines such as noradrenaline and 5-hydroxytryptamine are also affected. Gradual loss of dopamine occurs over several years, with symptoms of PD appearing only when the striatal dopamine content has fallen to 20%–40% of normal. Lesions of the nigrostriatal tract or chemically induced depletion of dopamine in experimental animals also

produce symptoms of PD. The symptom most clearly related to dopamine deficiency is *bradykinesia*, which occurs immediately and invariably in lesioned animals. Rigidity and tremor involve more complex neurochemical disturbances of other transmitters (particularly ACh, noradrenaline, 5-hydroxytryptamine and GABA) as well as dopamine. In experimental lesions, two secondary consequences follow damage to the nigrostriatal tract, namely a hyperactivity of the remaining dopaminergic neurons, which show an increased rate of transmitter turnover, and an increase in the number of dopamine receptors, which produces a state of denervation hypersensitivity (see **Ch. 13**). Neurons in the striatum express mainly D_1 (excitatory) and D_2 (inhibitory) receptors (see **Ch. 39**), but fewer D_3 and D_4 receptors. A simplified diagram of the neuronal circuitry involved, and the pathways primarily affected in PD and HD, is shown in **Fig. 40.4**.

Cholinergic interneurons of the corpus striatum (not shown in **Fig. 40.4**) are also involved in PD and HD. ACh release from the striatum is strongly inhibited by dopamine, and it is suggested that hyperactivity of these cholinergic neurons contributes to the symptoms of PD. The opposite happens in HD, and in both conditions therapies aimed at redressing the balance between the dopaminergic and cholinergic neurons are, up to a point, beneficial.

Pathogenesis of Parkinson's Disease

As with other neurodegenerative disorders, the neuronal damage in PD is caused by protein misfolding and aggregation, aided and abetted by other familiar villains, namely excitotoxicity, mitochondrial dysfunction, oxidative stress, inflammation and

apoptosis. Aspects of the pathogenesis and animal models of PD have been described by **Duty and Jenner (2011)**.

Neurotoxins

New light was thrown on the possible aetiology of PD by a chance event. In 1982, a group of young drug users in California suddenly developed an exceptionally severe form of PD (known as the 'frozen addict' syndrome), and the cause was traced to the compound 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (**MPTP**), which was a contaminant in the illegal preparation of a heroin substitute (see **Langston, 1985**). MPTP causes irreversible destruction of nigrostriatal dopaminergic neurons in various species, and produces a PD-like state in primates. MPTP acts by being converted to a toxic metabolite, MPP^+, by the enzyme monoamine oxidase (MAO; specifically by the MAO-B subtype that is located in glial cells; see Chs **15** and **48**). MPP^+ is then taken up by the dopamine transport system, and thus acts selectively on dopaminergic neurons; it inhibits mitochondrial oxidation reactions, producing oxidative stress. MPTP appears to be selective in destroying nigrostriatal neurons and does not affect dopaminergic neurons elsewhere – the reason for this is unknown. It is also less effective in rats than in primates, yet mice show some susceptibility. **Selegiline**, a selective MAO-B inhibitor, prevents MPTP-induced neurotoxicity by blocking its conversion to MPP^+. Selegiline is also used in treating PD (see later); as well as inhibiting dopamine breakdown, it might also work by blocking the metabolic activation of a putative endogenous, or environmental, MPTP-like substance, which is involved in the causation of PD. It is possible that dopamine itself could be the

culprit, because oxidation of dopamine gives rise to potentially toxic metabolites. Whether or not the action of MPTP reflects the natural pathogenesis of PD, the MPTP model is a very useful experimental tool for testing possible therapies.

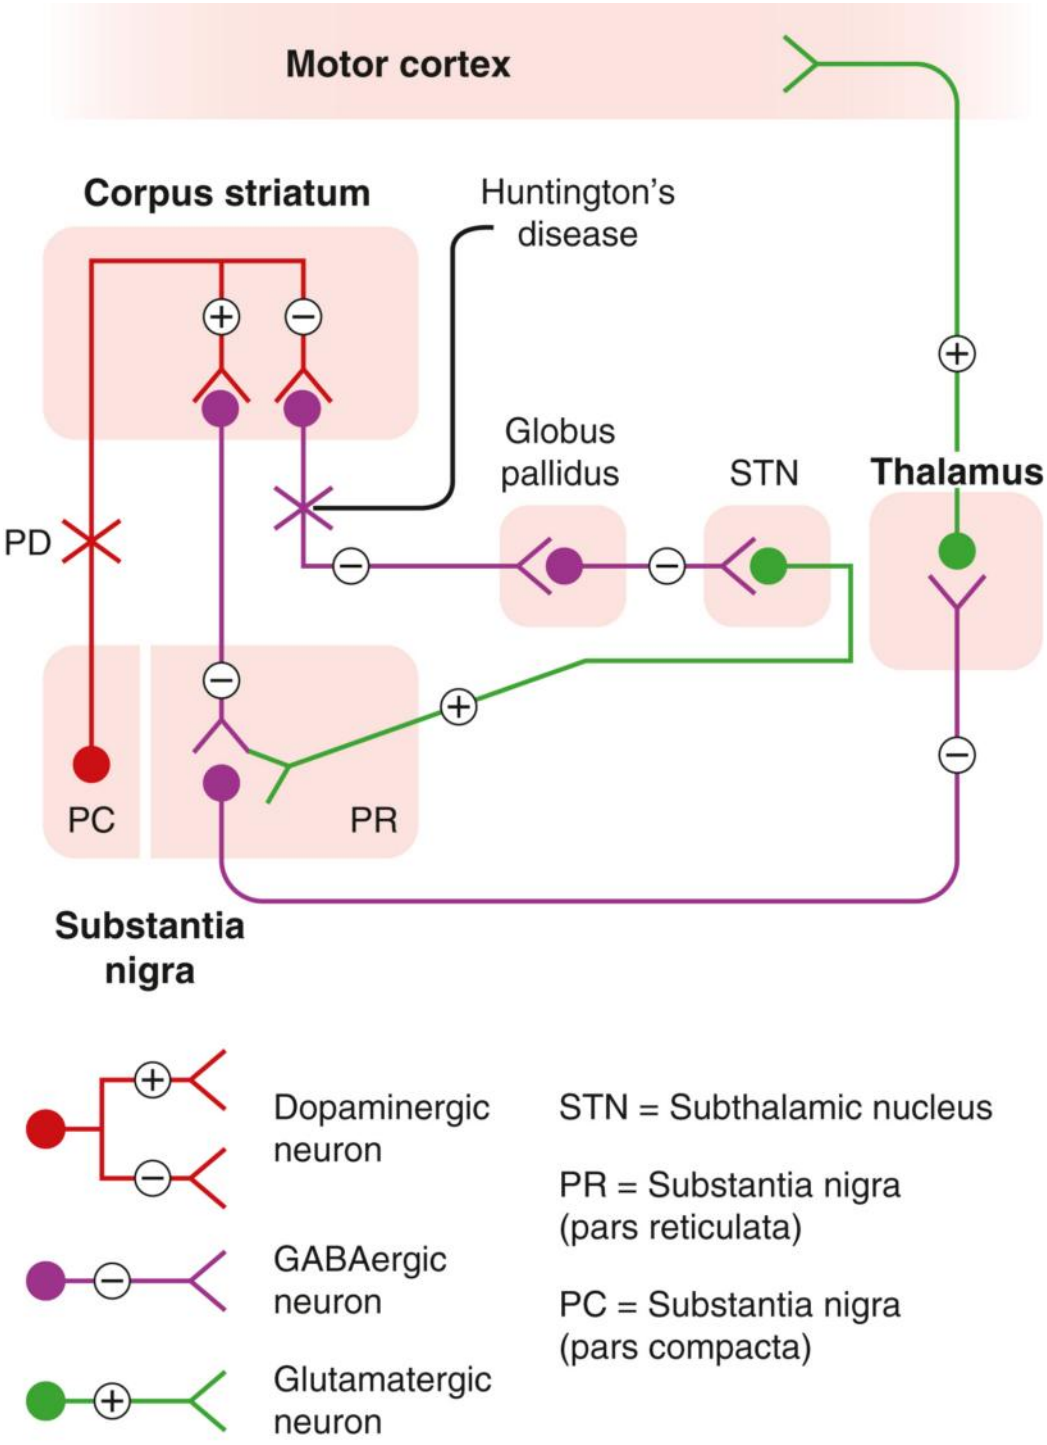

FIG. 40.4 Simplified diagram of the organisation of the extrapyramidal motor system and the defects that occur in Parkinson's disease (PD) and Huntington's disease.Normally, activity

> in nigrostriatal dopamine neurons causes excitation of striatonigral neurons and inhibition of striatal neurons that project to the globus pallidus. Because of the different pathways involved, the activity of *GABAergic neurons* in the *substantia nigra* is suppressed, releasing the restraint on the *thalamus* and *cortex*, causing motor stimulation. In PD, the dopaminergic pathway from the *substantia nigra (pars compacta)* to the *striatum* is impaired. In Huntington's disease, the GABAergic striatopallidal pathway is impaired, producing effects opposite to the changes in PD.

Impaired mitochondrial function is a feature of the disease in humans. Various herbicides, such as **rotenone**, that selectively inhibit mitochondrial function cause a PD-like syndrome in animals. PD in humans is more common in agricultural areas than in cities, suggesting that environmental toxins could be a factor in its causation.

PD is also associated with the development of *Lewy bodies* containing *α-synuclein* (see earlier discussion). It is possible (see **Lotharius and Brundin, 2002**) that the normal function of α-synuclein is related to synaptic vesicle recycling, and that the misfolded form loses this functionality, with the result that vesicular storage of dopamine is impaired. This may lead to an increase in cytosolic dopamine, degradation of which produces ROS and hence neurotoxicity. Consistent with the α-synuclein hypothesis, another mutation associated with PD (*parkin*) also

involves a protein that participates in the intracellular degradation of rogue proteins.

Other gene mutations that have been identified as risk factors for early-onset PD code for proteins involved in mitochondrial function, making cells more susceptible to oxidative stress. Thus, a picture similar to AD pathogenesis is slowly emerging. Misfolded α-synuclein, facilitated by overexpression, genetic mutations or possibly by environmental factors, builds up in the cell as a result of impaired protein degradation (resulting from defective parkin) in the form of Lewy bodies, which, by unknown mechanisms, compromise cell survival. If oxidative stress is increased, as a result of ischaemia, mitochondrial poisons or mutations of certain mitochondrial proteins, the result is cell death.

Parkinson's disease

- Degenerative disease of the basal ganglia causing hypokinesia, tremor at rest and muscle rigidity, often with dementia and autonomic dysfunction.
- Associated with aggregation of α-synuclein (a protein normally involved in vesicle recycling) in the form of characteristic Lewy bodies.
- Often idiopathic but may follow stroke or virus infection; can be drug induced (antipsychotic drugs). Rare familial forms also occur, associated with various gene mutations, including α-synuclein.
- Associated with degeneration of dopaminergic nigrostriatal neurons that gives rise to the motor symptoms, as well as

more general neurodegeneration resulting in dementia and depression.

- Can be induced by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (**MPTP**), a neurotoxin affecting dopamine neurons. Similar environmental neurotoxins, as well as genetic factors, may be involved in human Parkinson's disease.

Drug Treatment of Parkinson's Disease

Currently, the main drugs used (**Fig. 40.5**) are:

- **levodopa** (sometimes in combination with **carbidopa** and **entacapone**);
- dopamine agonists (e.g. **pramipexole**, **ropinirole**, **bromocriptine**);
- MAO-B inhibitors (e.g. **selegiline**, **rasagiline**);
- muscarinic ACh receptor antagonists (e.g. **orphenadrine, procyclidine** and **trihexyphenidyl**) are occasionally used.

None of the drugs used to treat PD affect the progression of the disease.

Levodopa

Levodopa is the first-line treatment for PD and is combined with a peripherally acting dopa decarboxylase inhibitor, such as **carbidopa** or **benserazide**, which reduces the dose needed by about 10-fold and diminishes the peripheral side effects. It is well

absorbed from the small intestine, a process that relies on active transport, although much of it is inactivated by MAO in the wall of the intestine. The plasma half-life is short (about 2 h). Oral and subcutaneous slow-release preparations have been developed. Conversion to dopamine in the periphery, which would otherwise account for about 95% of the levodopa dose and cause troublesome side effects, is largely prevented by the decarboxylase inhibitor. Decarboxylation occurs rapidly within the brain, because the decarboxylase inhibitors do not penetrate the blood–brain barrier. It is not certain whether the effect depends on an increased release of dopamine from the few surviving dopaminergic neurons or on a 'flooding' of the synapse with dopamine formed elsewhere. Because synthetic dopamine agonists are equally effective, the latter explanation is more likely, and animal studies suggest that levodopa can act even when no dopaminergic nerve terminals are present. On the other hand, the therapeutic effectiveness of levodopa decreases as the disease advances, so part of its action may rely on the presence of functional dopaminergic neurons. A combination of levodopa plus a dopa decarboxylase inhibitor with a catechol-*O*-methyl transferase (COMT) inhibitor (e.g. **entacapone**, **tolcapone** or **opicapone;** see **Ch. 15**) to inhibit its degradation is used in patients troubled by 'end of dose' motor fluctuations.

Therapeutic effectiveness

About 80% of patients show initial improvement with levodopa, particularly of rigidity and bradykinesia, and about 20% are restored virtually to normal motor function. As time progresses, the effectiveness of levodopa gradually declines (**Fig. 40.6**). In a

typical study of 100 patients treated with levodopa for 5 years, only 34 were better than they had been at the beginning of the trial, 32 patients having died and 21 having withdrawn from the trial. It is likely that the loss of effectiveness of levodopa mainly reflects the natural progression of the disease, but receptor down-regulation and other compensatory mechanisms may also contribute. There is no evidence that levodopa can actually accelerate the neurodegenerative process through overproduction of dopamine, as was suspected on theoretical grounds. Overall, levodopa increases the life expectancy of PD patients, probably as a result of improved motor function, although some symptoms (e.g. dysphagia, cognitive decline) are not improved.

Unwanted effects

There are two main types of unwanted effect:

1. Involuntary movements (dyskinesia), which do not appear initially but develop in the majority of patients within 2 years of starting levodopa therapy. These movements usually affect the face and limbs, and can become very severe. They occur at the time of the peak therapeutic effect, and the margin between the beneficial and the dyskinetic effect becomes progressively narrower. Levodopa is short acting, and the fluctuating plasma concentration of the drug may favour the development of dyskinesias, as longer-acting dopamine agonists are less problematic in this regard.

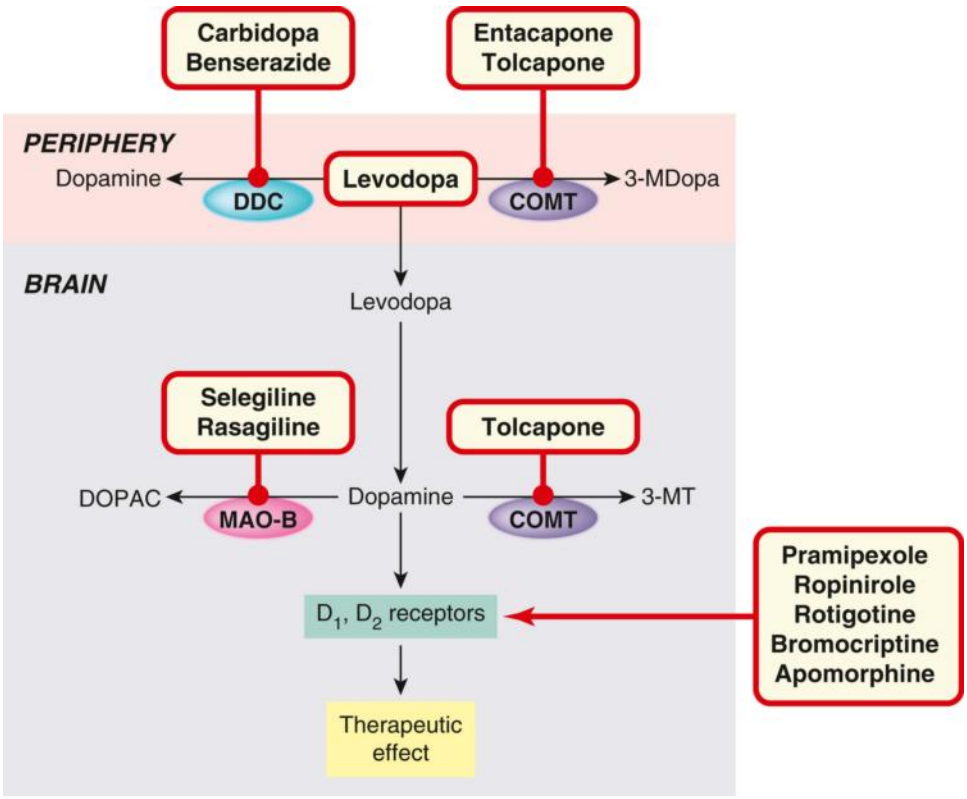

FIG. 40.5 Sites of action of drugs used to treat Parkinson's disease. *Levodopa* enters the brain and is converted to *dopamine* (the deficient neurotransmitter). Inactivation of levodopa in the periphery is prevented by inhibitors of dopa decarboxylase (DDC) and catechol-*O*-methyl transferase (COMT). Inactivation in the brain is prevented by inhibitors of COMT and monoamine oxidase-B (MAO-B). Dopamine agonists act directly on striatal dopamine receptors. *3-MDopa,* 3-Methoxydopa; *3-MT,* 3-methoxytyrosine; *DOPAC,* dihydroxyphenylacetic acid.

2. Rapid fluctuations in clinical state, where bradykinesia and rigidity may suddenly worsen for anything from a few minutes to a few hours, and then improve again. This 'on–off effect' is not seen in untreated PD patients or with other anti-PD drugs. The 'off effect' can be so sudden that the patient stops while walking and feels rooted to the spot, or is unable to rise from a chair, having sat down normally a few moments earlier. As with the dyskinesias, the problem seems to reflect the fluctuating plasma concentration of levodopa, and it is suggested that as the disease advances, the ability of neurons to store dopamine is lost, so the therapeutic benefit of levodopa depends increasingly on the continuous formation of extraneuronal dopamine, which requires a continuous supply of levodopa. The use of sustained-release preparations, or co-administration of COMT inhibitors such as **entacapone**, may be used to counteract the fluctuations in plasma concentration of levodopa. Recently, **istradefylline**, an adenosine A2A receptor antagonist, has been approved as an add-on treatment to levodopa and carbidopa to reduce 'off' periods. How it produces this effect is still somewhat unclear.

In addition to these slowly developing side effects, levodopa produces several acute effects, which are experienced by most patients at first but tend to disappear after a few weeks. The main ones are as follows:

- Nausea and anorexia. **Domperidone**, a dopamine antagonist that works in the chemoreceptor trigger zone

(where the blood–brain barrier is leaky) but does not gain access to the basal ganglia, may be useful in preventing this effect.

- Hypotension. Postural hypotension is a recognised problem, particularly in older patients.
- Psychological effects. Levodopa, by increasing dopamine activity in the brain, can produce a schizophrenia-like syndrome (see **Ch. 47**) with delusions and hallucinations. More commonly, in about 20% of patients, it causes confusion, disorientation, insomnia or nightmares.

Dopamine Agonists

Bromocriptine, **pergolide** and **cabergoline** exhibit slight selectivity for $D_{2/3}$ over D_1 receptors (see **Ch. 39**). Bromocriptine, which inhibits the release of prolactin from the anterior pituitary gland, was first introduced for the treatment of galactorrhoea and gynaecomastia (see **Ch. 33**). Although effective in controlling the symptoms of PD, their usefulness is limited by side effects, such as nausea and vomiting, somnolence and a risk of fibrotic reactions in the lungs, retroperitoneum and pericardium. These disadvantages have led to the replacement of these drugs by **pramipexole** and **ropinirole**, which are $D_{2/3}$ selective and better tolerated, and do not show the fluctuations in efficacy associated with levodopa. They do, however, cause somnolence and sometimes hallucinations, and recent evidence suggests that they may predispose to compulsive behaviours, such as excessive gambling, [8] over-eating and sexual excess, related to the 'reward' functions of dopamine (see **Ch. 50**).

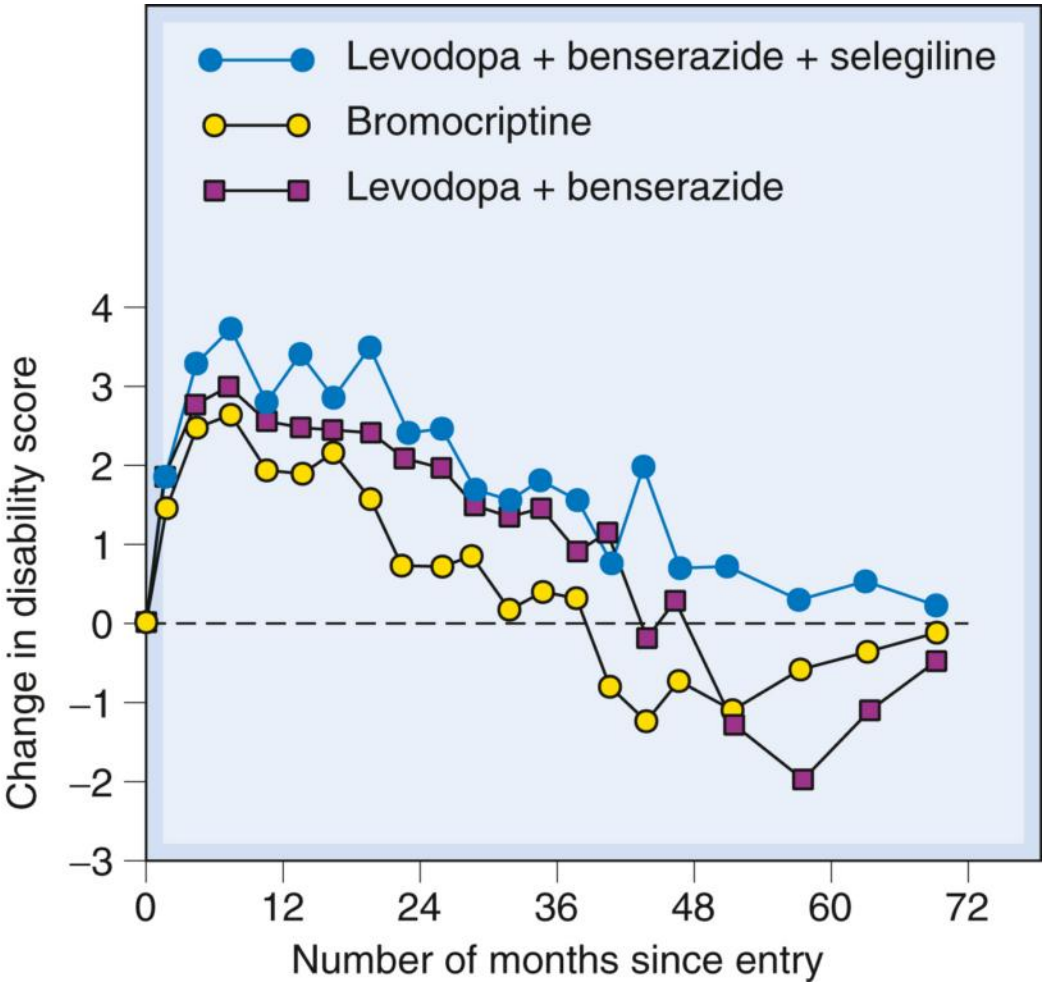

FIG. 40.6 Comparison of levodopa/benserazide, levodopa/benserazide/selegiline and bromocriptine on progression of Parkinson's disease symptoms.Patients (249–271 in each treatment group) were assessed on a standard disability rating score. Before treatment, the average rate of decline was 0.7 units/year. All three treatments produced improvement over the initial rating for 2–3 years, but the effect declined, either because of refractoriness to the drugs or disease progression. Bromocriptine

appeared slightly less effective than levodopa regimens, and there was a higher drop-out rate due to side effects in this group. From Parkinson's Disease Research Group, 1993. Br. Med. J. 307, 469–472.

A disadvantage of current dopamine agonists is their short plasma half-life (6–8 h), requiring three-times daily dosage, although slow-release once-daily formulations are now available.

Rotigotine is a newer agent, delivered as a transdermal patch, with similar efficacy and side effects.

Apomorphine, given by injection, is sometimes used to control the 'off effect' with levodopa. Because of its powerful emetic action, it must be combined with an oral antiemetic drug. It has other serious adverse effects (mood and behavioural changes, cardiac dysrhythmias, hypotension) and is a last resort if other drugs fail.

MAO-B Inhibitors

Selegiline is a selective MAO-B [9] inhibitor, which lacks the unwanted peripheral effects of non-selective MAO inhibitors used to treat depression (see **Ch. 48**) and, in contrast to them, does not provoke the 'cheese reaction' or interact so frequently with other drugs. Inhibition of MAO-B protects dopamine from extraneuronal degradation and was initially used as an adjunct to levodopa. Long-term trials showed that the combination of selegiline and levodopa was more effective than levodopa alone in relieving symptoms and prolonging life. Recognition of the role of MAO-B in neurotoxicity suggested that selegiline might be neuroprotective rather than merely enhancing the action of levodopa, but clinical studies do not

support this. A large-scale trial (see **Fig. 40.6**) showed no difference when selegiline was added to levodopa/benserazide treatment. Selegiline is metabolised to amphetamine, and sometimes causes excitement, anxiety and insomnia. **Rasagiline**, a very similar drug, does not have this unwanted effect, and may somewhat retard disease progression, as well as alleviating symptoms (**Olanow et al., 2009**). **Safinamide** inhibits both MAO-B and dopamine reuptake.

Other Drugs Used in Parkinson's Disease

Amantadine

Amantadine was introduced as an antiviral drug and discovered by accident in 1969 to be beneficial in PD. Many possible mechanisms for its action have been suggested based on neurochemical evidence of increased dopamine release, inhibition of amine uptake or a direct action on dopamine receptors. More recently block of NMDA receptors by stabilising closed states of the channel has been described and this may be a novel target for antiparkinsonian drugs.

Amantadine is less effective than levodopa or bromocriptine in treating PD, but it is effective in reducing the dyskinesias induced by prolonged levodopa treatment.

Acetylcholine antagonists

For more than a century, until levodopa was discovered, atropine and related drugs were the main form of treatment for PD. Muscarinic ACh receptors exert an inhibitory effect on dopaminergic nerve terminals, suppression of which compensates for a lack of dopamine. The side effects of muscarinic antagonists

(see **Ch. 14**) – dry mouth, constipation, impaired vision, urinary retention – are troublesome, and they are now rarely used, except to treat parkinsonian symptoms in patients receiving antipsychotic drugs (which are dopamine antagonists and thus nullify the effect of levodopa; see **Ch. 47**). Drugs used are **orphenadrine**, **procyclidine** and **trihexyphenidyl**.

Adjuncts to therapy

A range of drugs can be used to treat the non-motor symptoms associated with PD. These include cholinesterase inhibitors and memantine for dementia (see earlier), antidepressants for depression (see **Ch. 48**), quetiapine, clozapine and pimavanserin for hallucinations (see **Ch. 47**), modafinil for daytime sleepiness (see **Ch. 49**), clonazepam (see **Ch. 45**) and melatonin (see **Ch. 39**) for rapid-eye-movement (REM) sleep disturbances.

New Pharmacological Approaches

Potential new treatments for PD at various stages of clinical trial are reviewed by **Oertel and Schulz (2016)**. Sadly, several candidates that showed promise in preclinical studies lacked efficacy in subsequent clinical trials (e.g. preladenant and saritozan). Active and passive immunisation against α-synuclein and inhibitors or modulators of α-synuclein aggregation may prevent the progression of the disease.

Drugs used in Parkinson's disease

- Drugs act by counteracting deficiency of dopamine in basal ganglia or by blocking muscarinic receptors. None of the

available drugs affect the underlying neurodegeneration.

- Drugs include:
  - **levodopa** (dopamine precursor; see **Ch. 15**), given with an inhibitor of peripheral dopa decarboxylase (e.g. **carbidopa**) to minimise side effects; sometimes a COMT inhibitor (e.g. **entacapone**) is also given, especially to patients with 'end of dose' motor fluctuations;
  - dopamine receptor agonists (**pramipexole**, **ropinirole**, **rotigotine**, **bromocriptine**); **rotigotine** is available as a transdermal patch;
  - MAO-B inhibitors (**selegiline**, **rasagiline**);
  - **amantadine** (which may enhance dopamine release);
  - **orphenadrine** (muscarinic receptor antagonist used for parkinsonism caused by antipsychotic drugs).
- Stem cell transplantation, still in early clinical development, may be effective.

Neural Transplantation, Gene Therapy and Brain Stimulation

PD is the first neurodegenerative disease for which neural transplantation was attempted in 1982, amid much publicity. Various transplantation approaches have been tried, based on the injection of dissociated fetal cells (neuroblasts) directly into the striatum. Trials in patients with PD (**Barker et al., 2013**) mainly involved injection of midbrain cells from aborted human fetuses. Although such transplants have been shown to survive and

establish functional dopaminergic connections, this approach has fallen out of favour. Some patients have gone on to develop serious dyskinesias, possibly due to dopamine overproduction. The use of fetal material is, of course, fraught with ethical difficulties (usually cells from five or more fetuses are needed for one transplant) and hopes for the future rest mainly on developing stem cell transplants (**Nishimura and Takahashi, 2013**); small clinical trials are underway (**Schweitzer et al., 2020**).

Gene therapy (see **Ch. 5**) for PD is aimed at increasing the synthesis of neurotransmitters and neurotrophic factors such as:

- dopamine in the striatum – by expressing tyrosine hydroxylase or dopa decarboxylase;
- GABA in the subthalamic nucleus – by overexpression of glutamic acid decarboxylase (to reduce the excitatory input to the substantia nigra) (see **Fig. 40.4**);
- neurotrophic factors such as neurturin, a glial-derived neurotrophic factor (GDNF) analogue.

Electrical stimulation of the subthalamic nuclei with implanted electrodes (which inhibits ongoing neural activity, equivalent to reversible ablation) is used in severe cases, and can improve motor dysfunction in PD, but does not improve cognitive and other symptoms and does not stop the neurodegenerative process (see **Okun, 2012**).

Essential Tremor

ET is probably the most prevalent movement disorder, approximately 8 times more common than PD, but its underlying

pathology is very poorly understood and there has been surprisingly little progress in this area despite its prevalence. It is characterised by a rhythmic postural or kinetic tremor at 4–12 Hz and mainly affects the upper extremities although it can progress to include other locations including the head, laryngeal muscles and lower extremities. The differences between PD-related tremor and ET are not necessarily obvious from symptom presentation but they arise from very different aetiologies. Where PD is linked to the loss of dopaminergic neurons, the neurochemical basis of ET is unknown. Based on the ability to generate tremor in an animal model using the β-carboline, harmaline, a role for GABAergic dysfunction in ET has been suggested as has a shift in the balance between excitatory/inhibitory neurotransmission but there may also be involvement of other neurotransmitters including dopamine, adenosine and noradrenaline. ET has some genetic associations and likely arises from an interaction of genetics and environmental factors (**Clark and Louis, 2018**).

Whilst ET may remain relatively mild and show only a slow progression and hence have limited impact on the patient, it can in other patients progress to become debilitating and make basic tasks such as eating, writing and other simple day-to-day activities challenging. It also seems to have an interesting association with emotional states and can become much more evident during periods of emotional stress.

With very limited evidence of any specific neurochemical deficit, drug treatments have relied heavily on trials with drugs used for other conditions. The most effective treatments are the β-blocker propranolol (Chs **15** and **20**) and the anti-epileptic barbiturate

primidone (**Ch. 46**), although effectiveness varies and not all patients achieve good remediation of symptoms. It is well known that alcohol is effective at reducing the amplitude and severity of the ET but this leads to a risk of patients developing alcoholism. An alternative approach to treating the central mechanisms generating ET is to target the limbs directly and injections of botulinum toxin type A into the forearm flexor and extensor muscles can improve upper limb tremor with relatively few side effects. A recent review of pharmacological approaches to treating ET discusses a wide range of drugs that have undergone clinical evaluation but there remains a pressing need for more research and understanding of the underlying pathology (**Alonso-Navarro et al., 2020**).

Huntington's Disease

HD is an inherited (autosomal dominant) disorder resulting in progressive brain degeneration, starting in adulthood and causing rapid deterioration and death. As well as dementia, it causes severe motor symptoms in the form of choreiform (i.e. rapid, jerky involuntary) movements, especially of fingers, face or tongue. It is the commonest of a group of so-called *trinucleotide repeat* neurodegenerative diseases, associated with the expansion of the number of repeats of the CAG sequence in specific genes, and hence the number (50 or more) of consecutive glutamine residues at the N-terminal of the expressed protein (see **Walker, 2007**). The larger the number of repeats, the earlier the appearance of symptoms. The protein coded by the HD gene, *huntingtin*, which normally possesses a chain of fewer than 30 glutamine residues, is a soluble cytosolic protein of unknown function found in all cells. HD

develops when the mutant protein contains 40 or more repeats. The long poly-Gln chains reduce the solubility of huntingtin, and favour the formation of aggregates, which are formed by proteolytic cleavage of the mutant protein, releasing N-terminal fragments that include the poly-Gln region. As with AD and PD, aggregation is probably responsible for the neuronal loss, which affects mainly the cortex and the striatum, resulting in progressive dementia and severe involuntary choreiform movements. Studies on postmortem brains showed that the dopamine content of the striatum was normal or slightly increased, while there was a 75% reduction in the activity of glutamic acid decarboxylase, the enzyme responsible for GABA synthesis (see **Ch. 38**). It is believed that the loss of GABA-mediated inhibition in the basal ganglia produces a hyperactivity of dopaminergic synapses, so the syndrome is in some senses a mirror image of PD (see **Fig. 40.4**).

The effects of drugs that influence dopaminergic transmission are correspondingly the opposite of those that are observed in PD, dopamine antagonists being effective in reducing the involuntary movements, while drugs such as levodopa and bromocriptine make them worse. Drugs used to alleviate the motor symptoms include **tetrabenazine** (an inhibitor of the vesicular monoamine transporter) (see **Ch. 15**) that reduces dopamine storage, dopamine antagonists such as **chlorpromazine** and **haloperidol** (see **Ch. 47**) and the $GABA_B$ receptor agonist **baclofen** (see **Ch. 38**). Other drug treatments include antidepressants, mood stabilisers (see **Ch. 48**) and benzodiazepines (see **Ch. 45**) to reduce the depression, mood swings and anxiety associated with the disorder. None of these drugs affects dementia or retards the course of the disease.

Drugs (e.g. **branaplam**) and genetic approaches (e.g. antisense oligonucleotides, RNAi) that lower huntingtin levels are currently undergoing clinical investigation.

Amyotrophic Lateral Sclerosis

ALS is the most common form of motor neuron disease, in which degeneration of motor neurons leads to paralysis and eventual death. In ALS, degeneration occurs in both upper motor neurons, those projecting from higher centres to the spinal cord and in lower motor neurons, those projecting from the ventral horn of the spinal cord to skeletal muscle. The causes of ALS are not known, but there is evidence that both genetic and environmental factors such as exposure to bacterial toxins, heavy metals, pesticides and trauma are involved. [10] Mutations in several genes – *SOD1*, C9orf72 and NEK1 – have been associated with some cases of familial ALS (see **Pochet, 2017**).

The drugs currently used in ALS treatment are **riluzole** and **edaravone**. Riluzole may work by reducing glutamate release whereas edaravone may reduce oxidative stress. However, these drugs only provide limited improvement. A skeletal muscle troponin activator, **reldesemtiv**, which may slow progressive muscle weakness, has recently entered Phase 3 clinical trials. It may also be effective in spinal muscular atrophy (see later). Therapies, designed to suppress the expression of mutated genes, and stem cell therapies continue to be investigated. **Tofersen**, an antisense directed against SOD1, is currently in Phase 3 clinical trial for treatment of ALS associated with mutations of SOD1.

Spinal Muscular Atrophy

SMA is a group of inherited neuromuscular disorders in which there is degeneration of motor neurons and progressive muscle wasting. It is the most common genetic cause of infant death. Motor neurons require expression of a protein, appropriately called *survival motorneuron protein* (SMN), for them to survive and function normally. SMA is caused by a genetic defect in the SMN-1 gene encoding for SMN. In recent years there have been several gene therapies (see **Ch. 5**) developed for SMA, bringing hope to families affected by these devastating disorders. **Nusinersen**, an antisense oligonucleotide sequence given by intrathecal injection, facilitates SMN expression, not from the mutated SMN-1 gene but from SMN-2, a 'backup' gene that under normal conditions, due to exon skipping, does not produce much functional SMN. Nusinersen prevents the skipping, thus allowing the cell to produce SMN. **Risdiplam**, an orally active SMN 2-directed RNA splicing modifier, increases the production of functional SMN protein. **Onasemnogene abeparvovec**, [11] an SMN-1 transgene, is a non-replicating recombinant viral vector modified to contain the cDNA of the human SMN gene. The vector carries a functional copy of the SMN1 gene into motor neurons, thus providing an alternative source of SMN protein expression in these cells.

Multiple Sclerosis

MS is a disease associated with demyelination of nerve axons and neuronal degeneration resulting in lesions that may occur throughout the CNS. Symptoms usually start to develop between 20 and 30 years of age and depend upon the location of the lesions.

Common symptoms include problems with vision, dizziness, balance, walking, fatigue, incontinence, muscle stiffness and painful muscle spasms. MS can also affect cognitive processing and mood. It affects almost three times as many women as men. There are two forms of the disease*, relapse–remitting*, in which sufferers have attacks of symptoms which subsequently fade away partially or completely but then relapse at a later date, and *primary progressive*, in which the symptoms persist and increase over time. Relapse–remitting may, however, develop into secondary progressive in later life. The cause of MS is unknown; like other neurodegenerative conditions it may result from a combination of predisposing genetic factors (**Hollenbach and Oksenberg, 2015**) and exposure to environmental factors such as infection.

MS has long been considered an autoimmune demyelinating disease, although the proteins, lipids and gangliosides in myelin that act as antigens have not been identified. Inflammation (see **Ch. 25**), enhanced permeability of blood–brain barrier, demyelination and axonal degeneration are common pathological features. It is, however, still unclear whether MS is a primary autoimmune disease that affects the CNS or a neurodegenerative disease with secondary inflammatory demyelination (see **Trapp and Nave, 2008**). Current therapies are aimed at moderating the acute inflammatory components of MS (**Table 40.3**), but they are limited in effectiveness. They may reduce the rate of clinical deterioration and incidence of relapses but by and large they do not reverse the neurodegeneration that has occurred. Several (**natalizumab**, **alemtuzumab, daclizumab** and **ocrelizumab**) are monoclonal antibodies that target specific proteins expressed on B and T

lymphocytes to limit their spread into the brain and spinal cord where they attack the myelin sheath around motor nerves. Monoclonal antibody therapy does, however, carry the risk of serious autoimmune complications (see **Ch. 5**) that need to be monitored. The pathological mechanisms underlying the neurodegeneration, which renders the disease irreversible, are still not well understood but may hold the key to finding disease-curing treatments. Symptomatic treatment of MS includes **baclofen** and **nabiximols**, a botanical extract of cannabis containing tetrahydrocannabinol (THC) and cannabidiol (CBD) (see **Ch. 18**), for spasticity; and **fampridine** (a potassium-channel blocker that enhances action potential propagation in demyelinated axons) for a modest improvement in walking speed.

Table 40.3

MS, Multiple sclerosis.

Drug treatment of multiple sclerosis

Several new and efficacious agents have emerged in the treatment of multiple sclerosis (MS), but these treatments also bring with them a significant risk of serious adverse effects. As the severity and course of MS vary substantially amongst individuals, selection of appropriate therapy must consider not only the benefit and harm of the proposed agents, but also the patient's clinical condition and co-morbidities.

Prompt use of disease-modifying therapies is recommended in patients who have clinical and/or radiological evidence of active

disease. Examples of therapeutic options for patients with active relapsing–remitting MS are:

- Drugs of moderate efficacy such as **interferon-beta** or **glatiramer acetate** by injection. **Teriflunomide** or **dimethylfumarate** can be used if oral therapy is preferred.
- Drugs of high efficacy such as **natalizumab** or **alemtuzumab** may be considered in those with more active disease.

There is limited evidence for interferon in progressive MS, but **ocrelizumab** is an emerging option for primary progressive disease.

Drugs that are used to manage symptoms or disease complications in MS include **baclofen** (for muscle spasticity) and **amitriptyline** (for emotional lability).

QUESTIONS

QUESTION 40.1

Neurodegenerative disorders are characterised by pathological changes that result in neurotoxicity and neuronal cell death.

Which of the following may lead to increased neural damage?

OPTIONS:

A. Increased levels of superoxide dismutase

B. Increased levels of Bcl-2

C. Ubiquitination of amyloid proteins

D. Enhanced glutamate release

E. Reduction in voltage operated calcium channel (VOCC) activity

QUESTION 40.2

Many neurodegenerative disorders are caused by protein misfolding or imbalances in the release of neurotransmitters.

Which of the following statements about the aetiology of these disease states is incorrect?

OPTIONS:

A. In ischaemic stroke, the initial ischaemic damage in the centre of the lesion is caused by excitotoxicity.

B. The primary symptom of Alzheimer's disease is an increase in $AB_{42/40}$ ratio.

C. Dementia with Lewy bodies (DLB) is associated with aberrant folding of the α-synuclein protein.

D. Parkinson's disease (PD) is precipitated by a decrease in dopaminergic transmission.

E. Huntington's disease (HD) is associated with a decrease in GABA synthesis.

QUESTION 40.3

Genetic mutations underpin the development of many of the neurodegenerative disorders.

Which of the following genetic changes is not a contributing factor in Alzheimer's disease?

OPTIONS:

A. Overexpression of GSK-3β

B. Mutations in ApoE4 gene

C. Mutations in presenilins

D. Mutations in APP gene

E. Overexpression of α-secretase

ANSWERS

ANSWER 40.1

RATIONALE:

A. Superoxide dismutase (SOD) reduces levels of cytotoxic reactive oxygen species, which mediate neural damage.

B. Bcl-2 is a cytoprotective, antiapoptotic factor.

C. Ubiquitination removes misfolded and damaged proteins to prevent cytotoxicity.

D.

E. Reducing the influx of Ca^{2+} through VOCCs reduces the intracellular Ca^{2+} load and reduces cytotoxicity and neuronal death.

CORRECT ANSWER WITH EXPLANATION:

D. Enhanced glutamate release

Increased levels of glutamate, through binding to (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), *N*-methyl-D-aspartate (NMDA) and metabotropic receptors, cause neuronal excitotoxicity due to calcium overload.

ANSWER 40.2

RATIONALE:

A.

B. $A\beta_{42}$ is overproduced as a result of genetic mutations so increasing the $AB_{40/42}$ ratio. Both proteins aggregate to form amyloid plaques, but $A\beta_{42}$ shows a stronger tendency than $A\beta_{40}$ to do so, and appears to be the main culprit in amyloid formation.

C. Mutated or misfolded α-synuclein aggregates in the form of Lewy bodies may contribute to the neurodegeneration.

D. PD is associated with a loss of dopaminergic neurons in the substantia nigra and degeneration of nerve terminals in the striatum.

E. In HD there is a 75% reduction in the activity of glutamic acid decarboxylase, the enzyme responsible for GABA synthesis,

resulting in a hyperactivity of dopaminergic synapses, so the syndrome is in some senses a mirror image of PD.

CORRECT ANSWER WITH EXPLANATION:

A. In ischaemic stroke, the initial ischaemic damage in the centre of the lesion is caused by excitotoxicity.

The lesion produced by occlusion of a major cerebral artery consists of a central core in which the neurons quickly undergo irreversible necrosis, surrounded by a penumbra of compromised tissue in which inflammation and apoptotic cell death develop over a period of several hours.

ANSWER 40.3

RATIONALE:

A. Tau is abnormally phosphorylated by the action of various kinases, including glycogen synthase kinase-3β (GSK-3β).

B. The ApoE4 protein is implicated in amyloid clearance and tau neurofibrillary tangles.

C. Mutations of the presenilin genes result in increased activity of γ-secretase, because the presenilin proteins form part of the γ-secretase complex.

D. Mutations in the APP gene affect the preferred cleavage point of γ-secretase, tending to favour formation of $A\beta 4_2$.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Overexpression of α-secretase

α-Secretase targets APP to release the large extracellular domain as soluble APP, which is believed to serve a physiological trophic function.

[1] It is recognised that new neurons are formed from progenitor cells (neurogenesis) in certain regions of the adult brain and can become functionally integrated, even in primates (see Rakic, 2002; Zhao et al., 2008). Neurogenesis in the hippocampus is thought to play a role in learning and memory but plays little if any role in brain repair. However, learning how to harness the inherent ability of neuronal progenitors (stem cells) to form new neurons is seen as a promising approach to treating neurodegenerative disorders.

[2] Such prion diseases include Creutzfeldt–Jakob's disease (CJD) and the new variant CJD. Sadly, no pharmacological treatments that prevent disease progression are yet available and treatment is aimed at ameliorating the symptoms.

[3] Surprisingly, some SOD mutations associated with ALS are more, rather than less, active than the normal enzyme. The mechanism responsible for neurodegeneration probably involves abnormal accumulation of the enzyme in mitochondria.

[4] Nevertheless, early reperfusion (within 4.5 h of the thrombosis) is clearly beneficial, based on clinical evidence with fibrinolytic drugs.

[5] Eating dark chocolate is believed to reduce the risk of stroke. Flavonoids in the chocolate may be protective due to antioxidant, anti-clotting and anti-inflammatory properties. However, this is not a reason to overindulge!

[6] The APP gene resides on chromosome 21, of which an extra copy is the cause of Down's syndrome, in which early AD-like dementia occurs in association with overexpression of APP.

[7] It is emerging that other types of neuron are also affected. Here we concentrate on the dopaminergic nigrostriatal pathway as it is the most important in relation to current therapies.

[8] In 2008 a plaintiff was awarded $8.2 million damages by a US court, having become a compulsive gambler (and losing a lot of money) after taking pramipexole for PD – a side effect of which the pharmaceutical company had been aware.

[9] MAO-B in the brain is located mainly in glial cells, and also in 5-HT neurons (although, surprisingly, it does not appear to be expressed in dopamine neurons).

[10] Intense physical exercise has been suggested to be one potential environmental factor and there are examples of leading sportspersons succumbing to the disease in later life, for example, the late Joost van der Westhuizen, the great South African scrum half, the late Doddie Weir, who played for Scotland and the British and Irish Lions, and Rob Burrow, who played rugby league for England and Great Britain.

[11] Onasemnogene is currently the world's most expensive medicine, costing £1.79m for a one-off treatment.

41: General anaesthetic agents

Overview

General anaesthesia aims to provide balanced anaesthesia, meeting the requirements of amnesia, analgesia and muscle relaxation tailored for the intended medical procedure. In this chapter we describe the pharmacology of the main general anaesthetic agents in current use, which fall into two groups: intravenous agents and inhalation agents (gases and volatile liquids). General anaesthetics are given systemically and exert their main effects on the central nervous system (CNS), in contrast to local anaesthetics (see **Ch. 44**). Different general anaesthetic agents provide varying amounts of the components of balanced anaesthesia but they are rarely used in isolation nowadays. Sedative and anxiolytic drugs (see **Ch. 45**), analgesic drugs (see **Ch. 43**) and neuromuscular-blocking drugs (see **Ch. 14**) are normally co-administered. Although we now take them for granted, general anaesthetics are the drugs that paved the way for modern surgery. Without them, much of modern medicine would be impossible.

Detailed information on the clinical pharmacology and use of anaesthetic agents can be found in specialised textbooks (e.g. **Thompson et al., 2019**).

Introduction

It was only when inhalation anaesthetics were first discovered, in 1846, that most surgical operations became a practical possibility. Until that time, surgeons relied on being able to operate on struggling patients at lightning speed, and most operations were limited to amputations.

The use of **nitrous oxide** to relieve the pain of surgery was suggested by Humphrey Davy in 1800. He was the first person to make nitrous oxide, and he tested its effects on several people, including himself and the Prime Minister, noting that it caused euphoria, analgesia and loss of consciousness. The use of nitrous oxide, billed as 'laughing gas', became a popular fairground entertainment and came to the notice of an American dentist, Horace Wells, who had a tooth extracted under its influence, while he himself squeezed the inhalation bag. Ether also first gained publicity in a disreputable way, through the spread of 'ether frolics', at which it was used to produce euphoria among the guests. William Morton, also a dentist and a student at Harvard Medical School, used it successfully to extract a tooth in 1846 and then suggested to Warren, the illustrious chief surgeon at Massachusetts General Hospital, that he should administer it for one of Warren's operations. Warren grudgingly agreed, and on 16 October 1846 a large audience was gathered in the main operating theatre [1] ; after some preliminary fumbling, Morton's demonstration was a spectacular success. 'Gentlemen, this is no humbug' was the most gracious comment that Warren could bring himself to make to the assembled audience.

In the same year, James Simpson, Professor of Midwifery at Edinburgh University, used chloroform to relieve the pain of

childbirth, bringing on himself fierce denunciation from the clergy, one of whom wrote: ‘Chloroform is a decoy of Satan, apparently offering itself to bless women; but in the end it will harden society and rob God of the deep, earnest cries which arise in time of trouble, for help.’ Opposition was effectively silenced in 1853, when Queen Victoria gave birth to her seventh child under the influence of chloroform, and the procedure became known as *anaesthésie à la reine*.

The second half of the 20th century saw the introduction into clinical practice of a number of new general anaesthetic agents, most notably **isoflurane** and **propofol**, that were markedly superior to earlier agents such as **nitrous oxide** and **thiopental**. Despite the need for further improvement the pipeline has all but dried up in the 21st century, with only **fospropofol** being introduced.

Mechanism of Action of Anaesthetic Drugs

Unlike most drugs, anaesthetics, which include substances as diverse as simple gases (e.g. **nitrous oxide** and **xenon**), halogenated hydrocarbons (e.g. **isoflurane**), barbiturates (e.g. **thiopental**) and steroids (e.g. **alphaxalone**), belong to no recognisable chemical class. At one time it appeared that the shape and electronic configuration of the molecule were relatively unimportant, and the pharmacological action required only that the molecule had certain physicochemical properties. We now know much more about how different anaesthetics interact with neuronal membrane proteins and have come to realise that there are multiple

mechanisms by which anaesthesia can be produced and that different anaesthetics work by different mechanisms.

As the concentration of an anaesthetic is increased, the switch from being conscious to unconscious occurs over a very narrow concentration range (approximately 0.2 of a log unit). This is a much steeper concentration–response curve than that seen with drugs that interact as agonists or antagonists at classical receptors (see **Ch. 2**).

Lipid Solubility

Overton and Meyer, at the turn of the 20th century, showed a close correlation between anaesthetic potency and lipid solubility in a diverse group of simple and unreactive organic compounds that were tested for their ability to immobilise tadpoles. This led to a bold theory, formulated by Meyer in 1937: 'Narcosis commences when any chemically indifferent substance has attained a certain molar concentration in the lipids of the cell'.

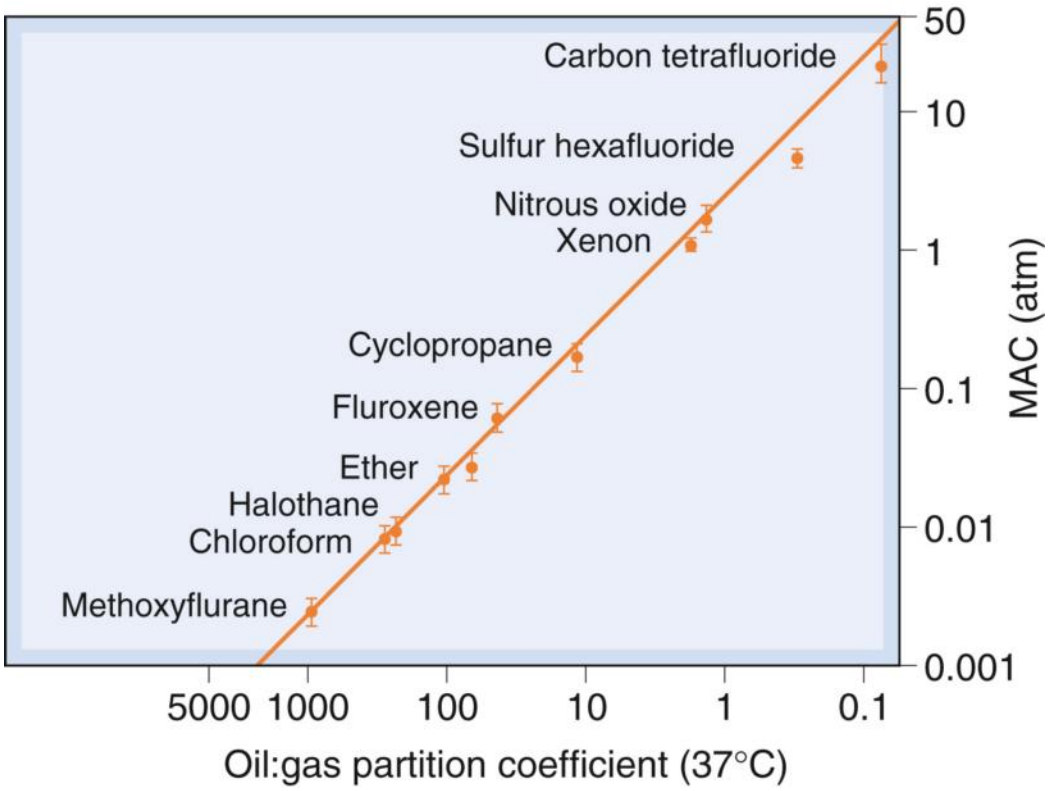

FIG. 41.1 Correlation of anaesthetic potency with oil:gas partition coefficient.Anaesthetic potency in humans is expressed as minimum alveolar partial pressure *(MAC)* required to produce surgical anaesthesia. There is a close correlation with lipid solubility, expressed as the oil:gas partition coefficient. From Halsey, M.J., 1989. Physicochemical properties of inhalation anaesthetics. In: Nunn, J.F., Utting, J.E., Brown, B.R. (Eds), General Anaesthesia. Butterworth, London.

The relationship between anaesthetic activity and lipid solubility has been repeatedly confirmed for a diverse array of agents. Anaesthetic potency in humans is usually expressed as the minimal

alveolar concentration (MAC) required to abolish the response to surgical incision in 50% of subjects. **Fig. 41.1** shows the correlation between MAC (inversely proportional to potency) and lipid solubility, expressed as the oil:gas partition coefficient, for a wide range of inhalation anaesthetics. The Overton–Meyer studies did not suggest any particular mechanism, but revealed an impressive correlation, for which any theory of anaesthesia needs to account. Oil:gas partition was assumed to predict partition into membrane lipids, consistent with the suggestion that anaesthesia results from an alteration of membrane function.

How the simple introduction of inert foreign molecules into the lipid bilayer could cause a functional disturbance was not explained. Two possible mechanisms, namely volume expansion and increased membrane fluidity, were suggested and tested experimentally, but both are now largely discredited and attention has swung from lipids to proteins, the correlation of potency with lipid solubility being explained by molecules of anaesthetic binding to hydrophobic pockets within specific membrane protein targets.

Effects on Ion Channels

Following early studies that showed that anaesthetics can bind to various proteins as well as lipids, it was found that anaesthetics affect several different types of ion channels (see **Franks, 2008**). For most anaesthetics, there are no known competitive antagonists, so this approach to identify sites of action is denied. Therefore the main criterion for identifying putative mechanisms of action of general anaesthetics is that, for a cellular effect to be relevant to the

anaesthetic or analgesic actions of these agents, it must occur at therapeutically relevant concentrations.

Cys-loop ligand-gated ion channels.Almost all anaesthetics (with the exceptions of **cyclopropane**, **ketamine** and **xenon** [2]) potentiate the action of GABA at $GABA_A$ receptors (**Antkowiak and Rudolph, 2016**). As described in detail in **Chapters 3** and 38, $GABA_A$ receptors are ligand-gated Cl^- channels made up of five subunits (generally comprising two α, two β and one γ or δ subunit). General anaesthetics target sites on the GABAA receptor and act as positive allosteric modulators of GABA activation (see **Ch. 38**). Recent ultrastructural studies of $GABA_A$ receptors have revealed that propofol and etomidate bind in cavities at the interface between the transmembrane domains of the β and α subunits whereas barbiturates bind at two other sites between the γ and β subunits and the α and β subunits as depicted in **Fig. 41.2** (see **Kim and Hibbs, 2021**). Mutation studies suggest that volatile anaesthetics may also bind to a site at the interface between α and β subunits (see **Franks, 2008**).

A further level of complexity arises because there are different subtypes of each subunit (see **Ch. 38**). Different subunit compositions give rise to subtly different subtypes of $GABA_A$ receptor and these may be involved in different aspects of anaesthetic action. $GABA_A$ receptors clustered at the synapse have different pharmacological and kinetic properties from those that are distributed elsewhere across the cell (extrasynaptic receptors; see **Ch. 38**). Extrasynaptic $GABA_A$ receptors contain α4 and α6 subunits as well as the δ subunit, and anaesthetics appear to have a greater potentiating effect on these extrasynaptic $GABA_A$ receptors.

General anaesthetics also affect other neuronal cys-loop ligand-gated channels such as those activated by glycine (see **Ch. 38**), acetylcholine and 5-hydroxytryptamine (see **Ch. 39**). Their actions on these channels are similar to those on $GABA_A$ receptors but the relative importance of such actions to general anaesthesia is still to be determined.

Two-pore domain K+ channels.These belong to a family of 'background' K^+ channels that modulate neuronal excitability. They are homomeric or heteromeric assemblies of a family of structurally related subunits (**Bayliss and Barrett, 2008**). Channels made up of TREK1, TREK2, TASK1, TASK3 or TRESK (see **Ch. 4**, **Table 4.2**) subunits can be directly activated by low concentrations of volatile and gaseous anaesthetics, thus reducing membrane excitability (see **Franks, 2008**). This may contribute to the analgesic, hypnotic and immobilising effects of these agents. Two-pore domain K^+ channels do not appear to be affected by intravenous anaesthetics.

NMDA receptors. **Glutamate**, the major excitatory neurotransmitter in the CNS, activates three main classes of ionotropic receptor – α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), kainate and *N*-methyl-D-aspartate (NMDA) receptors (see **Ch. 38**). NMDA receptors are an important site of action for anaesthetics such as **nitrous oxide**, **xenon** and **ketamine** which act, in different ways, to reduce NMDA receptor–mediated responses. Xenon appears to inhibit NMDA receptors by competing with glycine for its regulatory site on this receptor whereas ketamine blocks the pore of the channel (see **Ch. 38**). Other inhalation anaesthetics may also exert effects on the NMDA

receptor in addition to their effects on other proteins such as the $GABA_A$ receptor.

Other ion channels. Anaesthetics may also exert actions at cyclic nucleotide-gated K^+ channels and K_{ATP} channels. Some general anaesthetics inhibit certain subtypes of voltage-gated Na^+ channels. Inhibition of presynaptic Na^+ channels may give rise to the inhibition of transmitter release at excitatory synapses.

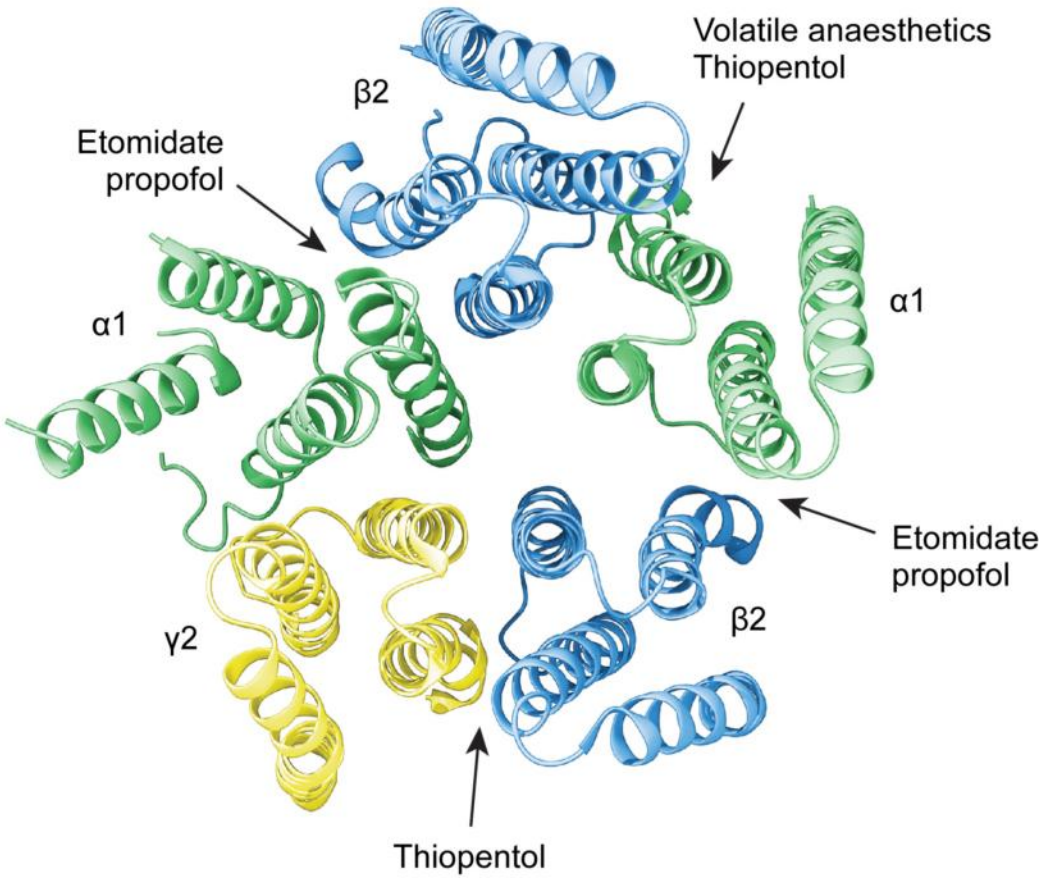

FIG. 41.2 Schematic of the putative binding sites in the clefts between the transmembrane domains of the subunits of the $GABA_A$ receptor.The view is from the extracellular side looking down and shows the transmembrane domains *(coloured helices)*. A more detailed description of the structure of a similar ligand-gated ion channel, the nicotinic acetylcholine receptor, is given in Fig 3.4. Adapted from Kim, J.J., Hibbs, R.E, 2021. Direct structural insights into GABAA receptor pharmacology. Trends Biochem. Sci. 46, 502–517.

It may be overly simplistic to think of each anaesthetic as having only one mechanism of action: individual anaesthetics differ in their actions and affect cellular function in several different ways, so a single mechanism is unlikely to be sufficient.

Theories of anaesthesia

- Many simple, unreactive compounds produce general anaesthesia, the extreme example being the inert gas **xenon.**
- Anaesthetic potency is closely correlated with lipid solubility (Overton–Meyer correlation), not with chemical structure.
- Earlier theories of anaesthesia postulated interaction with the lipid membrane bilayer. Recent work favours interaction with membrane ion channels.
- Most anaesthetics enhance the activity of inhibitory $GABA_A$ receptors and other cys-loop ligand-gated ion channels. Other important effects are the activation of a subfamily of potassium channels (the two-pore domain K^+ channels) and inhibition of excitatory NMDA receptors.

Effects on the Nervous System

At the cellular level, the effects of anaesthetics are to enhance tonic inhibition (through enhancing the actions of GABA), reduce excitation (opening K^+ channels) and inhibit excitatory synaptic transmission (by depressing transmitter release and inhibiting ligand-gated ion channels). Effects on axonal conduction are relatively unimportant.

The anaesthetised state comprises several components, including *unconsciousness*, loss of reflexes (*muscle relaxation*) and *analgesia*. Much effort has gone into identifying the brain regions on which anaesthetics act to produce these effects. The most sensitive regions appear to be the midbrain reticular formation, thalamic sensory relay nuclei and, to a lesser extent, parts of the cortex. Inhibition of these regions results in unconsciousness and analgesia. Some anaesthetics – particularly volatile anaesthetics – cause inhibition at the spinal level, producing a loss of reflex responses to painful stimuli, although, in practice, neuromuscular-blocking drugs (see **Ch. 14**) are used as an adjunct to produce muscle relaxation rather than relying on the anaesthetic alone. Anaesthetics, even in low concentrations, cause short-term amnesia. It is likely that interference with hippocampal function produces this effect, because the hippocampus is involved in short-term memory, and certain hippocampal synapses are highly susceptible to inhibition by anaesthetics.

As the anaesthetic concentration is increased, all brain functions are progressively affected, including motor control and reflex activity, respiration and autonomic regulation. Therefore it is not possible to identify a critical 'target site' in the brain responsible for all the phenomena of anaesthesia.

High concentrations of any general anaesthetic affect all parts of the CNS, causing profound inhibition which, in the absence of artificial respiration, leads to death from respiratory failure. The margin between surgical anaesthesia and potentially fatal respiratory and circulatory depression is quite narrow, requiring

careful monitoring by the anaesthetist and adjustment of the level of anaesthesia.

Effects on the Cardiovascular and Respiratory Systems

Most anaesthetics decrease cardiac contractility, but their effects on cardiac output and blood pressure vary because of concomitant actions on the sympathetic nervous system and vascular smooth muscle. **Isoflurane** and other halogenated anaesthetics inhibit sympathetic outflow, reduce arterial and venous tone and thus decrease arterial pressure and venous pressure. By contrast, **nitrous oxide** and **ketamine** increase sympathetic discharge and plasma noradrenaline concentration and, if used alone, increase heart rate and maintain blood pressure.

Halogenated anaesthetics cause ventricular extrasystoles. The mechanism involves sensitisation to adrenaline. Electrocardiogram monitoring shows that extrasystolic beats occur commonly in patients under anaesthesia, with no harm coming to the patient. If catecholamine secretion is excessive, however (*par excellence* in phaeochromocytoma, a neuroendocrine tumour that secretes catecholamines into the circulation; see **Ch. 15**), there is a risk of precipitating ventricular fibrillation.

With the exception of **nitrous oxide, ketamine** and **xenon**, all anaesthetics depress respiration markedly and increase arterial P_{CO_2}. Nitrous oxide has much less effect, in part because its low potency prevents very deep anaesthesia from being produced with this drug. Some inhalation anaesthetics are pungent, particularly **desflurane**, which is liable to cause coughing, laryngospasm and

bronchospasm, so desflurane is not used for induction of anaesthesia but only for maintenance.

Pharmacological effects of anaesthetic agents

- Anaesthesia involves three main neurophysiological changes: unconsciousness, loss of response to painful stimulation and loss of reflexes (motor and autonomic).
- At supra-anaesthetic doses, all anaesthetic agents can cause death by loss of cardiovascular reflexes and respiratory paralysis.
- At the cellular level, anaesthetic agents affect synaptic transmission and neuronal excitability rather than axonal conduction. GABA-mediated inhibitory transmission is enhanced by most anaesthetics. The release of excitatory transmitters and the response of the postsynaptic receptors are also inhibited.
- Although all parts of the nervous system are affected by anaesthetic agents, the main targets appear to be the cortex, thalamus, hippocampus, midbrain reticular formation and spinal cord.
- Most anaesthetic agents (with the exception of **ketamine**, **nitrous oxide** and **xenon**) produce similar neurophysiological effects and differ mainly in respect of their pharmacokinetic properties and toxicity.
- Most anaesthetic agents cause cardiovascular depression by effects on the myocardium and blood vessels, as well as on

the nervous system. Halogenated anaesthetic agents are likely to cause cardiac dysrhythmias, accentuated by circulating catecholamines.

Intravenous Anaesthetic Agents

Even the fastest-acting inhalation anaesthetics take a few minutes to act and cause a period of excitement before anaesthesia is induced. Intravenous anaesthetics act more rapidly, producing unconsciousness in about 20 s, as soon as the drug reaches the brain from its site of injection. These drugs (e.g. **propofol**, **thiopental** and **etomidate**) are normally used for induction of anaesthesia. They are preferred by many patients because injection avoids any unpleasantness that may be associated with the use of a face mask to administer the anaesthetic to an apprehensive individual. With propofol, recovery is also fast due to rapid metabolism.

Although many intravenous anaesthetics are not suitable for maintaining anaesthesia because their elimination from the body is relatively slow compared with that of inhalation agents, propofol can be administered either as a bolus for short procedures (<10 min) or as a continuous infusion. The duration of action of ketamine is sufficient that it can be administered as a single bolus for short procedures. Under these circumstances there is no need for an inhalation agent but a short-acting opioid such as **alfentanil** or **remifentanil** (see **Ch. 43**) may be co-administered to provide analgesia.

The properties of the main intravenous anaesthetics are summarised in **Table 41.1**. [3]

Propofol

Propofol, introduced in 1983, has now largely replaced thiopental as an induction agent. It has a rapid onset of action (approximately 30 s) and a rapid rate of redistribution ($t_{1/2}$ 2–4 min), which makes it short acting. Because of its low water solubility, it is administered as an oil-in-water emulsion, which can cause pain on injection, and supports microbial growth. **Fospropofol** is a recently developed water-soluble derivative that is less painful on injection and rapidly converted by alkaline phosphatases to propofol in the body. Propofol metabolism to inactive conjugates and quinols follows first-order kinetics, in contrast to thiopental metabolism (see later), resulting in more rapid recovery and less hangover effect than occurs with thiopental. It has a cardiovascular depressant effect that may lead to hypotension and bradycardia. Respiratory depression may also occur and this may be enhanced by concurrent administration of a benzodiazepine (see **Ch. 45**) or an opioid (see **Ch. 43**). It is particularly useful for day-case surgery, especially as it causes less nausea and vomiting than do inhalation anaesthetics.

There have been reports of a propofol infusion syndrome occurring in approximately 1 in 300 patients when it has been given for a prolonged period to maintain sedation, particularly to sick patients – especially children in whom it is contraindicated in this setting – in intensive care units. This is characterised by severe metabolic acidosis, skeletal muscle necrosis (rhabdomyolysis),

hyperkalaemia, lipaemia, hepatomegaly, renal failure, arrhythmia and cardiovascular collapse.

Propofol is used non-medicinally, especially by those, such as anaesthetists, who have ready access to the drug. Using propofol to obtain a sedative high is a risky business given its steep concentration–response curve. [4]

Thiopental

Thiopental is the only remaining barbiturate in common use as an anaesthetic. It has very high lipid solubility, and this accounts for the speed of onset and transience of its effect when it is injected intravenously. The free acid is insoluble in water, so thiopental is given as the sodium salt. On intravenous injection, thiopental causes unconsciousness within about 20 s, lasting for 5–10 min. The anaesthetic effect closely parallels the concentration of thiopental in the blood reaching the brain, because its high lipid solubility allows it to cross the blood–brain barrier without noticeable delay.

Table 41.1

The blood concentration of thiopental declines rapidly, by about 80% within 1–2 min, following the initial peak after intravenous injection, because the drug is redistributed, first to tissues with a large blood flow (liver, kidneys, brain, etc.) and more slowly to muscle. Uptake into body fat, although favoured by the high lipid solubility of thiopental, occurs only slowly, because of the low blood flow to this tissue. After several hours, however, most of the thiopental present in the body will have accumulated in body fat,

the rest having been metabolised. Recovery from the anaesthetic effect of a bolus dose occurs within about 5 min, governed entirely by redistribution of the drug to well-perfused tissues; very little is metabolised in this time. After the initial rapid decline, the blood concentration drops more slowly, over several hours, as the drug is taken up by body fat and metabolised in the liver. Consequently, thiopental produces a long-lasting hangover. Thiopental metabolism shows saturation kinetics (see **Ch. 11**). Because of this, large doses or repeated intravenous doses cause progressively longer periods of anaesthesia, as the plateau in blood concentration becomes progressively more elevated as more drug accumulates in the body and metabolism saturates. For this reason, thiopental is not used to maintain surgical anaesthesia but only as an induction agent. It is also still used to terminate status epilepticus if other measures fail (see **Ch. 46**) or (in patients with a secured airway) to lower intracranial pressure.

Thiopental binds to plasma albumin (roughly 85% of the blood content normally being bound). The fraction bound is less in states of malnutrition, liver disease or renal disease, which affect the concentration and drug-binding properties of plasma albumin, and this can appreciably reduce the dose needed for induction of anaesthesia.

If thiopental – a strongly alkaline solution – is accidently injected around rather than into a vein, or into an artery, this can cause pain, local tissue necrosis and ulceration or severe arterial spasm that can result in gangrene.

The actions of thiopental on the nervous system are very similar to those of inhalation anaesthetics, although it has little analgesic

effect and can cause profound respiratory depression, even in amounts that fail to abolish reflex responses to painful stimuli. Its long after-effect, associated with a slowly declining plasma concentration, means that drowsiness and some degree of respiratory depression persist for some hours.

Thiopental, like other barbiturates, induces production of various liver enzymes, including those involved in haem synthesis, and can precipitate attacks of porphyria in patients suffering from this genetic disorder.

Etomidate

Etomidate has gained favour over thiopental on account of the larger margin between the anaesthetic dose and the dose needed to produce cardiovascular depression. It is more rapidly metabolised than thiopental, and thus less likely to cause a prolonged hangover. It has no analgesic properties but causes less hypotension than propofol or thiopental. In other respects, etomidate is very similar to thiopental, although involuntary movements during induction, postoperative nausea and vomiting and pain at the injection site are problems with its use. Etomidate suppresses the production of adrenal steroids, an effect that has been associated with an increase in mortality in severely ill patients. It should be avoided in patients at risk of having adrenal insufficiency, e.g. in sepsis. It is preferable to thiopental in patients at risk of circulatory failure.

Other Intravenous Agents

Ketamine

In human medicine **ketamine** is useful in short procedures that do not require skeletal muscle relaxation, e.g. for realignment and splinting of fractures and wound repair. It can be used in lower doses as an analgesic (see **Ch. 43**) and low doses have been found to induce rapid and sustained improvements in the symptoms of depression (see **Ch. 48**). It acts as a non-competitive channel blocker of the NMDA receptor (see **Ch. 38**).

In veterinary medicine, **ketamine** is commonly used for procedures in large animals and is normally given in combination with an a_2-adrenoceptor agonist, e.g. xylazine, or dexmedetomidine, providing rapid recumbency, immobilisation and analgesia which can also be reversed by administration of an a_2-adrenoceptor antagonist, e.g. atipamezole. Surgical procedures may also require the use of additional local anaesthesia.

Given intravenously, ketamine takes effect more slowly (1–2 min) than thiopental, and produces a different effect, known as 'dissociative anaesthesia', in which there is a marked sensory loss and analgesia, as well as amnesia, without complete loss of consciousness and no skeletal muscle relaxation. During induction and recovery, involuntary movements and peculiar sensory experiences often occur. Ketamine does not act simply as a CNS depressant, and it produces cardiovascular and respiratory effects quite different from those of most anaesthetics. Blood pressure and heart rate are usually increased, and respiration is unaffected by effective anaesthetic doses. This makes it relatively safe to use in low-technology healthcare situations or in accident and emergency situations where it can be administered intramuscularly if intravenous administration is not possible. [5] It is useful in patients

with bronchospasm because of its bronchodilatory properties. However, ketamine, unlike other intravenous anaesthetic drugs, can increase intracranial pressure, so it should not be given to patients with raised intracranial pressure or at risk of cerebral ischaemia. Ketamine metabolism is age dependent, being faster in children and slower in the elderly.

A drawback of ketamine is that hallucinations, and sometimes delirium and irrational behaviour, may occur during recovery. These after-effects limit the usefulness of ketamine but are said to be less marked in children, and ketamine, often in conjunction with a benzodiazepine, may be used for minor procedures in paediatrics.

Ketamine is also used non-medicinally for its pronounced effects on sensory perception (see **Ch. 49**).

Midazolam

Midazolam, a benzodiazepine (see **Ch. 45**), is slower in onset and offset than the drugs discussed earlier but, like ketamine, causes less respiratory or cardiovascular depression. Midazolam is often used as an intravenous preoperative anxiolytic/sedative prior to a general anaesthetic or as a sedative during minor invasive procedures such as endoscopy or dental work, where drowsiness, sleep and amnesia are sufficient. It can be administered in combination with an analgesic such as **alfentanil**. In the event of overdose it can be reversed by **flumazenil** (see **Ch. 45**). **Remimazolam** is similar but has a more rapid onset and a shorter duration of action.

Intravenous anaesthetic agents

- Most commonly used for induction of anaesthesia, followed by inhalation agent. **Propofol** can also be used to maintain anaesthesia during surgery.
- **Propofol, thiopental** and **etomidate** are most commonly used; all act within 20–30 s if given intravenously.
- **Propofol:**
  - potent;
  - rapid onset and distribution;
  - rapidly metabolised;
  - very rapid recovery, limited cumulative effect;
  - useful for day-case surgery;
  - low incidence of nausea and vomiting;
  - risk of bradycardia;
  - may induce an adverse 'propofol infusion syndrome' when administered at high doses for prolonged periods of time.
- **Thiopental:**
  - barbiturate with very high lipid solubility;
  - rapid action due to rapid transfer across blood–brain barrier; short duration (about 5 min) due to redistribution, mainly to muscle;
  - reduces intracranial pressure;
  - slowly metabolised and liable to accumulate in body fat, therefore may cause prolonged effect if given repeatedly;
  - narrow margin between anaesthetic dose and dose causing cardiovascular depression;
  - risk of tissue damage if accidently injected extravascularly or into an artery;

– can precipitate an attack of porphyria in susceptible individuals (see **Ch. 12**).

• **Etomidate:**

– similar to thiopental but more quickly metabolised;
– less risk of cardiovascular depression;
– may cause involuntary movements during induction and high incidence of nausea;
– possible risk of adrenocortical suppression.

• **Ketamine:**

– non-competitive channel blocker of NMDA receptors;
– onset of effect is relatively slow (1–2 min);
– powerful analgesic;
– produces 'dissociative' anaesthesia, in which the patient may remain conscious although amnesic and insensitive to pain;
– dysphoria and sometimes hallucinations may occur during recovery;
– can raise intracranial pressure.

• **Midazolam:**

- used to induce sedation, sleep and amnesia rather than full anaesthesia with loss of reflexes;
- may be supplemented with an analgesic (e.g. alfentanil) if analgesia is required.

Inhalation Anaesthetics

Many inhalation anaesthetics that were once widely used, such as ether, chloroform, trichloroethylene, cyclopropane, methoxyflurane and enflurane, have now been replaced in clinical practice, particularly by **isoflurane**, **sevoflurane** and **desflurane**, which have improved pharmacokinetic properties, fewer side effects and are non-flammable. Of the older agents, **nitrous oxide** is still used (especially in obstetric practice), and **halothane** now only occasionally.

Pharmacokinetic Aspects

An important characteristic of an inhalation anaesthetic is the speed at which the arterial blood concentration, which governs the pharmacological effect in the brain, follows changes in the partial pressure of the drug in the inspired gas mixture. Ideally, the blood concentration should follow as quickly as possible, so that the depth of anaesthesia can be controlled rapidly. In particular, the blood concentration should fall to a subanaesthetic level rapidly when administration is stopped, so that the patient recovers consciousness with minimal delay. A prolonged semi-comatose state, in which vomiting is likely and respiratory reflexes are weak or absent, is particularly hazardous.

The lungs are the only quantitatively important route by which inhalation anaesthetics enter and leave the body. For modern inhalation anaesthetics, metabolic degradation is generally insignificant in determining their duration of action. Inhalation anaesthetics are all small, lipid-soluble molecules that readily cross alveolar membranes. It is therefore the rates of delivery of drug to and from the lungs, via (respectively) the inspired air and

bloodstream, which determine the overall kinetic behaviour of an anaesthetic. The reason that anaesthetics vary in their kinetic behaviour is that their relative solubilities in blood, and in body fat, vary between one drug and another.

The main factors that determine the speed of induction and recovery can be summarised as follows:

- Properties of the anaesthetic:
  - – blood:gas partition coefficient (i.e. solubility in blood)
  - – oil:gas partition coefficient (i.e. solubility in fat)
- Physiological factors:
  - – alveolar ventilation rate
  - – cardiac output

Solubility of Inhalation Anaesthetics

Inhalation anaesthetics can be regarded physicochemically as ideal gases: their solubility in different media is expressed as *partition coefficients*, defined as the ratio of the concentration of the agent in two phases at equilibrium.

The *blood:gas partition coefficient* is the main factor that determines the rate of induction and recovery of an inhalation anaesthetic, and the lower the blood:gas partition coefficient, the faster is induction and recovery (**Table 41.2**). This is because it is the partial pressure of the gas in the alveolar space that governs the concentration in the blood. The lower the blood:gas partition coefficient, the more rapidly the partial pressure of the gas in the alveolar space will equal that being administered in the inspired air (see later).

The *oil:gas partition coefficient*, a measure of fat solubility, determines the potency of an anaesthetic (as already discussed) and also influences the kinetics of its distribution in the body, the main effect being that high lipid solubility, by causing accumulation in body fat, delays recovery from anaesthesia. Values of blood:gas and oil:gas partition coefficients for some anaesthetics are given in **Table 41.2**.

Induction and Recovery

Cerebral blood flow is a substantial fraction of cardiac output (~15%), and the blood–brain barrier is freely permeable to anaesthetics, so the concentration of anaesthetic in the brain closely tracks that in the arterial blood. The kinetics of transfer of anaesthetic between the inspired air and the arterial blood therefore determine the kinetics of the pharmacological effect.

When a volatile anaesthetic is first administered, the initial breaths are diluted into the residual gas volume in the lungs, resulting in a reduction in the alveolar partial pressure of the anaesthetic as compared with the inspired gas mixture. With subsequent breaths, the alveolar partial pressure rises towards equilibrium. For an anaesthetic with a low blood:gas partition coefficient, the absorption into the blood will be slower, so with repeated breaths the partial pressure in the alveolar space will rise faster than with an agent of high blood:gas partition coefficient. Thus a smaller number of breaths (i.e. a shorter time) will be needed to reach equilibrium. Therefore, contrary to what one might intuitively suppose, the *lower* the solubility in blood, the *faster* is the process of equilibration. **Fig. 41.3** shows the much faster

equilibration for **nitrous oxide**, a low-solubility agent, than for **ether**, a high-solubility agent.

The rate of absorption into the blood can be enhanced by administering a volatile anaesthetic along with nitrous oxide. The rapid movement of nitrous oxide from the alveoli into the blood concentrates the volatile anaesthetic in the alveoli which will increase its movement into the blood – referred to as the *concentration effect*. Furthermore, the volume of nitrous oxide taken up from the alveoli into the blood is replaced by inspired gas, thus augmenting the delivery to the alveoli of the volatile anaesthetic and speeding its absorption – referred to as the *second gas effect*.

The transfer of anaesthetic between blood and tissues also affects the kinetics of equilibration. **Fig. 41.4** shows a very simple model of the circulation, in which two tissue compartments are included. Body fat has a low blood flow but has a high capacity to take up anaesthetics, and constitutes about 20% of the volume of a non-obese human. Therefore for a drug such as **halothane**, which is about 100 times more soluble in fat than in water, the amount present in fat after complete equilibration would be roughly 95% of the total amount in the body. Because of the low blood flow to adipose tissue, it takes many hours for the drug to enter and leave the fat, which results in a pronounced slow phase of equilibration following the rapid phase associated with the blood–gas exchanges (see **Fig. 41.3**). The more fat-soluble the anaesthetic and the more obese the patient, the more pronounced this slow phase becomes and recovery will also be delayed.

Of the physiological factors affecting the rate of equilibration of inhalation anaesthetics, alveolar ventilation is the most important. The greater the minute volume (respiration rate × tidal volume), the faster is equilibration, particularly for drugs that have high blood:gas partition coefficients. Respiratory depressant drugs such as **morphine** (see **Ch. 43**) can thus retard recovery from anaesthesia. The effect of changes in cardiac output on the rate of equilibration is more complex. By reducing alveolar perfusion, a reduction of cardiac output reduces alveolar absorption of the anaesthetic, and thus speeds up induction, but this is partially offset by a reduction of cerebral blood flow slowing down delivery to the brain.

Table 41.2

[a] Theoretical value based on experiments under hyperbaric conditions.

Recovery from anaesthesia involves the same processes as induction but in reverse, the rapid phase of recovery being followed by a slow 'hangover'. Because of these kinetic factors, the search for improved inhalation anaesthetics has focused on agents with low blood and tissue solubility. Newer drugs, which show kinetic properties similar to those of nitrous oxide but have higher potency, include **sevoflurane** and **desflurane** (see **Table 41.2** and **Fig. 41.3**).

Metabolism and Toxicity

Metabolism, although not quantitatively important as a route of elimination of inhalation anaesthetics, can generate toxic

metabolites (see **Ch. 58**). [6] This is the main reason that agents that are now obsolete or obsolescent, such as chloroform, methoxyflurane and halothane, have been replaced by the less toxic alternatives described later.

Malignant hyperthermia is an important but rare *idiosyncratic reaction* (see **Ch. 58**), caused by heat production in skeletal muscle, due to excessive release of Ca^{2+} from the sarcoplasmic reticulum. The result is muscle contracture, acidosis, increased metabolism and an associated dramatic rise in body temperature that can be fatal unless treated promptly. Triggers include halogenated anaesthetics and depolarising neuromuscular-blocking drugs (see **Ch. 14**). Susceptibility has a genetic basis, being associated with mutations in the gene encoding the ryanodine receptor, which controls Ca^{2+} release from the sarcoplasmic reticulum (see **Ch. 4**). Malignant hyperthermia is treated with **dantrolene**, a muscle relaxant drug that blocks these calcium-release channels.

Pharmacokinetic properties of inhalation anaesthetics

- Rapid induction and recovery are important properties of an anaesthetic agent, allowing flexible control over the depth of anaesthesia.
- Speed of induction and recovery are determined by two properties of the anaesthetic: solubility in blood (blood:gas partition coefficient) and solubility in fat (lipid solubility).
- Agents with low blood:gas partition coefficients produce rapid induction and recovery (e.g. **nitrous oxide**, **desflurane**);

agents with high blood:gas partition coefficients show slow induction and recovery.

- Agents with high lipid solubility accumulate gradually in body fat and may produce a prolonged ‘hangover’ if used for a long operation.
- Some halogenated anaesthetics (especially **halothane** and **methoxyflurane**) are metabolised. This is not very important in determining their duration of action but contributes to toxicity (e.g. renal toxicity associated with fluoride production with **methoxyflurane** – no longer used).

FIG. 41.3 Rate of equilibration of inhalation anaesthetics in humans.The curves show alveolar concentration (which closely reflects arterial blood concentration) as a function of time during induction. The initial rate of equilibration reflects solubility in blood. There is also a slow phase of equilibration, most marked with highly lipid-soluble drugs (ether and halothane), owing to the slow transfer between blood and fat (see Fig. 41.4). Adapted from Yasuda, N., Lockhart, S.H., Eger, E.I. II, et al., 1991. Comparison of kinetics of sevoflurane and isoflurane in humans. Anesth. Analg. 72, 316–324.

Individual Inhalation Anaesthetics

The main inhalation anaesthetics currently used in developed countries are **isoflurane**, **desflurane** and **sevoflurane**, sometimes used in combination with **nitrous oxide**. Due to its relatively rapid onset of action and pleasant smell, **sevoflurane** is used, under some circumstances, on its own to induce anaesthesia, e.g. in paediatrics or in adults frightened by the prospect of venous cannulation. **Xenon**, an inert gas shown many years ago to have anaesthetic properties, is making something of a comeback in the clinic because – not surprisingly for an inert gas – it lacks toxicity, but its relatively low potency and high cost are disadvantages. It may also be neuroprotective in neonatal hypoxia (see **Ch. 40**).

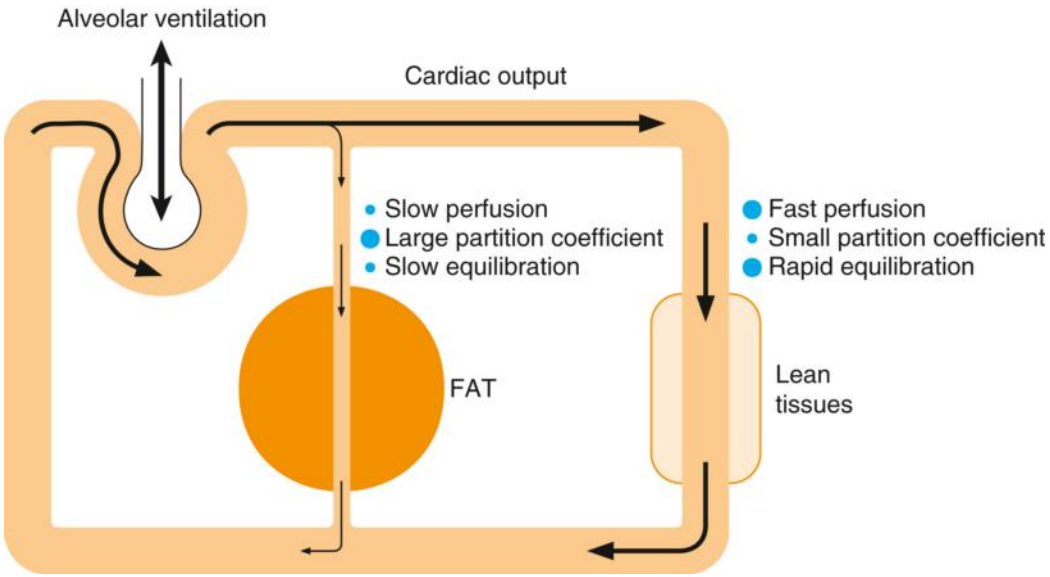

FIG. 41.4 Factors affecting the rate of equilibration of inhalation anaesthetics in the body.The body is represented as two compartments. Lean tissues, including the brain, have a large blood flow and low partition coefficient for anaesthetics, and therefore equilibrate rapidly with the blood. Fat tissues have a small blood flow and large partition coefficient, and therefore equilibrate slowly, acting as a reservoir of drug during the recovery phase.

Isoflurane, Desflurane, Sevoflurane, Enflurane and Halothane

These volatile anaesthetics are liquids at room temperature and require the use of vaporisers for inhalational administration.

Isoflurane is a non-flammable volatile anaesthetic that is now the most widely used volatile anaesthetic. It is not appreciably

metabolised and lacks the proconvulsive property of enflurane. It can cause hypotension and is a powerful coronary vasodilator. Paradoxically, this can exacerbate cardiac ischaemia in patients with coronary disease, because of the 'steal' phenomenon (see **Ch. 20**).

Desflurane is chemically similar to isoflurane, but its lower solubility in blood and fat means that adjustment of anaesthetic depth and recovery are faster, so it is increasingly used as an anaesthetic in obese patients undergoing bariatric surgery and for day-case surgery. It is not appreciably metabolised. It is less potent than the other halogenated general anaesthetics. At the concentrations used for induction of anaesthesia (about 10%), desflurane causes some respiratory tract irritation, which can lead to coughing and bronchospasm. Rapid increases in the depth of desflurane anaesthesia can be associated with a striking increase in sympathetic activity, which is undesirable in patients with ischaemic heart disease.

Sevoflurane resembles desflurane but is more potent and does not cause the same degree of respiratory irritation. It is partially (about 3%) metabolised, and detectable levels of fluoride are produced, although this does not appear to be sufficient to cause toxicity.

Enflurane has a moderate speed of induction but is little used nowadays. It was originally introduced as an alternative to methoxyflurane. It can cause seizures, either during induction or following recovery from anaesthesia, especially in patients suffering from epilepsy. In this connection, it is interesting that a related substance, the fluorine-substituted diethyl-ether hexafluoroether, is

a powerful convulsant agent, although the mechanism is not understood.

Halothane was an important drug in the development of volatile inhalation anaesthetics, but its use has declined in favour of isoflurane due to the potential for accumulation of toxic metabolites. Halothane has a marked relaxant effect on the uterus which can cause postpartum bleeding and limits its usefulness for obstetric purposes.

Nitrous Oxide

Nitrous oxide (N_2O, not to be confused with nitric oxide, NO) is an odourless gas. Its use as an anaesthetic is declining in the developed world. It has a global warming potential much higher than CO_2 and is regulated under the Kyoto Protocol (1997). It is the third largest contributor to the greenhouse effect in the United Kingdom.

Nitrous oxide is rapid in onset of action because of its low blood:gas partition coefficient (see **Table 41.2**), and is an effective analgesic in concentrations too low to cause unconsciousness. At low doses it induces euphoria, hence its nickname 'laughing gas'; its psychoactive effects are described in **Chapter 49**. Its anaesthetic potency is low. It is used as a 50:50 mixture with O_2 to reduce pain during childbirth. It must never be given as 100% of the inspired gas as patients do need to breathe oxygen! Even at 80% in the inspired gas mixture, nitrous oxide does not produce surgical anaesthesia. It is not therefore used on its own as an anaesthetic, but is used (as 70% nitrous oxide in oxygen) as an adjunct to volatile anaesthetics to speed up induction – see earlier description of the second gas effect. During recovery from nitrous oxide anaesthesia, the transfer

of the gas from the blood into the alveoli can be sufficient to reduce, by dilution, the alveolar partial pressure of oxygen, producing transient hypoxia (known as *diffusional hypoxia*). This is important for patients with respiratory disease.

Nitrous oxide tends to enter gaseous cavities in the body causing them to expand. This can be dangerous if a pneumothorax or vascular air embolus is present, or if the intestine is obstructed.

Given for brief periods, nitrous oxide is devoid of any serious toxic effects, but prolonged or repeated exposure oxidises and inactivates vitamin B_{12}. [7] In its inactive form, vitamin B_{12} is unable to function as a co-factor for methionine synthase and this can produce peripheral neuropathy and bone marrow depression. The latter may cause anaemia and leukopenia, so its use should be avoided in patients with anaemia related to vitamin B_{12} deficiency.

Individual inhalation anaesthetics

- The main agents in current use in developed countries are **isoflurane**, **desflurane** and **sevoflurane**, sometimes supplemented with **nitrous oxide.**
- As a rare but serious hazard, inhalation anaesthetics can cause malignant hyperthermia.
- **Isoflurane:**
  - similar to **enflurane** but lacks epileptogenic property
  - may precipitate myocardial ischaemia in patients with coronary disease
  - irritant to respiratory tract
- **Desflurane:**

  - similar to **isoflurane** but with faster onset and recovery
  - respiratory irritant, so liable to cause coughing and laryngospasm
  - useful for day-case surgery
- **Sevoflurane:**
  - similar to **desflurane**, with lack of respiratory irritation
- **Nitrous oxide:**
  - good analgesic properties
  - low potency as an anaesthetic, therefore must be combined with other agents
  - rapid induction and recovery
  - risk of peripheral neuropathy and bone marrow depression with prolonged administration
  - accumulates in gaseous cavities

Clinical uses of general anaesthetics

- *Intravenous anaesthetics* are used for:
  - induction of anaesthesia (e.g. **propofol** or **thiopental**);
  - maintenance of anaesthesia throughout surgery ('total intravenous anaesthesia', e.g. **propofol** sometimes in combination with muscle relaxants and analgesics).
- *Inhalational anaesthetics* (gases or volatile liquids) are used for maintenance of anaesthesia. Points to note are that:
  - volatile anaesthetics (e.g. **isoflurane**, **sevoflurane**) are delivered in air, oxygen or oxygen–nitrous oxide mixtures

as the carrier gas;
- **nitrous oxide** must always be given with oxygen;
- because of its potential for inducing hepatotoxicity, **halothane** has largely been replaced by newer volatile anaesthetics such as **isoflurane;**
- all inhalational anaesthetics can trigger *malignant hyperthermia* in susceptible individuals.

Sedation and Balanced Anaesthesia

Sedation is a continuum which extends from normal consciousness to being fully unresponsive. Sedation rather than general anaesthesia is often sufficient for short, non-invasive procedures. Conscious sedation is used in dentistry and endoscopic examinations to reduce fear and anxiety, control pain and minimise excessive movement. It does not involve sleep or loss of consciousness. **Midazolam** is often administered for this purpose. Deeper procedural sedation, where the patient becomes sleepy and is less easily aroused, can be achieved by administration of **midazolam**, **propofol**, **etomidate** or **ketamine** along with an opioid analgesic (e.g. **fentanyl** or **morphine**).

In complex surgery, an array of drugs will be given at various times throughout the procedure to produce what is termed *balanced anaesthesia*. The drugs administered may include a sedative or anxiolytic premedication (e.g. a benzodiazepine, see **Ch. 45**), an intravenous anaesthetic for rapid induction (e.g. **propofol**), a perioperative opioid analgesic (e.g. **alfentanil** or **remifentanil**, see **Ch. 43**), an inhalation anaesthetic to maintain anaesthesia

during surgery (e.g. **nitrous oxide** and **isoflurane**), a neuromuscular-blocking agent to produce adequate muscle relaxation (e.g. **vecuronium**, see **Ch. 14**) for access to the abdominal cavity for example, an antiemetic agent (e.g. **ondansetron**, see **Ch. 30**) and a muscarinic antagonist to prevent or treat bradycardia or to reduce bronchial and salivary secretions (e.g. **atropine** or **glycopyrrolate**, see **Ch. 14**). Towards the end of the procedure, an anticholinesterase agent (e.g. **neostigmine**, see **Ch. 14**) to reverse the neuromuscular blockade (**sugammadex**, which binds and inactivates steroidal neuromuscular-blocking drugs, can also be used for this purpose) and an analgesic for postoperative pain relief (e.g. an opioid such as **morphine** and/or a non-steroidal anti-inflammatory drug, see **Ch. 43**) may be used. Such combinations of drugs result in much faster induction and recovery, avoiding long (and potentially hazardous) periods of semiconsciousness, produce good analgesia and muscle relaxation and enable surgery to be carried out with less undesirable cardiorespiratory depression.

Low doses of general anaesthetics may be used to provide sedation where a local anaesthetic (see **Ch. 44**), administered intrathecally, is used to provide analgesia and relaxation needed to perform surgery to the lower parts of the body.

QUESTIONS

QUESTION 41.1

General anaesthetics form a diverse group of chemical agents that mediate anaesthesia through a variety of different pharmacological mechanisms.

Which of the following is NOT believed to be a major mechanism by which general anaesthetic agents mediate their effects?

OPTIONS:

A. Inhibition of excitatory transmitter function

B. Activation of two pore domain K^+ channels

C. Enhancement of GABA signalling

D. Disruption of lipid membranes

E. Inhibition of voltage gated Na^+ channels

QUESTION 41.2

Due to their inhibitory effects on excitatory transmission, there is a narrow margin between the beneficial effects of anaesthesia and potentially fatal respiratory and circulatory depression. Minimising the depth and duration of the anaesthesia is therefore of great importance.

Which of the following would increase the rate of onset/recovery from an anaesthetic?

OPTIONS:

A. Low blood:gas partition coefficient

B. Co-administration of a volatile anaesthetic with nitrous oxide (NO)

C. Increasing the oil:gas partition coefficient

D. Decreased cardiac output

E. Co-administration of morphine

QUESTION 41.3

Whilst the use of general anaesthetics is beneficial in a range of surgical procedures, specific side effects associated with particular agents contraindicate their use in certain conditions.

Which of the following regimens would be appropriate?

OPTIONS:

A. Enflurane in patients with epilepsy

B. Halothane in obstetrics

C. Desflurane for bariatric surgery

D. Isoflurane in coronary ischaemia

E. Nitrous oxide (NO) in vitamin B_{12} deficiency anaemia

ANSWERS

ANSWER 41.1

RATIONALE:

A. Several general anaesthetics (e.g. nitric oxide (NO), xenon, ketamine) act via inhibition of *N*-methyl-D-aspartate (NMDA) receptor function through competition for binding sites or channel blocking.

B. Activation of these channels modulates neuronal excitability and hence contributes to the analgesic, hypnotic and immobilising effects of volatile and gaseous general anaesthetics.

C. Most general anaesthetics potentiate the effects of GABA-mediated inhibition of excitatory neurotransmission by binding $GABA_A$ receptors and enhancing channel function.

D.

E. Some general anaesthetics inhibit voltage-gated Na^+ channels to decrease neuronal excitation release.

CORRECT ANSWER WITH EXPLANATION:

D. Disruption of lipid membranes

A strong correlation between lipid solubility and effective anaesthesia led to a hypothesis that anaesthesia results from a disruption to the lipid membrane. This has largely now been

disproved with attention focusing on the effects on membrane channels.

ANSWER 41.2

RATIONALE:

A. For an anaesthetic with a low blood:gas partition coefficient, the absorption into the blood will be slower although the alveolar partial pressure equilibrium is achieved at a faster rate than with anaesthetics with a high blood:gas partition coefficient.

B.

C. The oil:gas partition coefficient determines the potency of the anaesthetic with a high coefficient, leading to accumulation of the drug in body fat and a slow recovery.

D. A reduction of cardiac output reduces alveolar absorption of the anaesthetic, and thus speeds up induction, but this is partially offset by a reduction of cerebral blood flow slowing down delivery to the brain.

E. An opioid is often co-administered with an intravenous anaesthetic to provide more immediate analgesia. However, the respiratory depression induced by opioids such as morphine can retard recovery from anaesthesia.

CORRECT ANSWER WITH EXPLANATION:

B. Co-administration of a volatile anaesthetic with nitrous oxide

The rapid absorption of NO into the blood increases the inspiration rate (second gas effect) and so increases the concentration of the volatile anaesthetic in the alveoli. This enhances its movement into the blood by the concentration effect.

ANSWER 41.3

RATIONALE:

A. Enflurane can cause seizures during induction or recovery in patients with epilepsy.

B. Halothane relaxes the uterus and can cause postpartum bleeding.

C.

D. Isoflurane is a powerful coronary vasodilator and can cause hypotension but exacerbates cardiac ischaemia due to the 'steal' phenomenon.

E. Prolonged NO exposure oxidises and inactivates vitamin B_{12} exacerbating the anaemia.

CORRECT ANSWER WITH EXPLANATION:

C. Desflurane for bariatric surgery

Desflurane has a low blood and fat solubility so results in faster recovery for patients who are obese undergoing bariatric surgery.

[1] Now preserved as the Ether Dome, a museum piece at Massachusetts General Hospital.

[2] There is some controversy about whether or not xenon potentiates $GABA_A$ responses, but at present the weight of evidence suggests it does not.

[3] **Propanidid** and **alphaxalone** were withdrawn because of allergic reactions causing hypotension and bronchoconstriction – probably attributable to the solvent cremophor – but a new formulation of alphaxalone has been reintroduced to veterinary medicine and is thought to be less allergenic.

4 Propofol is referred to as the ‘milk of amnesia’. The singer Michael Jackson died of a propofol overdose.

5 An anaesthetist colleague tells of coming across a motorway accident where most of a victim was hidden under a mass of distorted metal but enough of a limb was available for an intramuscular injection of ketamine to be given.

6 The problem of toxicity of low concentrations of anaesthetics inhaled over long periods by operating theatre staff was at one time a cause for concern. Strict measures are now used to minimise the escape of anaesthetics into the air of operating theatres.

7 In operating theatres scavenging systems are used to prevent staff being exposed to nitrous oxide. People who overuse nitrous oxide for its euphoric effects do expose themselves to side effects associated with vitamin B_{12} deficiency (Ch. 49).

42: Headache

OVERVIEW

In this chapter we discuss the pharmacological treatment of headache. We first outline the spectrum of headache disorders, discuss the various drug therapies available and review their mechanisms of action. We focus particularly on the therapy of migraine, a condition which has a high morbidity.

Headache

The overwhelming majority of people will suffer from headaches (*cephalalgias*) at some point in their lives. These range from the inconvenience of occasional headaches to the life-changing and debilitating effects of chronic migraine. 'Headache' is ranked among the top 10 causes of disability worldwide. While many sufferers self-treat with simple analgesics or proprietary preparations available from pharmacies, the condition can be complex and often requires careful differential diagnosis. While accounting for 4%–5% of consultations in primary care, headaches are responsible for approximately 30% of referrals to neurologists in the United Kingdom (cited in **McCrone et al., 2011**). In some cases, headaches may be severe enough to require hospitalisation, and according to one survey in the United States (**Burch et al., 2015**),

headache is the fourth leading cause of visits to emergency departments.

The economic burden of headache in general, and migraine in particular, is huge. According to recent estimates, the total cost of treating headache in the United Kingdom is some £250 million per annum and the economic cost in lost productivity has been estimated to be £5–7 billion annually (cited by **The Migraine Trust, 2021**), although other studies have estimated that the economic cost of migraine alone could be as high as £8.8 billion (**The Work Foundation 2018**) and more than $14.4 billion in the United States (**McCrone et al., 2011**). Despite the obvious impact on healthcare resources and national economic performance, there is little public awareness of the causes of headaches and apparently minimal time devoted to the subject during professional medical training. Three quarters of all medical schools do not even include headache in their undergraduate syllabus (**The Migraine Trust, 2021**).

Types of Headaches

Although some patients may suffer from both types simultaneously, headaches are usually classified as either ‘primary’ or ‘secondary’. The latter term refers to headaches associated with some type of underlying clinical condition such as malignancy, trauma, infections, cerebrovascular disease or trauma (e.g. subarachnoid haemorrhage), medication overuse or drug withdrawal. Today, this list of potential causes also includes ‘COVID-19 headache’ which seems to afflict about 10% of all patients who have caught this disease (**Islam et al., 2020**). In all cases of secondary headache,

clinical investigations may be required to establish the root cause before choosing a treatment plan for resolving the problem.

In this chapter we will deal mainly with *primary headache* which is not caused by an underlying pathology, but which may have a genetic component or other causation (**Robbins, 2021**). *The International Headache Society* (**IHS, 2018**) has classified headaches into four main groups: *tension-type headaches*, *trigeminal autonomic cephalalgias, migraine* and *others*. These groups present with different clinical symptoms and, despite some overlap, often have different underlying mechanisms requiring different pharmacological approaches to treatment. We will deal with each group separately.

Migraine [1]

This is the most complex of these cephalalgias. It is a common and debilitating condition affecting 10%–15% of people and is often stated to be the third most common disease in the world. Some estimates place the total number of sufferers globally at 1 billion with some 45 million years of life compromised by the misery of this disease (**Nature Outlook, 2020**). The WHO has classified migraine as among the 20 most disabling lifetime conditions.

Although the causes are not completely understood, both genetic and environmental factors seem to be important. The frequency of attacks varies, with about three-quarters of *migraineurs* (as they are called) having more than one episode per month. Generally, the onset of attacks begins at puberty and wanes with increasing age. Women are twice as likely as men to suffer from the disorder, and it appears that rapidly falling oestrogen levels can precipitate bouts of

migraine in susceptible subjects so that the attacks are often linked to the menstrual cycle or other reproductive events.

Migraine can be *episodic*, when the attacks are relatively infrequent, or *chronic*, if the frequency and severity become a major burden to the patient. Chronic migraine may be accompanied by comorbidities such as gastrointestinal problems or mental health issues. Pharmacotherapy of the two manifestations of migraine is a little different but it is likely that episodic attacks eventually transform into a more chronic illness unless treated.

Clinical Symptoms

The symptomology of migraine is complex: in about a third of cases, attacks may be accompanied by an *aura* (a term taken to include any sensory changes that occur before the onset of the headache: 'classic migraine'). The onset of an attack is heralded by a *premonitory phase*, with symptoms including nausea, mood changes as well as sensitivity to light and sound (photophobia and phonophobia). These may occur hours before the onset of the *aura* phase and may be accompanied by more specific visual symptoms such as a slowly moving blind spot with associated flashing lights ('scintillating scotoma') or geometric patterns of coloured lights ('fortification spectra') or the illusion of looking through the wrong end of a telescope. The *headache* phase proper is characterised by a moderate or severe headache, starting unilaterally, but then usually spreading to both sides of the head. It may have a pulsating or throbbing quality and may be accompanied by nausea, vomiting and prostration. There may also be sensitivity to movement. This phase may persist for hours or even days. Following resolution of the

headache, a *postdromal* phase may include feelings of fatigue, altered cognition or mood changes. While these different phases probably represent discrete biological events, in practice they overlap and may run in parallel. A good account of these is given by **Charles (2013)** and in the comprehensive review of headache disorders by the **IHS (2018)**.

Pathophysiology

The causes of migraine are incompletely understood although the pathogenesis is becoming clearer. Historically there have been three main hypotheses advanced to account for the pain and other symptoms including: the notion that inappropriate vasoconstriction and vasodilatation were responsible for the symptoms; that cortical activation accompanied by *cortical spreading depression* was the cause; or that inflammatory activation of trigeminal nerve terminals in the meninges and extracranial vessels was the primary event in a migraine attack. These are summarised and explained in more detail by **Eadie (2005)**. It is likely that elements of all these phenomena play a role in the pathogenesis of migraine to a greater or lesser extent, but the consensus of opinion now is that the source of the pain is inflammatory activation of the *trigeminovascular system* – the sensory neurons that innervate the cerebral vessels (see **Moreno-Ajona et al., 2019**) – while the cortical spreading depression, triggered by changes in ion channel activity in the cortex, is responsible for the aura.

Pharmacological and other evidence strongly implicates a key role for neurotransmitters such as calcitonin gene-related peptide (CGRP) (see **Ch. 43**) and 5-hydroxytryptamine (5-HT) (see **Ch. 16**)

in the onset of migraine. CGRP is a major nociceptive transmitter in the trigeminal vascular system and blood neuropeptide levels are raised in patients during episodes of migraine and fall as the condition improves or following treatment with anti-CGRP drugs (**Moreno-Ajona et al., 2019**). Conversely, infusion of CGRP can induce migraine attacks in susceptible people. It has long been suspected that 5-HT also plays a significant role in the pathogenesis of migraine: There is a sharp increase in the urinary excretion of the main 5-HT metabolite, 5-hydroxyindole acetic acid (5-HIAA), during a migraine attack while the blood concentration of 5-HT falls, probably because of depletion of platelet 5-HT. In addition, many selective 5-HT receptor agonists or antagonists are found to be effective in treating migraine. Originally, this was considered to be because of their ability to block the effects of 5-HT on cerebrovascular vessels. However, the consensus now is that the main site of action of these drugs is presynaptic receptors in the trigeminal neurovascular system where they inhibit the release of proinflammatory neuropeptides such as CGRP.

The symptoms associated with the premonitory phase of migraine are largely dopaminergic in origin. The onset of the aura phase coincides with the cortical spreading depression, and imaging studies have indicated widespread changes in brain perfusion during this phase. There may be *hypoperfusion* of some brain areas as well as *hyperperfusion* in others, suggesting that the physiological mechanisms that normally regulate the relationship between brain activity and blood flow become disengaged. Such *neurovascular uncoupling* is also a feature of cortical spreading depression.

Imaging studies suggest that migraine attacks are triggered by signals originating from the hypothalamus (see **Haanes and Edvinsson 2019**). These in turn activate the *trigeminal nucleus caudalis*, and after passing through the *trigeminal ganglion*, activated efferent C fibres dilate meningeal blood vessels, probably releasing further inflammatory mediators such as prostaglandins and nitric oxide. Activated afferent A-δ fibres signal this inflammatory state back through the trigeminal neural pathways, where it is relayed to the cortex and perceived as a painful event. Central sensitisation increases the migraineur's sensitivity to sound, light, cutaneous sensations and other normally non-painful stimuli. Many of the observed vascular and other changes may persist into the postdromal phase, which may last for hours or days.

It is noteworthy that these mechanisms do not offer a totally conclusive account of the complex symptomology of migraine, or explain how attacks are initiated or which underlying abnormality predisposes particular individuals to suffer from migraine. Some authors have identified the 'gut brain axis' (**Arzani et al., 2020**) or endothelial dysfunction (**Paolucci et al., 2021**) as being of significance. In some rare types of familial migraine, inherited mutations affecting calcium channels and Na^+-K^+-ATPase have been found, suggesting that abnormal membrane function may be responsible and **levcromakalim**, a drug which opens ATP-sensitive potassium channels, can provoke migraine attacks in sensitive subjects (**Al-Karagholi et al., 2019**). It is thought that activation of such channels in the cranial arteries and the trigeminal nerve is the cause of the pain. In most forms of migraine, however, there is no clear genetic cause.

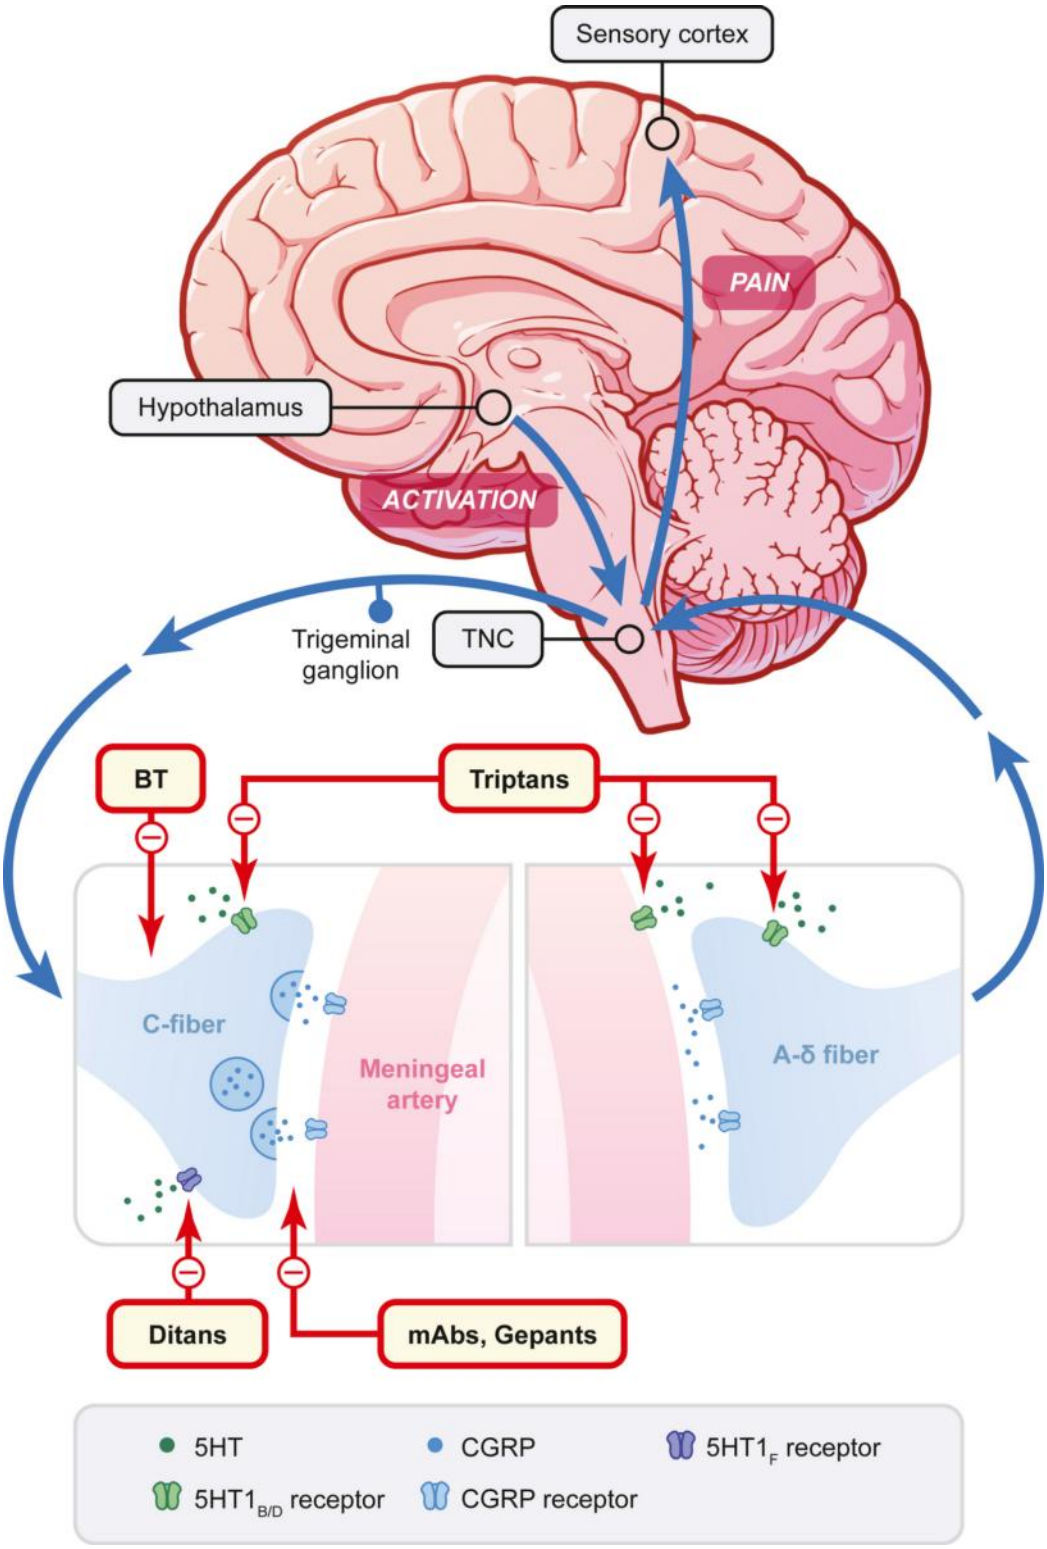

FIG. 42.1 Mechanisms of migraine pain.A diagrammatic representation of the current view

of the origins of migraine pain and the sites at which antimigraine drugs act. Migraine attacks are initiated by signals arising from the hypothalamus and feeding into the *trigeminal nucleus caudalis (TNC)*. These are relayed through efferent C fibres through the trigeminal ganglion (TG) to the vascular system of the meninges. These activated C fibres release calcitonin gene-related peptide (CGRP) from their terminals which dilate meningeal arteries and cause inflammation probably by releasing prostaglandins and other mediators including nitric oxide. These events activate afferent A-δ fibres which signal the sensation of pain back through the TG and TNC to the cortex. Triptans inhibit the release of CGRP by an action at presynaptic $5HT_{1B/D/F}$ receptors or by constricting the meningeal vessels through an action on $5\text{-}HT_{1B/D}$ receptors. Ditans inhibit CGRP release through an action at the $5\text{-}HT_{1F}$ presynaptic receptor. Gepants antagonise the action of CGRP at its target receptor on the vasculature or the A-δ fibre. Monoclonal antibodies (mAbs) neutralise the CGRP (or its receptor) while botulinum toxin (BT) 'denervates' the neurons.

Fig. 42.1 shows, in a diagrammatic way, our current understanding of the factors implicated in migraine pain.

Tension-Type Headaches

These are the most common type of headache (incidence ~40%). There are several subtypes differentiated by their frequency and persistence. Attacks generally have a rapid (30 min or less) onset but can last for some days. They are more prevalent among women (especially those in their 30s) than men. The pain is of usually mild to moderate intensity and is often accompanied by a feeling of ‘pressure’ in the head. The headache may be bilateral or may be predominately located in the frontal or temporal region of the head and there may be associated cranial tenderness. Although they are sometimes confused with migraines, these headaches are generally not exacerbated by physical exercise, and seldom involve nausea, photophobia or phonophobia.

Table 42.1

Drug therapy of headaches

Type of headache	Acute treatment	Prophylactic treatment
Tension headache	NSAIDs and simple analgesics (recommended only for occasional use due to risk of medication overuse headache)	Tricyclic antidepressants; SSRIs; mirtazapine
Cluster headache	Triptans; methysergide; pizotifen	Anti-CGRP mAbs; glucocorticoids
Migraine	NSAIDs and simple analgesics; triptans; ergot derivatives; gepants; ditans	β-blockers; tricyclic depressants; mirtazapine; antiepileptics; candesartan; anti-CGRP mAbs; botulinum toxin; gepants; pizotifen

Type of headache	Acute treatment	Prophylactic treatment
Other miscellaneous headaches	NSAIDs and simple analgesics	N/A

CGRP, Calcitonin gene-related peptide; *mAb*, monoclonal antibody; *NSAID*, non-steroidal anti-inflammatory drug; *SSRI*, selective serotonin reuptake inhibitor.

Adapted and modified from Robbins, M.S., 2021. Diagnosis and management of headache: a review. JAMA 325, 1874–1885; and Headache Classification Committee of the International Headache Society (IHS), 2018. The International Classification of Headache Disorders, third ed. Cephalalgia 38, 1–211.

The underlying cause is neurobiological and is generally thought to involve activation of nociceptors in the facial musculature, provoked by some trigger mechanism. Tension headaches may be *acute* or *chronic*, with acute cases comprising the bulk of cases. Chronic tension headaches may be caused by medication overuse, or possibly depression or anxiety. Triptans are ineffective in tension-type headaches, but acute cases usually respond well to simple non-steroidal anti-inflammatory drugs (NSAIDs) (see **Ch. 25**), although chronic or recurrent cases may require prophylactic treatment with tricyclic antidepressants such as **amitriptyline**, selective serotonin reuptake inhibitors (SSRIs) such as **venlafaxine** or the a_2 adrenoceptor and 5-$HT_{2/3}$ antagonist **mirtazapine** (see **Ch. 48**).

Trigeminal Autonomic Cephalalgias

This type of headache is caused by excessive central activation of the cranial parasympathetic system. There are several different subtypes differentiated by their frequency and persistence. *Cluster headaches* are probably the most prominent type in this group, with an incidence of <0.5% of the population and affecting more males than females. The pain which is unilateral is usually severe, often being described as 'searing', 'sharp' or 'throbbing', and may be located unilaterally in the frontal or orbital region of the head. The pain is associated with ipsilateral activation of the trigeminal nerve causing lacrimation, and other ocular symptoms including ptosis and photophobia, rhinorrhoea (running nose), facial sweating, restlessness or agitation. There may be a genetic basis for these symptoms. The attacks have a rapid (30 min) onset and can last for hours. Some patients experience attacks every other day, suggesting some circadian influence; others may experience a chronic form of the headache lasting months or years. Environmental triggers may be important: for example, some patients experience symptoms at the same time each year in response to changes in the weather (**Suri and Ailani, 2021**). Once again, CGRP can induce cluster headaches in susceptible subjects.

Pharmacological therapy usually consists of triptans, but more chronic manifestations may require anti-CGRP monoclonal antibody treatment or corticosteroids.

Miscellaneous Primary Headaches

This group includes headaches associated with exercise, sudden exertion, sex or coughing spasms, 'thunderclap' headache, cold

stimulus headache, hypnic headache (occurring during sleep) and other headaches caused by pressure on the scalp. The causes of such headaches are generally unknown, but they often respond to simple analgesics. *New daily persistent headache* may appear suddenly and last for months and may require a treatment plan similar to migraine.

Drug Therapy for Headache

Perhaps reflecting the multifactorial nature of headaches, a multitude of different drugs have been tested, and reported to be effective, in treating headaches of all types. For convenience, a summary of these appears in **Table 42.1**.

Drugs Acting on the 5-HT System

Historically, this group of drugs was among the first to be utilised for the treatment of migraines and continues to be an important component of treatment regimens for both migraine and cluster headaches. They all posess 5-$HT_{1A/B/D/F}$ agonist properties. The original notion that the chief target for these drugs was the vasculature has now been largely replaced by the idea that the presynaptic 5-HT receptors controlling neuropeptide release from the trigeminovascular system are more significant sites of action (**Haanes and Edvinsson, 2019**; **Robbins, 2021**).

Ergot Derivatives

Ergotamine and **dihydroergotamine** are the two most commonly used drugs in this class and among the oldest drugs to be used for treatment of migraine. They have antidopaminergic and α-

adrenoceptor blocking actions as well as multiple actions at 5-HT receptors, among which (probably crucially) are 5-HT_{1D} partial agonist properties. **Methysergide** is another related drug with promiscuous actions on 5-HT receptors, including agonism at the 5-$HT_{1A/B}$ and 5-HT_2 subtypes.

Clinical use

The only current use of **ergotamine** is in the treatment of attacks of migraine or cluster headaches unresponsive to simple analgesics (see Chs **25** and **43**). It is sometimes given in a proprietary formulation with **caffeine** and the antihistamine/anticholinergic drug **cyclizine** which has antiemetic properties. **Methysergide** was formerly used for migraine prophylaxis, and for treating the symptoms of carcinoid tumours. It is seldom used today because of potentially serious toxicity problems, although it is sometimes still employed for the treatment of cluster headaches which are refractory to other drugs.

All these drugs can be used orally or by injection.

Unwanted effects

Ergotamine often causes nausea and vomiting, and it must be avoided in patients with peripheral vascular disease because of its vasoconstrictor action. **Methysergide** also causes nausea and vomiting, but its most serious side effect, which considerably restricts its clinical usefulness, is *retroperitoneal* and *mediastinal fibrosis*, which impairs the functioning of the gastrointestinal tract, kidneys, heart and lungs. The mechanism of this is unknown, but it is noteworthy that similar fibrotic reactions also occur in carcinoid syndrome, in which there is a high circulating level of 5-HT. In high

doses, **methysergide** can cause hallucinogenic effects, possibly through an effect at 5-HT_{2A} receptors.

Triptans

This important group of drugs group includes **almotriptan**, **eletriptan**, **frovatriptan**, **naratriptan**, **rizatriptan**, **sumatriptan** and **zolmitriptan**. The triptans are among the most important agents for the treatment of acute migraine and cluster headache attacks. They are usually classified as 5-$HT_{1B/1D/F}$ agonists (see **Ch. 16**). However, selective high-affinity 5-HT_{1D} subtype agonists have proved disappointing in the clinic (see **Agosti, 2007**). Their principal target is probably the presynaptic 5-$HT_{1B/D}$ receptors on CGRP secreting neurons but they also have vasoconstrictor actions through their action on these receptors on the meningeal vessels.

Clinical use

Triptans are mainly used to treat acute migraine but also may be given to provide prophylactic treatment of predictable (e.g. menstrual) attacks of migraine. They can also be used to treat cluster headaches. These drugs are mainly administered orally but **sumatriptan** and **zolmitriptan** are available as nasal sprays, and **rizatriptan** as a tablet that disperses on the tongue, which can be advantageous if the patient is vomiting. **Sumatriptan** is also available as an injection for subcutaneous administration.

Unwanted effects

Side effects common to many members of this group include asthenia, dizziness, drowsiness, gastrointestinal symptoms

including nausea and vomiting. A major potential problem is the fact that triptans have vasoconstrictor properties and so must be used cautiously in patients who have (for example) hypertension, ischaemic heart disease, cerebrovascular disease or peripheral vascular disease.

Ditans

Lasmiditan, a new non-triptan drug, is highly effective in aborting migraine attacks (**Ferrari and Rustichelli, 2021**). It was approved by the FDA in 2019 but has not yet been approved in the United Kingdom. **Lasmiditan** is a selective $5HT_{1F}$-receptor agonist. Interestingly, this receptor subtype is scarce in the vasculature, casting further doubt on the role of vascular changes per se in the pain experienced by migraine patients. This is significant because a major drawback to triptan therapy is vasoconstriction in other peripheral vascular beds, including the heart.

Clinical use

The drug is given orally for the treatment of acute migraine. It is not suitable for migraine prophylaxis.

Unwanted effects

While **lasmiditan** would be expected to be free of the vasoconstrictor effects of the triptans, it commonly causes other adverse effects (e.g. dizziness, drowsiness and nausea) which can be severe.

Drugs Acting on the CGRP System

Gepants

Based upon the notion that CGRP is a crucial player in the pathogenesis of migraine and possibly other headaches, a group of small-molecule CGRP antagonists have been developed. These drugs, known as *gepants*, were first developed at the beginning of this century. **Telcagepant** was the first of these, but while it showed efficacy, it was discontinued because of liver toxicity problems. Two second-generation gepants, **rimegepant** and **ubrogepant**, were approved by the FDA in the United States in 2019. They are not yet approved in the United Kingdom. Both of these drugs have shown good efficacy and tolerability in trials in which they have been used acutely to treat migraine and **rimegepant** has shown efficacy as a prophylactic drug. Uniquely, the gepants may be the first specific antimigraine drugs which are effective for both acute and prophylactic treatment (**Moreno-Ajona et al., 2019**). Also in the process of late-stage development are the 'third-generation' gepants, **atogepant** and **vazegepant**.

Clinical use

These drugs are given by oral administration. **Vazegepant** (not yet approved) is designed to be administered nasally.

Unwanted effects

Unlike the triptans, the gepants lack any cardiovascular effects. However, nausea is a common feature of these drugs, sometimes accompanied by dizziness and vomiting (**rimegepant**) or dry mouth and drowsiness (**ubrogepant**).

Anti-CGRP mabs

An alternative approach to abolishing the actions of CGRP is to immunoneutralise the neuropeptide(s) or its receptor with neutralising monoclonal antibodies (mAbs: **Abu-Zaid et al., 2020**; **Drellia et al., 2021**). Several preparations have been approved for clinical use. These include **eptinezumab** (not UK), **fremanezumab** and **galcenezumab** (anti-neuropeptide mAbs) and **erenumab** (antireceptor mAb). These drugs are all humanised (or human) mAbs and are used for prophylactic treatment of migraine and cluster headache which does not respond to other therapy regimes. While more expensive and more difficult to administer, their effects are long-lasting (weeks) rather than hours.

Clinical use

These drugs are generally administered subcutaneously each month but **eptinezumab** (a human monoclonal antibody) is given intravenously each quarter.

Unwanted effects

These mAbs produce several common side effects which often include hypersensitivity reactions such as skin reactions and constipation. Vertigo, oedema and muscle spasms may also occur in some instances.

Anti-Inflammatory Drugs

The notion that migraine and some other forms of headache are caused by the release of neuropeptides which in turn release prostaglandins, nitric oxide and other mediators provides a rationale for the well-established use of anti-inflammatory/analgesic drugs in headache disorders. There are several types.

Non-Steroidal Anti-Inflammatory Agents

NSAIDs (see **Ch. 25**) are also among the oldest drugs to be utilised for treating headaches. **Paracetamol** is one the most commonly used treatments for occasional headaches and is mostly effective. In migraine NSAIDs seem to have a variable effect, being useful for some patients but not others. **Paracetamol** is sometimes given in combination with the vasoconstrictor **isometheptene**. Among other most commonly employed NSAIDs are **ibuprofen**, **aspirin**, **naproxen** and **diclofenac**. The main mode of action of these drugs is inhibition of the synthesis of pain-producing prostaglandins which are probably released by neuropeptides.

Clinical use

Generally, therapy for migraine is begun with **aspirin** or **ibuprofen** using the other members of this group or more potent drugs such as **tolfenamic** or **mefenamic** acid if these fail.

Unwanted effects

The unwanted effects of NSAIDs are detailed in **Chapter 25**. The gastrointestinal side effects of these drugs are of significance because migraine is often accompanied by nausea and NSAIDs may exacerbate the issue. **Metoclopramide** (see **Ch. 30**) can be used to control the nausea and is sometimes given in the form of combined therapy (e.g. **metoclopramide** with **aspirin**).

Glucocorticoids

Anti-inflammatory glucocorticoids are sometimes useful for the prophylactic treatment of cluster headaches. The pharmacology of these drugs is discussed in **Chapters 3** and **25**.

Centrally Acting Drugs

Antihistamines

Pizotifen is a non-sedating antihistamine that also has some anticholinergic actions and is also a 5-$HT_{2A/2C}$ receptor antagonist (although the anatomical site of its action is unknown). **Buclizine** is a sedating antihistamine and anticholinergic with additional antiemetic properties. It is usually administered in a proprietary formulation together with **paracetamol** and **codeine.**

Clinical use

Pizotifen is useful in some patients for the prophylactic treatment of vascular, cluster headache and migraine. **Buclizine** is used to treat acute attacks of migraine.

Unwanted effects

The typical effects of **pizotifen** include cholinergic effects such as dry mouth and also an increase in appetite and weight gain as well as central effects such as dizziness, fatigue and nausea.

Antiepileptic Drugs

Antiepileptic drugs have been found to be sometimes effective in prophylaxis of migraine. Commonly employed drugs include **topiramate** and **levetiracetam** (**Yen et al., 2021**). The general pharmacology of these drugs is discussed in **Chapter 46**. A reduction in glutamate transmission or enhanced $GABA_A$ activity may result in decreased cortical excitability which may be their chief mechanism of action.

Tricyclic Antidepressants and SSRIs

The most commonly used drugs in this group are the tricyclic drugs **amitriptyline** and **nortriptyline** and the SSRIs **venlafaxine** and **mirtazapine**.

The general pharmacology of these drugs is discussed in **Chapter 48**. In the prophylactic treatment for tension headaches and migraine, their hypothesised mechanism is via an increase in GABA-mediated inhibition secondary to inhibition of monoamine reuptake. However, the link between stress and tension headaches and migraine may suggest that antidepressant and anxiolytic effects may contribute to their efficacy.

Cardiovascular Drugs

β-Blockers

The β-blockers **propranolol**, **metoprolol** and **timolol** are first-line agents for migraine prophylaxis. Their general pharmacology is discussed in **Chapters 15**, **20** and **21**, and their anxiolytic properties, in **Chapter 45**. Their mode of action in migraine is probably associated with a reduction of neurotransmitter release and of neuronal excitability.

Other cardiovascular drugs used in the prophylaxis of headache include calcium channel blockers (see **Ch. 20**) such as **verapamil** (for cluster headache) and **flunarizine** (approved in Europe and Asia for migraine; prescribed off-license in UK specialist centres). **Candesartan,** an AT1 antagonist (see **Ch. 21**), is sometimes prescribed for migraine prophylaxis; it reduces glutamate release and enhances GABA-ergic tone.

Miscellaneous Group

Botulinum Toxin

Botulinum toxin A is a neurotoxin produced by the gram-positive anaerobic bacterium *Clostridium botulinum* and is intensely poisonous. It produces muscular paralysis ('botulism') by inhibiting the release of acetylcholine from motor nerve terminals (see **Ch. 14**). The toxin is a dimer which, upon entering the cell following combination with a cell surface glycoprotein, is cleaved to release the light chain of the dimer. This moiety cleaves the SNARE 25 protein which is responsible for tethering and binding of acetylcholine vesicles to the cell membrane and forming a synaptic fusion complex prior to release (**Burstein et al., 2020**). The same mechanism also prevents the release of neuropeptides as well as the replenishment of normal receptors such as transient receptor potential (TRP) receptors on neurons. This produces a type of chemical denervation of the neuron.

Clinical use

The use of the drug **onabotulinumtoxin** is usually restricted to those patients in whom at least two other agents seem to be ineffective. Administration, which is a specialist procedure, entails multiple (usually about 30) discrete subcutaneous injections at sites on the scalp of the cranial musculature. Treatment is usually repeated every 3 months.

Unwanted effects

Onabotulinumtoxin is usually better tolerated than oral preventive therapies but there is a high incidence of muscular

weakness in the neck with associated pain (**Barbanti and Ferroni, 2017**).

Other Non-Pharmacological Treatments

A raft of other non-pharmacological treatments have been trialled, sometimes successfully, to treat migraines and other types of headache. These include external neuromodulation devices (see **Gupta et al., 2019**), acupuncture, as well as psychological approaches such as cognitive behavioural therapy (CBT), autogenic feedback and other techniques. Sometimes, these are combined with drug therapy to produce an effect superior to that which could be achieved by monotherapy.

Summary

The term *headache* is a compendium definition which embraces several complex disorders which can be difficult to differentiate clinically, and which can sometimes be difficult to treat successfully.

While the foregoing chapter is of necessity rather incomplete in its coverage of the many different drugs now available, further information on these may be found in **Chapters 5**, 13, 16, 17, 25, 37 and 43.

Drugs used for migraine

Aspirin, ibuprofen, or other non-steroidal anti-inflammatory agents are recommended for pain relief in acute migraine, and best administered early during onset of symptoms. Antiemetics

such as **metoclopramide** are given at the same time for patients who suffer with nausea.

Triptans (5-$HT_{1B/1D/F}$ agonists) are widely used for acute relief of moderate to severe migraine that has not responded to simple analgesics. The triptans are also effective in cluster headaches.

Medication overuse headaches can occur with persistent daily use of analgesics and triptans.

Regular use of prophylactic agents (such as **propranolol**, **topiramate** or **amitriptyline**) is therefore indicated for patients who suffer frequent and troubling migraine attacks. Patients who fail to respond to these oral agents can move on to injectable options such as the anti-CGRP antibodies or botulinum toxin.

QUESTIONS

QUESTION 42.1

Migraine is the most complex of the cephalalgias. It is a common and debilitating condition affecting 10%–15% of people and is often stated to be the third most common disease in the world.

Which characteristic/symptom is specific for migraine headaches?

OPTIONS:

A. Photophobia

B. Unilateral pattern

C. Increased prevalence in women

D. Nausea

E. Facial sweating

QUESTION 42.2

The symptomology of migraine is complex and various hypotheses have been proposed to account for the different phases.

Which of the following statement(s) relating to our current understanding of the pathogenesis of migraine is correct?

OPTIONS:

A. The symptoms associated with the premonitory phase of migraine are largely dopaminergic in origin.

B. Blood levels of 5-hydroxytryptamine (5-HT) are increased during a migraine attack.

C. The presence of the aura is due to activation of the trigeminovascular system, the sensory neurones that innervate the cerebral vessels.

D. Cortical spreading depression is responsible for the pain.

E. Levels of calcitonin gene-related peptide (CGRP) in the blood are raised during episodes of migraine.

QUESTION 42.3

The triptans are amongst the most important agents for the treatment of acute migraine and cluster headache attacks.

The main mechanism by which triptans exert their therapeutic effect is ...?

OPTIONS:

A. Antagonist activity at CGRP receptors

B. Through inhibition of the synthesis of pain-producing prostaglandins

C. Agonist activity at presynaptic 5-$HT_{1B/D}$ receptors

D. Through vasoconstrictor actions on the meningeal vessels

E. Through reduction in noradrenergic transmission

ANSWERS

ANSWER 42.1

RATIONALE:

A. This also occurs in trigeminal autonomic cephalalgias.

B. Trigeminal autonomic cephalalgias also show a unilateral pattern.

C. Whilst women are twice as likely as men to suffer from migraines, tension headaches are also more common in women (whilst trigeminal autonomic cephalalgias are more common in males).

D.

E. This is a symptom of trigeminal autonomic cephalalgias rather than migraines.

CORRECT ANSWER WITH EXPLANATION:

D. Nausea

The onset of a migraine attack is heralded by a *premonitory phase*, with symptoms including nausea, mood changes as well as sensitivity to light and sound (photophobia and phonophobia).

ANSWER 42.2

RATIONALE:

A. The symptoms associated with the premonitory phase of migraine are largely dopaminergic in origin.

B. There is a sharp increase in the urinary excretion of the main 5-HT metabolite, 5-HIAA, during a migraine attack while the blood concentration of 5-HT falls, probably because of depletion of platelet 5-HT.

C. The source of the pain is inflammatory activation of the *trigeminovascular system* – the sensory neurones that innervate the cerebral vessels.

D. The cortical spreading depression, triggered by changes in ion channel activity in the cortex, is responsible for the aura.

E.

CORRECT ANSWER WITH EXPLANATION:

E. CGRP is a major nociceptive transmitter in the trigeminal vascular system and blood neuropeptide levels are raised in patients during episodes of migraine.

ANSWER 42.3

RATIONALE:

A. Triptans reduce CGRP activity through inhibiting the release of CGRP from nerve terminals rather than acting directly on CGRP receptors.

B. Triptans do not have direct effects on pro-inflammatory prostaglandins.

C.

D. The triptans have vasoconstrictor actions through their action on these receptors on the meningeal vessels but this is not thought to be their main mechanism of action.

E. Triptans mediate their vasoconstrictor effects through 5-HT receptors rather than noradrenaline (NA) receptors.

CORRECT ANSWER WITH EXPLANATION:

C. Agonist activity at presynaptic 5-$HT_{1B/D}$ receptors

The principal target of triptans is probably the presynaptic 5-$HT_{1B/D}$ receptors on CGRP secreting neurons which inhibit the release of CGRP.

---

[1] The word is apparently of French origin and is probably a corruption of *hemicrania*, the Latin name for the disease.

43: Analgesic drugs

OVERVIEW

Pain is a disabling accompaniment of many acute and chronic medical conditions, and pain control is one of the most important therapeutic priorities.

In this chapter, we discuss the neural mechanisms responsible for different types of acute and chronic pain, and the various drugs that are used to reduce the sensation of pain. The 'classic' analgesic drugs, notably opioids and non-steroidal anti-inflammatory drugs (NSAIDs; described in **Ch. 25**), have their origins in natural products that have been used for centuries. The original compounds, typified by morphine and aspirin, are still in widespread use, but many synthetic compounds that act by the same mechanisms have been developed. In recent years it has become apparent that chronic pains respond poorly to opioids and NSAIDs. We therefore consider various other drug classes, such as antidepressant and antiepileptic drugs, which clinical experience has shown may have efficacy in ameliorating the suffering of chronic pain.

Introduction

Pain is a subjective experience, hard to define exactly, even though we all know what we mean by it. Typically, it is a direct response to

an untoward event associated with tissue damage, such as injury, inflammation or cancer, but severe pain can occur as a consequence of brain or nerve injury (e.g. following a stroke or herpes infection, and as a consequence of diabetes or multiple sclerosis) and persist long after the precipitating injury has healed (e.g. phantom limb pain). In some instances pain can arise without any obvious cause (e.g. lower back pain, fibromyalgia).

Clinically, pain is broadly categorised as ‘acute’ or ‘chronic’. Acute pain comes on suddenly and is caused by something specific (e.g. an ankle sprain, broken bones, burns, cuts or surgery). It is sharp in nature and may last for a considerable time. It goes away when there is no longer an underlying cause for the pain. Chronic pain usually lasts longer than 3 months and may persist after the injury or illness that caused it has healed or gone away.

Acute pain, cancer pain and pain associated with inflammation generally respond to conventional analgesic drugs such as NSAIDs (see **Ch. 25**) and opioids. Chronic, noninflammatory pains which are very common and a major cause of disability and distress in general respond poorly to conventional analgesic drugs. All is not doom and gloom however; the good news is that a number of drugs originally developed to treat other conditions such as depression and epilepsy can reduce the suffering of chronic pains but there is still a need for more effective agents. We should think of chronic pain in terms of disordered neural function rather than simply as a ‘normal’ response to tissue injury. The perception of noxious stimuli (termed *nociception* by Sherrington) is not the same thing as pain, which is a subjective experience and includes a strong

emotional (affective) component, especially in people suffering from chronic pain.

Neural Mechanisms of Pain

Under normal conditions, pain is associated with impulse activity in small-diameter (C and Aδ) primary afferent fibres of peripheral nerves. These nerves have sensory endings in peripheral tissues and are activated by stimuli of various kinds (mechanical, thermal, chemical). The majority of non-myelinated (C) fibres are associated with *polymodal nociceptive* endings and convey a dull, diffuse burning pain, whereas myelinated (Aδ) fibres convey a sensation of sharp, well-localised pain. C and Aδ fibres convey nociceptive information from muscle and viscera as well as from the skin. Good accounts of the neural basis of pain can be found in **McMahon et al. (2013)**.

With many pathological conditions, tissue injury is the immediate cause of the pain and results in the local release of a variety of chemicals that act on the nerve terminals, either activating them directly or enhancing their sensitivity to other forms of stimulation (**Fig. 43.1**). The pharmacological properties of nociceptive nerve terminals are discussed in more detail later in this chapter.

The cell bodies of spinal nociceptive afferent fibres lie in dorsal root ganglia; fibres enter the spinal cord via the dorsal roots, ending in the grey matter of the dorsal horn (see **Fig. 43.4**). Most of the nociceptive afferents terminate in the superficial region of the dorsal horn, the C fibres and some Aδ fibres innervating cell bodies in laminae I and II (also known as the *substantia gelatinosa* (SG)), while other A fibres penetrate deeper into the dorsal horn (lamina

V). The SG is rich in both endogenous opioid peptides and opioid receptors, and may be an important site of action for morphine-like drugs. Cells in laminae I and V give rise to the main projection pathways from the dorsal horn to the thalamus. For a more detailed account of dorsal horn circuitry, see **Todd and Koerber (2013)**.

Nociceptive afferent neurons release glutamate and possibly ATP as the fast neurotransmitters at their central synapses in the dorsal horn. Glutamate acting on (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors is responsible for fast synaptic transmission at the first synapse in the dorsal horn. There is also a slower NMDA receptor-mediated response, which is important in relation to the phenomenon of 'wind-up' (**Fig. 43.2**). The analgesia produced by **ketamine** most likely results from blockade of this phenomenon. The nociceptive afferent neurons also contain several neuropeptides, particularly calcitonin gene-related peptide (CGRP) and substance P. These are released as mediators at both the central and the peripheral terminals, and play an important role in the pathology of pain. In the periphery, substance P and CGRP produce some of the features of neurogenic inflammation. CGRP antagonists are used in the treatment of migraine (see **Ch. 42**) but have not proved effective for other pain states. In animal models, substance P acting on NK_1 receptors was shown to be involved in wind-up and central sensitisation in the dorsal horn (see **Fig. 43.2**). Surprisingly, however, antagonists of substance P at NK_1 receptors turned out to be ineffective as analgesics in humans, although they do have antiemetic activity (see **Ch. 30**).

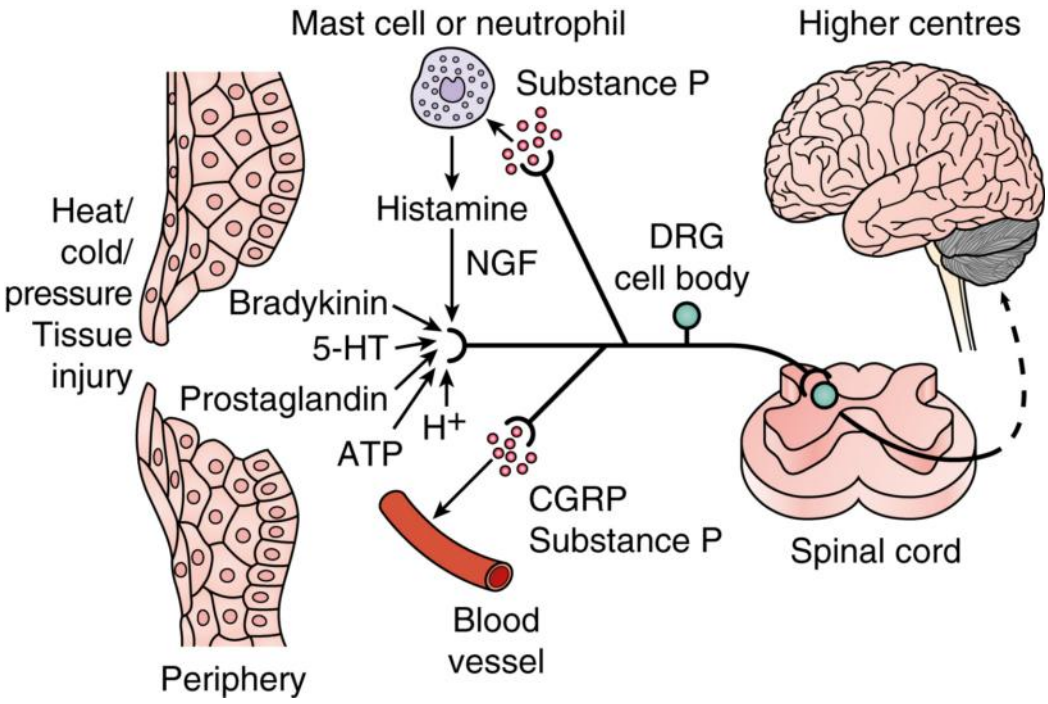

FIG. 43.1 Activation of nociceptive neurons.Various stimuli (physical and chemical), some shown here, can initiate or enhance the rate of action potential firing in nociceptive primary afferent neurons (i.e. induce pain). These afferent fibres project to the dorsal horn of the spinal cord where they synapse on neurons projecting to higher centres. *5-HT,* 5-Hydroxytryptamine; *CGRP,* calcitonin gene-related peptide; *DRG,* dorsal root ganglion; *NGF,* nerve growth factor. Adapted from Julius, D., Basbaum, A.I., 2001. Molecular mechanisms of nociception. Nature 413, 203–210.

Modulation in the Nociceptive Pathway

Pain resulting from trauma, inflammation or cancer is generally well accounted for in terms of nociception – an excessive noxious stimulus giving rise to an intense and unpleasant sensation. More prolonged pain and chronic pain states such as neuropathic pain are associated with aberrations of the normal physiological pathway, giving rise to the phenomena of *hyperalgesia* (an increased amount of pain associated with a mild noxious stimulus) and *allodynia* (pain evoked by a non-noxious stimulus). Some of the main mechanisms are summarised in **Fig. 43.3**.

Hyperalgesia and Allodynia

Anyone who has suffered a burn or sprained ankle has experienced hyperalgesia and allodynia. Hyperalgesia involves both sensitisation of peripheral nociceptive nerve terminals and central facilitation of transmission at the level of the dorsal horn and thalamus. The peripheral component is due to the action of mediators such as bradykinin and prostaglandins acting on the nerve terminals. The central component reflects facilitation of synaptic transmission in the dorsal horn of the spinal cord (see **Yaksh, 1999**). The synaptic responses of dorsal horn neurons to nociceptive inputs display the phenomenon of 'wind-up' – i.e. the synaptic potentials steadily increase in amplitude with each stimulus – when repeated stimuli are delivered at physiological frequencies. This activity-dependent facilitation of transmission has features in common with the phenomenon of long-term potentiation, described in **Chapter 38**, and the chemical mechanisms underlying it may also be similar. In the dorsal horn, the facilitation is blocked by NMDA receptor

antagonists and also in part by antagonists of substance P and by inhibitors of nitric oxide (NO) synthesis (see Figs **43.2** and **43.3**).

FIG. 43.2 Effect of glutamate and substance P antagonists on nociceptive transmission in the rat spinal cord.The rat paw was inflamed by ultraviolet irradiation 2 days before the experiment, a procedure that induces hyperalgesia and spinal cord facilitation. The synaptic response was recorded from the ventral root, in response to stimulation of C fibres in the dorsal root with (A) single stimuli or (B) repetitive stimuli. The effects of the NMDA receptor antagonist D-AP-5 (see ‘) and the substance P antagonist RP 67580 (selective for neurokinin type 2 (NK_2) receptors) are shown. The slow component of the synaptic response is reduced by both antagonists (A), as is the ‘wind-up’ in response to repetitive stimulation (B). These effects are much less pronounced in the normal animal. Thus both glutamate, acting on NMDA receptors, and substance P, acting on NK_2 receptors, are involved in nociceptive transmission, and their contribution increases as a result of inflammatory hyperalgesia. *NMDA, N*-methyl-D-aspartate. Records kindly provided by L. Urban and S.W. Thompson.

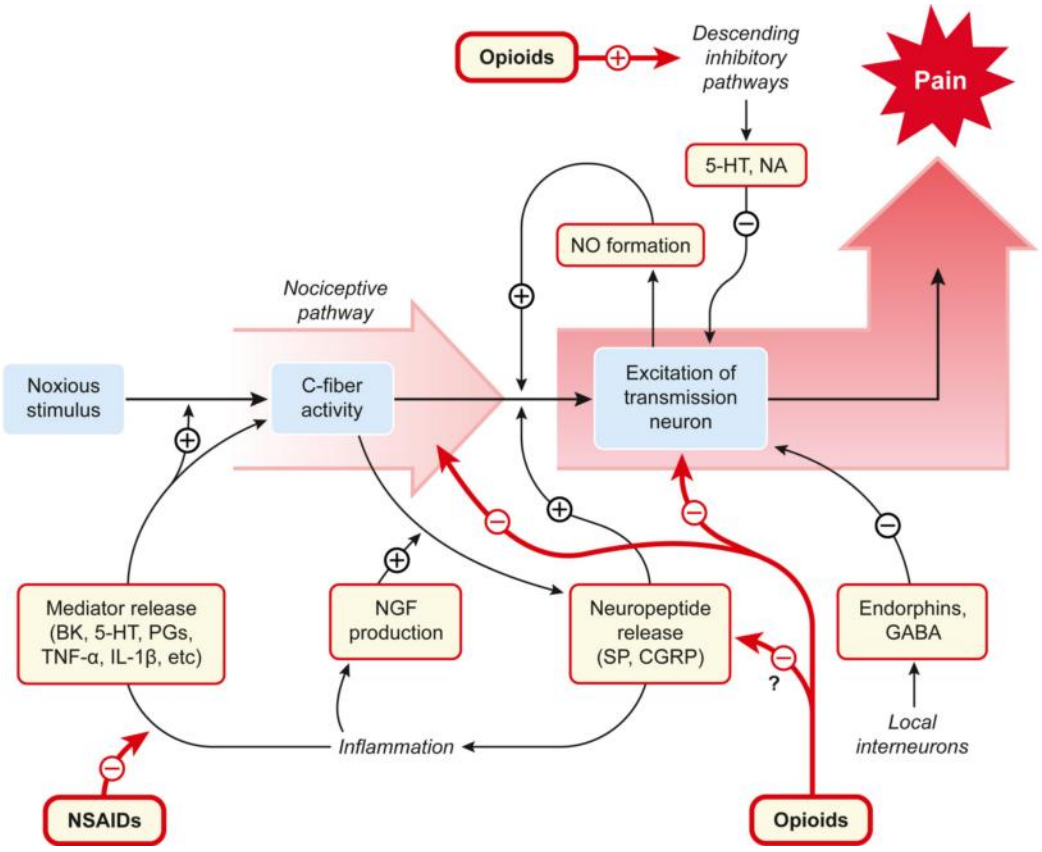

FIG. 43.3 Summary of modulatory mechanisms in the nociceptive pathway. *5-HT,* 5-Hydroxytryptamine; *BK,* bradykinin; *CGRP,* calcitonin gene-related peptide; *IL-1β,* interleukin; *NA,* noradrenaline; *NGF,* nerve growth factor; *NO,* nitric oxide; *NSAID,* non-steroidal anti-inflammatory drug; *PG,* prostaglandin; *SP,* substance P; *TNF-α,* tumour necrosis factor-α.

Substance P and CGRP released from primary afferent neurons (see **Fig. 43.1**) also act in the periphery, promoting inflammation by their effects on blood vessels and cells of the immune system. This mechanism, known as *neurogenic inflammation,* amplifies and

sustains the inflammatory reaction and the accompanying activation of nociceptive afferent fibres.

Central facilitation is an important component of pathological hyperalgesia (e.g. that associated with inflammatory responses). The mediators responsible for central facilitation include substance P, CGRP, brain-derived neurotrophic factor (BDNF) and NO, as well as many others. For example, nerve growth factor (NGF), a cytokine-like mediator produced by peripheral tissues, particularly in inflammation, acts on a kinase-linked receptor (known as TrkA) on nociceptive afferent neurons, increasing their electrical excitability, chemosensitivity and peptide content, and also promoting the formation of synaptic contacts. Increased NGF production may be an important mechanism by which nociceptive transmission becomes facilitated by tissue damage, leading to hyperalgesia (see **Mantyh et al., 2011**). Increased gene expression in sensory neurons is induced by NGF and other inflammatory mediators; the up-regulated genes include those for neuropeptides and neuromodulators (e.g. CGRP, substance P and BDNF) as well as for receptors (e.g. transient receptor potential (TRP) TRPV1 and the ATP receptor P2X) and sodium channels, and have the overall effect of facilitating transmission at the first synaptic relay in the dorsal horn. BDNF released from primary afferent nerve terminals activates the kinase-linked TrkB receptor on postsynaptic dorsal horn neurons leading to phosphorylation of the NMDA subunit GluN1 and thus sensitisation of these glutamate receptors, resulting in synaptic facilitation, in the dorsal horn.

Excitation of nociceptive sensory neurons depends, as in other neurons (see **Ch. 4**), on voltage-gated sodium channels. Individuals

who express non-functional mutations of *Na $_v$1.7* are unable to experience pain. The expression and/or activity of certain sodium-channel subtypes (e.g. $Na_v1.3$, $Na_v1.7$, $Na_v1.8$ and $Na_v1.9$ channels) is increased in sensory neurons in various pathological pain states and their enhanced activity underlies the sensitisation to external stimuli that occurs in inflammatory pain and hyperalgesia (see **Ch. 4** for more detail on voltage-activated sodium channels). Consistent with this hypothesis is the fact that some antiepileptic and antidysrhythmic drugs, which act by blocking sodium channels (see Chs **20** and **46**), also find clinical application as analgesics.

Transmission of Pain to Higher Centres

From the dorsal horn, ascending nerve axons travel in the contralateral spinothalamic tracts, and synapse on neurons in the ventral and medial parts of the thalamus, from which there are further projections to the somatosensory cortex. In the medial thalamus in particular, many cells respond specifically to noxious stimuli in the periphery, and lesions in this area cause analgesia. Functional brain imaging studies in conscious subjects have been performed to localise regions involved in pain processing. These include sensory, discriminatory areas such as primary and secondary somatosensory cortex, thalamus and posterior parts of insula as well as affective, cognitive areas such as the anterior parts of insula, anterior cingulate cortex and prefrontal cortex (see **Apkarian et al., 2013**).

Descending Inhibitory Controls

Descending pathways (**Fig. 43.4**) control impulse transmission in the dorsal horn. A key part of this descending system is the

periaqueductal grey (PAG) area of the midbrain, a small area of grey matter surrounding the central canal. In 1969, Reynolds found that electrical stimulation of this brain area in the rat caused analgesia sufficiently intense that abdominal surgery could be performed without anaesthesia and without eliciting any marked response. The responses to non-painful stimuli were unaffected. The PAG receives inputs from many other brain regions, including the hypothalamus, amygdala and cortex, and is the main pathway through which cortical and other inputs act to control the nociceptive ‘gate’ in the dorsal horn.

FIG. 43.4 The descending pain control system and sites of action of opioids to relieve pain.Opioids induce analgesia when microinjected into the insular cortex (IC), amygdala (A), hypothalamus (H), periaqueductal grey (PAG) region and rostroventral medulla (RVM), as well as into the dorsal horn of the spinal cord. The PAG receives input from higher centres and is the main output centre of the limbic system. It projects to the RVM. From the RVM, descending inhibitory fibres, some of which contain 5-hydroxytryptamine, project to the dorsal horn of the spinal cord. *Pink shaded areas* indicate regions expressing μ opioid receptors. The pathways shown in this diagram represent a considerable oversimplification. Adapted from Fields, H., 2001. Pain modulation: expectation, opioid analgesia and virtual pain. Prog. Brain Res. 122, 245–253. For a fuller account of the descending pain modulating pathways, see Todd and Koerber, 2013.

The PAG projects first to the rostroventral medulla (RVM) and thence via the dorsolateral funiculus of the spinal cord to the dorsal horn. Important transmitters in this pathway are 5-hydroxytryptamine (5-HT; serotonin) and endogenous opioid

peptides, which act directly or via interneurons to inhibit the discharge of spinothalamic neurons (see **Fig. 43.4**).

The descending inhibitory pathway is probably an important site of action for opioid analgesics (**Bagley and Ingram, 2020**). Both PAG and SG are particularly rich in endogenous opioid peptide–containing neurons, and opioid antagonists such as naloxone can prevent analgesia induced by PAG stimulation, which would suggest that endogenous opioid peptides may function as transmitters in this system. The physiological role of opioid peptides in regulating pain transmission has been controversial, mainly because under normal conditions naloxone has relatively little effect on pain threshold. Under pathological conditions, however, when stress is present, naloxone causes hyperalgesia, implying that the opioid system is active.

Interneurons in the dorsal horn release GABA (see **Ch. 38**), which inhibits transmitter release from primary afferent terminals.

There is also a noradrenergic pathway from the *locus coeruleus* (LC; see **Ch. 39**), which has a similar inhibitory effect on transmission in the dorsal horn. Surprisingly, opioids inhibit rather than activate this pathway. The use of tricyclic antidepressants in managing chronic pain may involve potentiating this pathway.

It is thought that descending inhibitory purinergic pathways may release adenosine on to A_1 receptors on dorsal horn neurons to produce analgesia.

Placebo Analgesia

Placebo analgesia is the phenomenon of reduced sensation of pain when the subject believes that they have been given a drug that will

suppress pain, when in fact no drug has been administered at all. It is often a substantial effect that poses problems in clinical trials of analgesic drugs. Placebo analgesia is reduced by administration of an opioid antagonist such as **naloxone**, indicating that it involves the release of endogenous opioid peptides. Brain imaging studies have revealed that the placebo response results from changes in neuronal activity in the prefrontal cortex and PAG, resulting in activation of descending inhibitory pathways to the spinal cord to suppress the processing of pain information.

Expectation can also modify the response when an analgesic drug is given. Subjects receiving an intravenous infusion of remifentanil, an opioid analgesic, showed more pain relief when they were told that they were receiving the drug than when the drug was administered without them knowing (see **Bingel et al., 2012**). Even more surprising was the observation that when the subjects received the same dose of remifentanil, but were told the infusion was of a substance that would exacerbate pain, they did not show any analgesic response to the opioid.

Modulation of pain transmission

- Descending pathways from the midbrain and brain stem exert a strong inhibitory effect on dorsal horn transmission. Electrical stimulation of the midbrain PAG area causes analgesia through this mechanism.
- The descending inhibition is mediated mainly by endogenous opioid peptides, 5-HT (serotonin), noradrenaline and adenosine. Opioids cause analgesia partly by activating these

descending pathways, partly by inhibiting transmission in the dorsal horn and partly by inhibiting excitation of sensory nerve terminals in the periphery.

- Repetitive C-fibre activity facilitates transmission through the dorsal horn ('wind-up') by mechanisms involving activation of NMDA and substance P receptors. This results in pain sensitisation.

Chemical Signalling in the Nociceptive Pathway

Chemosensitivity of Nociceptive Nerve Endings

In most cases, stimulation of nociceptive endings in the periphery is chemical in origin. Excessive mechanical or thermal stimuli can obviously cause acute pain, but the persistence of such pain after the stimulus has been removed, or the pain resulting from inflammatory or ischaemic changes in tissues, generally reflects an altered chemical environment of the pain afferents. The current state of knowledge is summarised in **Fig. 43.5**.

Transient receptor potential channels – thermal sensation and pain

The *TRP* channel family comprises some 27 or more structurally related ion channels that serve a wide variety of physiological functions (see **Nilius and Szallasi, 2014**). Within this family are a group of channels present on sensory neurons that are activated both by thermal stimuli across a wide range of temperatures and by chemical agents (**Table 43.1**). With respect to pain, the most

important channels are TRPV1, TRPA1 and TRPM8 (**Jardin et al., 2017**).

Capsaicin, the substance in chilli peppers that gives them their pungency, selectively excites nociceptive nerve terminals, causing intense pain if injected into the skin or applied to sensitive structures such as the cornea. [1] It produces this effect by activating TRPV1. [2] Agonists such as capsaicin open the channel, which is permeable to Na^+, Ca^{2+} and other cations, causing depolarisation and initiation of action potentials. The large influx of Ca^{2+} into peripheral nerve terminals also results in peptide release (mainly substance P and CGRP), causing intense vascular and other physiological responses. The Ca^{2+} influx may be enough to cause nerve degeneration (see **Ch. 40**). Applied topically, capsaicin reduces neuropathic and osteoarthritic pain by this mechanism, but the initial strong irritant effect is a major disadvantage.

TRPV1 responds not only to capsaicin-like agonists but also to other stimuli (see **Table 43.1**), including temperatures in excess of about 42°C (the threshold for pain) and proton concentrations in the micromolar range (pH 5.5 and below), which also cause pain. The receptor thus has unusual 'polymodal' characteristics and is believed to play a central role in nociception. TRPV1 is, like many other ionotropic receptors, modulated by phosphorylation, and several of the pain-producing substances that act through G protein–coupled receptors (e.g. bradykinin) work by sensitising TRPV1. A search for endogenous ligands for TRPV1 revealed, surprisingly, that **anandamide** (a lipid mediator previously identified as an agonist at cannabinoid receptors; see **Ch. 18**) is also a TRPV1 agonist, although less potent than capsaicin. TRPV1 knock-

out mice show reduced responsiveness to noxious heat and also fail to show thermal hyperalgesia in response to inflammation. The latter observation is interesting, because TRPV1 expression is known to be increased by inflammation and this may be a key mechanism by which hyperalgesia is produced. A number of pharmaceutical companies developed TRPV1 agonists – to act as desensitising agents – and antagonists as analgesic agents. However, TRPV1 agonists were found to induce hypothermia, associated with activation of hypothalamic thermosensitive neurons, and TRPV1 antagonists were found to induce hyperthermia, consistent with a role of TRPV1 in body temperature control as well as nociception.

TRPA1 and TRPM8 respond to cold rather than heat (see **Table 43.1**). TRPA1 is activated in some experimental settings by noxious cold temperatures, calcium, pain-producing substances and inflammatory mediators; it can therefore also be considered to be a polymodal sensor. It may be important for the analgesic and antipyretic actions of paracetamol. TRPM8 is important in cold hypersensitivity, which is often a feature of neuropathic pain.

Kinins

When applied to sensory nerve endings, *bradykinin* and *kallidin* induce intense pain. These two closely related peptides are produced under conditions of tissue injury by the proteolytic cleavage of the active kinins from a precursor protein contained in the plasma. Bradykinin acts partly by release of prostaglandins, which strongly enhance the direct action of bradykinin on the nerve terminals (**Fig. 43.6**). Bradykinin acts on B_2 receptors on nociceptive neurons. B_2

receptors are coupled to activation of a specific isoform of protein kinase C (PKCε), which phosphorylates TRPV1 and facilitates opening of the TRPV1 channel.

Bradykinin is converted in tissues by removal of a terminal arginine residue to *des-Arg9 bradykinin*, which acts selectively on B_1 receptors. B_1 receptors are normally expressed at very low levels, but their expression is strongly up-regulated in inflamed tissues. Genetically modified knock-out animals lacking either type of receptor show reduced inflammatory hyperalgesia. Specific competitive antagonists for both B_1 and B_2 receptors have been developed, such as the B_2 antagonist **icatibant,** used in the treatment of angioedema, but none have yet been developed as analgesic agents.

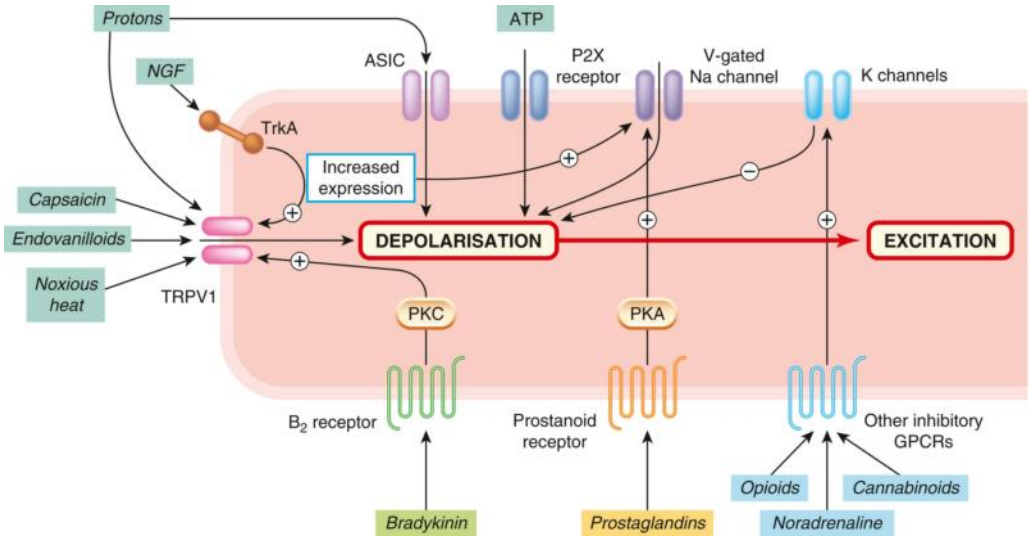

FIG. 43.5 Channels, receptors and transduction mechanisms of nociceptive afferent terminals.Only the main channels and receptors are shown. Ligand-gated channels include acid-sensitive ion channels (ASICs), ATP-sensitive channels (P2X receptors) and the capsaicin-sensitive channel (TRPV1), which is also sensitive to protons and to temperature. Various facilitatory and inhibitory G protein–coupled receptors (GPCRs) are shown, which regulate channel function through various second messenger systems. Growth factors such as nerve growth factor (NGF) act via kinase-linked receptors (TrkA) to control ion channel function and gene expression. *B_2 receptor,* Bradykinin type 2 receptor; *PKA,* protein kinase A; PKC, protein kinase C.

Table 43.1

4αPDD, 4 Alpha-phorbol 12,13-didecanoate; *Δ 9 -THC,* Δ^9-tetrahydrocannabinol; *TRP,* transient receptor protein.

Prostaglandins

Prostaglandins do not themselves cause pain, but they strongly enhance the pain-producing effect of other agents such as 5-HT or bradykinin (see **Fig. 43.6**). Prostaglandins of the E and F series are released in inflammation (see **Ch. 17**) and also during tissue ischaemia. Antagonists at EP_1 receptors decrease inflammatory hyperalgesia in animal models. Prostaglandins sensitise nerve terminals to other agents, partly by inhibiting potassium channels and partly by facilitating – through second messenger-mediated phosphorylation reactions (see **Ch. 3**) – the cation channels opened by noxious agents. It is of interest that bradykinin itself causes prostaglandin release, and thus has a powerful 'self-sensitising' effect on nociceptive afferents. Other eicosanoids, including prostacyclin, leukotrienes and the unstable hydroxyeicosatetraenoic acid (HETE) derivatives (see **Ch. 17**), may also be important. The analgesic effects of NSAIDs (see **Ch. 25**) result from inhibition of prostaglandin synthesis.

Other peripheral mediators

Pro-inflammatory cytokines such as tumour necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) (described in detail in **Ch. 25**) are released from macrophages to activate and sensitise nociceptive neurons (see **Fig. 43.3**) and contribute to persistent pain states.

Various metabolites and substances are released from damaged or ischaemic cells, or inflamed tissues, including ATP, protons (produced by lactic acid), 5-HT, histamine and K^+, many of which affect nociceptive nerve terminals.

ATP excites nociceptive nerve terminals (see **Fig. 43.5**) by acting on homomeric $P2X_3$ receptors or heteromeric $P2X_2/P2X_3$ receptors (see **Ch. 16**), ligand-gated ion channels that are selectively expressed by these neurons. Down-regulation of $P2X_3$ receptors, by antisense DNA, reduces inflammatory pain. [3] Antagonists at this receptor were developed as potential analgesic drugs. In a surprising development one such $P2X_3$ antagonist, **gefapixant** (formerly known as AF-219), has been shown to be effective in treating refractory cough (see **Ch. 28**). Other P2X receptors ($P2X_4$ and $P2X_7$) are expressed on microglia in the spinal cord; activation results in the release of cytokines and chemokines that then act on neighbouring neurons to promote hypersensitivity. ATP and other purine mediators, such as adenosine, also play a role in the dorsal horn, and other types of purinoceptor may also be targeted by analgesic drugs in the future. Adenosine exerts dual effects – acting on A_1 receptors it causes analgesia but on A_2 receptors it does the opposite.

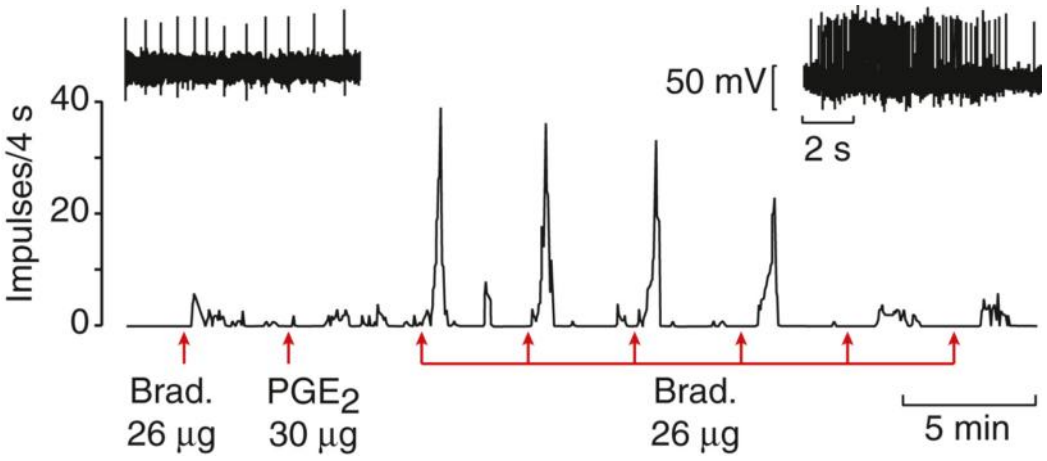

FIG. 43.6 Response of a nociceptive afferent neuron to bradykinin and prostaglandin.Recordings were made from a nociceptive afferent fibre supplying a muscle, and drugs were injected into the arterial supply. Upper records: single-fibre recordings showing discharge caused by bradykinin (Brad) alone *(left)*, and by bradykinin following injection of prostaglandin *(right)*. Lower trace: ratemeter recording of single-fibre discharge, showing long-lasting enhancement of response to bradykinin after an injection of prostaglandin E_2 (PGE_2). Prostaglandin itself did not evoke a discharge. From Mense, S., 1981. Sensitization of group IV muscle receptors to bradykinin by 5-hydroxytryptamine and prostaglandin E_2. Brain Res. 225, 95–105.

Low pH excites nociceptive afferent neurons partly by opening proton-activated cation channels (acid-sensitive ion channels, ASICs) and partly by activation of TRPV1. Given the acidic nature of

inflamed tissue, ASICS are an exciting target for novel analgesic drug development but to date efforts in this regard have been unsuccessful (**Dibas et al., 2019**).

5-HT causes excitation, but studies with antagonists suggest that it plays at most a minor role. Histamine is also active but causes itching rather than pain. Both these substances are released locally in inflammation (see Chs **16** and **17**).

In summary, nociceptive nerve endings can be activated or sensitised by a wide variety of endogenous mediators, the receptors for which are often up- or down-regulated under pathophysiological conditions.

Mechanisms of pain and nociception

- Nociception is the mechanism whereby noxious peripheral stimuli are transmitted to the central nervous system. Pain is a subjective experience not always associated with nociception.
- Polymodal nociceptors (PMNs) are the main type of peripheral sensory neuron that responds to noxious stimuli. The majority are non-myelinated C fibres whose endings respond to thermal, mechanical and chemical stimuli.
- Chemical stimuli acting on PMNs to cause pain include bradykinin, protons, ATP and vanilloids (e.g. **capsaicin**). PMNs are sensitised by prostaglandins, which explains the analgesic effect of **aspirin**-like drugs, particularly in the presence of inflammation.

- The TRPV1 receptor responds to noxious heat as well as to **capsaicin**-like agonists.
- Nociceptive fibres terminate in the superficial layers of the dorsal horn, forming synaptic connections with transmission neurons running to the thalamus.
- PMN neurons release glutamate (fast transmitter) and various peptides that act as slow transmitters. Peptides are also released peripherally and contribute to neurogenic inflammation.

Analgesic Drugs

Opioid Drugs

Opium is an extract of the juice of the poppy *Papaver somniferum* that contains **morphine**, the prototypic opioid agonist, and other related alkaloids. It has been used for social and medicinal purposes for thousands of years as an agent to produce euphoria, analgesia and sleep, and to prevent diarrhoea. It was introduced in Britain at the end of the 17th century, usually taken orally as 'tincture of laudanum', addiction to which acquired a certain social cachet during the next 200 years. The situation changed when the hypodermic syringe and needle were invented in the mid-19th century, and opioid addiction began to take on a more sinister significance (see **Ch. 50**).

The history of opioid research is reviewed by **Corbett et al. (2006)**.

Chemical Aspects

The structure of morphine (**Fig. 43.7**) was determined in 1902, and since then many semisynthetic compounds (some produced by chemical modification of morphine) and fully synthetic opioids have been developed in attempts to develop better analgesic drugs devoid of the unwanted side effects of morphine.

Morphine is a phenanthrene derivative with two planar rings and two aliphatic ring structures, which occupy a plane roughly at right angles to the rest of the molecule (see **Fig. 43.7**). The most important parts of the molecule for opioid activity are the free hydroxyl on the benzene ring that is linked by two carbon atoms to a nitrogen atom. Variants of the morphine molecule have been produced by substitution at one or both of the hydroxyls (e.g. **diamorphine** [4] 3,6-diacetylmorphine, **codeine** 3-methoxymorphine and **oxycodone**). **Pethidine** and **fentanyl** represent more dramatic changes to the basic morphine structure whereas **methadone** and the novel opioid analgesic, **oliceridine**, bear little obvious chemical relationship to morphine. Substitution of a bulky substituent on the nitrogen atom of morphine introduces antagonist activity to the molecule (e.g. **naloxone**).

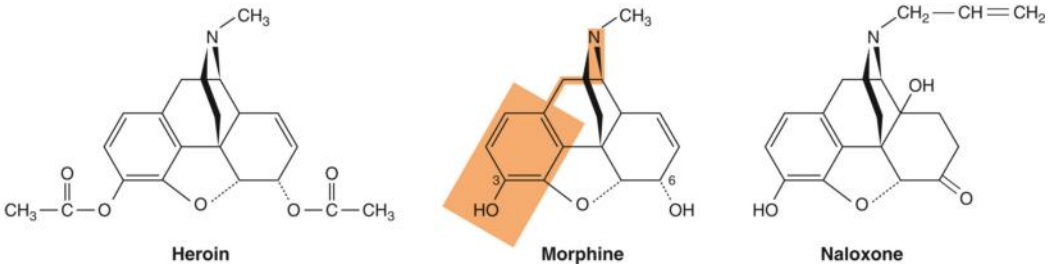

FIG. 43.7 Chemical structures of morphine and related drugs.The *shaded area* indicates the part of the morphine molecule that is structurally similar to tyrosine, the N-terminal amino acid in the endorphins. Carbon atoms 3 and 6 in the *morphine* structure are indicated. Diamorphine (heroin) is 3,6-diacetylmorphine, and morphine is metabolised by addition of a glucuronide moiety at either position 3 or position 6.

Opioid analgesics

- Terminology:
  - *opioid*: any substance, whether endogenous or synthetic, that produces **morphine**-like effects that are blocked by antagonists such as **naloxone**;
  - *opiate*: compounds such as **morphine** and **codeine** that are found in the opium poppy;
  - *narcotic analgesic*: old term for opioids; *narcotic* refers to their ability to induce sleep. Unfortunately, the term narcotic has subsequently been hijacked and used

inappropriately by some to refer generically to drugs of abuse (see **Ch. 50**).

- Important structurally related agonists include **diamorphine**, **oxycodone** and **codeine.**
- Synthetic analogues include **pethidine**, **fentanyl**, **methadone**, **buprenorphine.**
- Opioid analgesics may be given orally, by injection or intrathecally to produce analgesia.

Opioid Receptors

The proposal that opioids produce analgesia and their other effects by interacting with specific receptors first arose in the 1950s, based on the strict structural and stereochemical requirements essential for activity. It was, however, only with the development of molecules with antagonist activity (e.g. naloxone) that the notion of a specific receptor became accepted. Martin and co-workers then provided pharmacological evidence for multiple types of opioid receptors. They proposed three different types of receptor, called μ, κ and σ. [5] Subsequently, in the early 1970s, radioligand binding (see **Ch. 2**) was used to demonstrate the presence of μ receptors in the brain.

Why are there specific receptors in the brain for morphine, a drug that is present in the opium poppy? Hughes and Kosterlitz argued that there must be an endogenous substance or substances in the brain that activated these receptors. [6] In 1975 they reported the isolation and characterisation of the first endogenous opioid peptide ligands, the *enkephalins*. We now know that the enkephalins are

two members of a larger family of endogenous opioid peptides known collectively as the *endorphins*, all of which possess a tyrosine residue at their N-terminus. The chemical structure of tyrosine includes an amine group separated from a phenol ring by two carbon atoms. This same structure (phenol-2 carbon atom chain-amine) is also contained within the morphine structure (see **Fig. 43.7**). It is probably just chance (good or bad luck depending on one's viewpoint) that the opium poppy synthesises a semi-rigid alkaloid molecule, morphine, part of which structurally resembles the tyrosine residue in the endogenous opioid peptides.

Following on from the discovery of the enkephalins, in vitro pharmacological studies revealed another receptor, δ, and the three recognised receptor types (μ, δ and κ) were cloned. Later, another opioid receptor that has a high a degree of amino acid sequence homology (>60%) towards the μ, δ and κ opioid receptors was identified by cloning techniques, although the antagonist, naloxone, did not bind to this new receptor. The terminology used for opioid receptors has over the years been through several revisions; in this chapter we shall use the classical terminology. The four opioid receptors, μ, δ, κ and NOP (originally referred to as opioid receptor like receptor 1 or ORL_1) are all G protein–coupled receptors (see **Ch. 3**). [7] The main behavioural effects resulting from their activation are summarised in **Table 43.2**.

Table 43.2

[a] NOP receptor agonists were originally thought to produce nociception or hyperalgesia but it was later shown that they reverse the supraspinal analgesic effects of endogenous and exogenous μ receptor agonists.

The development of genetically modified mouse strains lacking each of the opioid receptor types has revealed that the major pharmacological effects of morphine, including analgesia, are mediated by the μ receptor.

All four opioid receptors appear to form homomeric as well as heteromeric receptor complexes (see **Ch. 3**). Opioid receptors are, in fact, quite promiscuous and can form heteromers with non-opioid receptors. Heteromerisation between opioid receptors has been shown to result in pharmacological characteristics distinct from those observed with the monomeric receptors and may explain some of the subtypes of each receptor that have been proposed (see **Fujita et al., 2014**). Another level of complexity may reflect 'bias' (see **Ch. 3**), whereby different ligands acting on the same opioid receptor can elicit different cellular responses and differential receptor trafficking (see **Kelly, 2013**). [8]

Opioid receptors

- μ Receptors are responsible for most of the analgesic effects of opioids, and for some major unwanted effects (e.g. respiratory depression, constipation, euphoria, sedation and dependence).

- δ Receptor activation results in analgesia but also can be proconvulsant.
- κ Receptors contribute to analgesia at the spinal level and may elicit sedation, dysphoria and hallucinations. Some analgesics are mixed κ agonists/μ antagonists.
- NOP receptors are also members of the opioid-receptor family. Activation results in an antiopioid effect (supraspinal), analgesia (spinal), immobility and impairment of learning.
- σ Receptors are not true opioid receptors but are the site of action of certain psychotomimetic drugs, with which some opioids also interact.
- All opioid receptors are linked through G_i/G_o proteins and thus open potassium channels (causing hyperpolarisation) and inhibit the opening of calcium channels (inhibiting transmitter release). In addition, they inhibit adenylyl cyclase and activate the MAP kinase (ERK) pathway.
- Functional heteromers, formed by combination of different types of opioid receptor or with other types of G protein–coupled receptor, may occur and give rise to further pharmacological diversity.

Mechanism of Action of Opioids

The opioids have probably been studied more intensively than any other group of drugs in the effort to understand their powerful effects in molecular, cellular and physiological terms, and to use this understanding to develop new drugs as analgesics with

significant advantages over morphine. Even so, morphine – described by Osler as 'God's own medicine' – remains the standard against which any new analgesic is assessed.

Cellular actions

All four types of opioid receptor belong to the family of G_i/G_o protein–coupled receptors. Opioids thus exert powerful effects on ion channels on neuronal membranes through a direct G protein coupling to the channel. Opioids promote the opening of potassium channels (see **Ch. 4**) and inhibit the opening of voltage-gated calcium channels. These membrane effects decrease neuronal excitability (because the increased K^+ conductance causes hyperpolarisation of the membrane making the cell less likely to fire action potentials) and reduce transmitter release (due to inhibition of Ca^{2+} entry). The overall effect is therefore inhibitory at the cellular level. Nonetheless, opioids do increase activity in some neuronal pathways (**Fig. 43.4**). They cause excitation of projection neurons by suppressing the activity of inhibitory interneurons that tonically inhibit the projection neurons, a process referred to as 'disinhibition' (see **Ch. 37**).

At the biochemical level, all four receptor types inhibit adenylyl cyclase and cause MAP kinase (ERK) activation (see **Ch. 3**). These cellular responses are likely to be important in mediating the long-term adaptive changes that occur in response to prolonged receptor activation and which, for μ receptor agonists, may underlie the phenomenon of physical dependence (see **Ch. 50**).

At the cellular level, therefore, all four types of opioid receptor mediate very similar effects. It is their heterogeneous anatomical

distributions across the central nervous system (CNS) that give rise to the different behavioural responses seen with selective agonists for each type of receptor.

Sites of action of opioids to produce analgesia

Opioid receptors (μ, δ and κ) are widely distributed in the brain and spinal cord. Opioids are effective as analgesics when injected in minute doses into a number of specific brain nuclei (such as the insular cortex, amygdala, hypothalamus, PAG region and RVM) as well as into the dorsal horn of the spinal cord (see **Fig. 43.4**). Supraspinal analgesia results primarily from μ receptor activation but there is some evidence for the involvement of supraspinal δ receptors as well. Supraspinal opioid analgesia involves disinhibition resulting in endogenous opioid peptide release both at supraspinal and spinal sites and of serotonin (5-HT) from descending inhibitory fibres in the dorsal horn of the spinal cord. Surgical interruption of the descending pathway from the RVM to the spinal cord reduces analgesia induced by opioids that have been given systemically or microinjected into supraspinal sites, implying that a combination of effects at supraspinal and spinal sites contributes to the analgesic response.

At the spinal level, opioids inhibit transmission of nociceptive impulses through the dorsal horn and suppress nociceptive spinal reflexes, even in patients with spinal cord transection. They can act presynaptically to inhibit release of various neurotransmitters from primary afferent terminals in the dorsal horn as well as acting postsynaptically to reduce the excitability of dorsal horn neurons.

There is also evidence (see **Sawynok, 2003**) that opioids inhibit the discharge of nociceptive afferent terminals in the periphery, particularly under conditions of inflammation, in which the expression of opioid receptors by sensory neurons is increased. Injection of morphine into the knee joint following surgery to the joint provides effective analgesia, undermining the age-old belief that opioid analgesia is exclusively a central phenomenon.

Pharmacological Actions

Morphine is typical of many opioid analgesics and will be taken as the reference compound. Its effects are mediated predominately through μ receptors.

The most important effects of morphine are on the CNS and the gastrointestinal tract, although numerous effects of lesser significance on many other systems have been described.

Effects on the central nervous system

Analgesia

Morphine and other opioids are highly effective in most kinds of acute pain as well as in 'end of life' pain resulting from cancer. They are much less effective in treating neuropathic and other chronic pain states (see later).

Hyperalgesia

In both animal studies and in patients receiving opioids for pain relief, prolonged exposure to opioids may paradoxically induce a state of hyperalgesia in which pain sensitisation or allodynia occurs (see **Lee et al., 2011**). This can appear as a reduced analgesic

response to a given dose of opioid but should not be confused with tolerance, which is a reduced responsiveness due in large part to μ receptor desensitisation and occurs with other opioid-induced effects such as euphoria and to a lesser extent respiratory depression. Hyperalgesia appears to have peripheral, spinal and supraspinal components. At the neuronal level, an array of mediators and mechanisms have been proposed to contribute to this phenomenon (**Roeckel et al., 2016**). These include NO, PKC and NMDA receptor activation. In addition, $P2X_4$ receptor expression in microglia is up-regulated resulting in BDNF release, TrkB signalling and down-regulation of the K^+/Cl^- co-transporter KCC2. In mice in which BDNF has been deleted from microglia, hyperalgesia to morphine does not occur, whereas antinociception and tolerance are unaffected.

Opioid-induced hyperalgesia declines on cessation of opioid administration. Clinically, it can be reduced by opioid rotation – switching from one to another opioid drug (e.g. from morphine to fentanyl or methadone, the latter having weak NMDA-receptor antagonist action which may be helpful). Another approach is to co-administer an adjuvant such as ketamine (an NMDA antagonist), propofol (an intravenous anaesthetic), dexmedetomidine (an α_2-adrenoceptor agonist) or a cyclo-oxygenase (COX)-2 inhibitor.

Euphoria

Morphine causes a powerful sense of contentment and well-being (see also **Ch. 50**). This may contribute to its analgesic effect. If morphine or diamorphine (heroin) is given intravenously, the result is a sudden ‘rush’ likened to an ‘abdominal orgasm’. The euphoria

produced by morphine depends considerably on the circumstances. In patients who have become accustomed to pain, morphine causes analgesia with little or no euphoria. Some patients report restlessness rather than euphoria under these circumstances.

Euphoria is mediated through μ receptors, whereas κ receptor activation produces dysphoria and hallucinations (see **Table 43.2**). Thus, different opioid drugs vary greatly in the amount of euphoria that they produce. It does not occur with codeine to any marked extent. There is evidence that antagonists at the κ receptor have antidepressant properties which may indicate that release of endogenous κ agonists may occur in depression.

Respiratory depression

Respiratory depression occurs with a normal analgesic dose of morphine or related compounds, although in patients in severe pain the degree of respiratory depression produced may be less than anticipated. For drug users who inject illicit opioids (see **Ch. 50**), respiratory depression leading to overdose death is a constant danger.

Respiratory depression results from μ receptor activation in several regions of the brainstem including the pre-Bötzinger complex, which controls inspiratory drive, and the Kölliker-fuse and lateral parabrachial nuclei, which control upper airway coordination and termination of inspiration. The overall effect produced is a reduction in respiratory rate. The depressant effect is also associated with a decrease in the sensitivity of the respiratory centres to arterial $P\,CO_2$. Changes in $P\,CO_2$ are detected by chemosensitive neurons in a number of brain stem and medullary

nuclei. Increased arterial CO_2 (hypercapnia) thus normally results in a compensatory increase in minute ventilation rate (V_E).

Depression of cough reflex

Cough suppression (antitussive effect; see also **Ch. 28**), surprisingly, does not correlate closely with the analgesic and respiratory depressant actions of opioids, and its mechanism at the receptor level is unclear. In general, increasing substitution on the phenolic hydroxyl group of morphine increases antitussive relative to analgesic activity. **Codeine** and **pholcodine** suppress cough in subanalgesic doses but they cause constipation as an unwanted effect.

Dextromethorphan, the dextro-isomer of the opioid analgesic **levorphanol**, suppresses cough but has very low affinity for opioid receptors and its cough suppressing action, unlike that of opioids, is not antagonised by naloxone. It is an uncompetitive NMDA receptor antagonist – this might explain why at high doses it evokes CNS effects similar to ketamine and may be used for its psychoactive effects (see **Ch. 49**) – and has putative actions at σ receptors. It is believed to work at various sites in the brain stem and medulla to suppress cough. In addition to its antitussive action, dextromethorphan is neuroprotective (see **Ch. 40**) and has an analgesic action in neuropathic pain.

Nausea and vomiting

Nausea and vomiting occur in up to 40% of patients to whom morphine is given, and do not seem to be separable from the analgesic effect among a range of opioid analgesics. The site of action is the *area postrema* (chemoreceptor trigger zone), a region

of the medulla where chemical stimuli of many kinds may initiate vomiting (see **Ch. 30**). [9] Nausea and vomiting following morphine injection are usually transient and disappear with repeated administration, although in some individuals they persist and can limit patient compliance.

Pupillary constriction

Pupillary constriction is caused by μ and κ receptor–mediated stimulation of the oculomotor nucleus. Pinpoint pupils are an important diagnostic feature in opioid poisoning [10] because most other causes of coma and respiratory depression produce pupillary dilatation. Tolerance does not develop to the pupillary constriction induced by opioids and therefore can be observed in opioid-dependent drug users who may have been taking opioids for a considerable time.

Effects on the gastrointestinal tract

Opioids increase tone and reduce motility in many parts of the gastrointestinal system, resulting in constipation, which may be severe and very troublesome to the patient. [11] The resulting delay in gastric emptying can considerably retard the absorption of other drugs. Pressure in the biliary tract increases because of contraction of the gall bladder and constriction of the biliary sphincter. Opioids should be avoided in patients suffering from biliary colic due to gallstones, in whom pain may be increased rather than relieved. The rise in intrabiliary pressure can cause a transient increase in the concentration of amylase and lipase in the plasma.

The action of morphine on visceral smooth muscle is probably mediated mainly through the intramural nerve plexuses, because

the increase in tone is reduced or abolished by atropine. It is also partly mediated by a central action, because intracerebroventricular injection of morphine inhibits propulsive gastrointestinal movements. **Methylnaltrexone bromide** (see also **Ch. 9**), **alvimopan**, **naloxegol** and **naldemedine** are opioid antagonists that do not cross the blood–brain barrier. They have been developed to reduce unwanted peripheral side effects of opioids, such as constipation, without significantly reducing analgesia or precipitating withdrawal in dependent individuals.

Other actions of opioids

Morphine releases histamine from mast cells by an action unrelated to opioid receptors. Pethidine and fentanyl do not produce this effect. The release of histamine can cause local effects, such as urticaria and itching at the site of the injection, or systemic effects, namely bronchoconstriction and hypotension.

Hypotension and bradycardia occur with large doses of most opioids, due to an action on the medulla. With morphine and similar drugs, histamine release may contribute to the hypotension.

Effects on smooth muscle other than that of the gastrointestinal tract and bronchi are slight, although spasms of the ureters, bladder and uterus sometimes occur. Opioids also exert complex immunosuppressant effects, which may be important as a link between the nervous system and immune function. The pharmacological significance of this is not yet clear, but there is evidence in humans that the immune system is depressed by long-term opioid use, and that in drug users suffering from AIDS the use of opioids may exacerbate the immune deficiency.

Actions of morphine

- The main pharmacological effects are:
  - analgesia
  - euphoria and sedation
  - respiratory depression
  - suppression of cough
  - nausea and vomiting
  - pupillary constriction
  - reduced gastrointestinal motility, causing constipation
  - histamine release, causing itch, bronchoconstriction and hypotension
- The most troublesome unwanted effects are nausea and vomiting, constipation and respiratory depression.
- Acute overdosage with **morphine** produces coma and respiratory depression.
- **Diamorphine** (heroin) is inactive at opioid receptors but is rapidly cleaved in the brain to 6-acetylmorphine and **morphine.**
- **Codeine** is also converted to **morphine** but more slowly by liver metabolism.

Tolerance, Physical Dependence and Addiction

Tolerance to many of the actions of opioids (i.e. an increase in the dose needed to produce a given pharmacological effect) develops within a few days during repeated administration. There is some

controversy over whether significant tolerance develops to the analgesic effects of morphine, especially in palliative care patients with severe cancer pain (see **McQuay, 1999**; **Ballantyne and Mao, 2003**). Drug rotation (changing from one opioid to another) is frequently used clinically to overcome loss of effectiveness.

In animal experiments, tolerance can be detected even with a single dose of morphine. Tolerance extends to most of the pharmacological effects of morphine, including analgesia, emesis, euphoria and respiratory depression, but affects the constipating and pupil-constricting actions much less. As tolerance is likely to depend upon the level of receptor occupancy, the degree of tolerance observed may reflect the response being assessed, the intrinsic efficacy of the drug and the dose being administered (see **Hayhurst and Durieux, 2016**). The cellular mechanisms responsible for tolerance are discussed in **Chapter 2**. Tolerance results in part from desensitisation of the μ receptors (i.e. at the level of the drug target) as well as from long-term adaptive changes at the cellular, synaptic and network levels (see **Williams et al., 2013**). Cross-tolerance occurs between drugs acting at the same receptor, but not between opioids that act on different receptors.

Physical dependence refers to a state in which cessation of drug treatment causes adverse physiological effects, i.e. a withdrawal syndrome (see also **Ch. 50**). Although it can develop along with tolerance the two adaptive phenomena result from different adaptive cellular mechanisms (see **Williams et al., 2013**). In experimental animals (e.g. rats), abrupt withdrawal of morphine after repeated administration for a few days, or the administration of an antagonist such as naloxone, causes an increase in diarrhoea,

loss of weight and a variety of abnormal behaviour patterns, such as body shakes, writhing, jumping and signs of aggression. These reactions decrease after a few days, but abnormal aggression persists for many weeks. The signs of physical dependence are much less intense if the opioid is withdrawn gradually. Patients on an opioid for pain relief often experience withdrawal symptoms such as restlessness, runny nose, diarrhoea, shivering and piloerection when drug administration is stopped. [12]

Addiction refers to the compulsive use of opioid drugs. Misuse of prescription and illicit opioids can result in the development of addiction. The processes involved in opioid addiction are described in **Chapter 50**.

Tolerance and physical dependence

– Tolerance and physical dependence develop on repeated administration of μ receptor agonists.
– The mechanism of tolerance involves receptor desensitisation. It is not pharmacokinetic in origin.
– Physical dependence is evidenced by the appearance of withdrawal symptoms on cessation of drug administration and lasts for a few days. The withdrawal syndrome can also be precipitated by μ receptor antagonists such as naloxone.
– Certain opioid analgesics, such as **codeine**, **buprenorphine** and **tramadol**, are much less likely to cause physical dependence.

Pharmacokinetic Aspects

Table 43.3 summarises the pharmacokinetic properties of the main opioid analgesics. The absorption of morphine congeners by mouth is variable. Morphine itself is slowly and erratically absorbed, and is commonly given by intravenous injection to treat acute severe pain; oral morphine is, however, often used in treating prolonged pain, and slow-release preparations are available to increase its duration of action. Oxycodone is also available as a slow-release oral preparation. Codeine is well absorbed and normally given by mouth. Most morphine-like drugs undergo considerable first-pass metabolism, and are therefore markedly less potent when taken orally than when injected.

Opioids that have no free hydroxyl in the 3 position (i.e. diamorphine, codeine) are inactive at opioid receptors. The substitution at the 3 position must be cleaved and replaced with a hydroxyl for the molecule to become pharmacologically active. With diamorphine the conversion occurs rapidly in the plasma and brain but with codeine the effect is slower and occurs by metabolism in the liver.

The plasma half-life of most morphine analogues is 3–6 h. Hepatic metabolism is the main mode of inactivation, usually by conjugation with glucuronide. This occurs at the 3- and 6-OH groups (see **Fig. 43.7**), and these glucuronides constitute a considerable fraction of the drug in the bloodstream. Morphine-6-glucuronide is more active as an analgesic than morphine itself, and contributes to the pharmacological effect. Morphine-3-glucuronide has been claimed to antagonise the analgesic effect of morphine, but the significance of this experimental finding is uncertain, as this

metabolite has little or no affinity for opioid receptors. Morphine glucuronides are excreted in the urine, so the dose needs to be reduced in cases of renal failure. Glucuronides also reach the gut via biliary excretion, where they are hydrolysed, most of the morphine being reabsorbed (enterohepatic circulation). Because of low conjugating capacity in neonates, morphine-like drugs have a much longer duration of action; because even a small degree of respiratory depression can be hazardous, morphine congeners should not be used in the neonatal period, nor used as analgesics during childbirth. Pethidine is a safer alternative for this purpose.

Morphine produces very effective analgesia when administered intrathecally, and is used in this way by anaesthetists, the advantage being that the sedative and respiratory depressant effects are reduced, although not completely avoided. **Remifentanil** is rapidly hydrolysed and eliminated with a half-life of 3–4 min. The advantage of this is that when given by intravenous infusion during general anaesthesia, the level of the drug can be manipulated rapidly when required (see **Ch. 11** for a description of how, for intravenous infusion, both the rate of rise and the rate of decay of the plasma concentration are determined by the half-time of elimination).

Table 43.3

[a] Injections may be given intravenously, intramuscularly or subcutaneously for most drugs.

In postoperative and cancer pain, opioids are often given ‘on demand’ (patient-controlled analgesia). The patients are provided with an infusion pump that they control, the maximum possible

rate of administration being limited to avoid acute toxicity. Patients show little tendency to use excessively large doses and so do not become dependent; instead, the dose is adjusted to achieve analgesia without excessive sedation, and is reduced as the pain subsides. Being in control of their own analgesia, the patients' anxiety and distress are reduced, and analgesic consumption actually tends to decrease. In cancer pain, patients often experience sudden, sharp increases in the level of pain they are experiencing. This is referred to as breakthrough pain. To combat this, there is a therapeutic need to be able to increase rapidly the amount of opioid being administered. This has led to the development of touch-sensitive transdermal patches containing potent opioids such as fentanyl that rapidly release drug into the bloodstream. Fentanyl lozenges and lollipops, producing rapid absorption through the buccal mucosa, are also used.

The opioid antagonist, naloxone, has a shorter biological half-life than most opioid agonists. In the treatment of opioid overdose, it must be given repeatedly to avoid the respiratory depressant effect of the agonist reoccurring once the naloxone has been eliminated. Naltrexone has a longer biological half-life.

Unwanted Effects

The main unwanted effects of morphine and related drugs are listed in **Table 43.3**.

Acute overdosage with morphine results in coma and respiratory depression, with characteristically constricted pupils. It is treated by giving naloxone. This also serves as a diagnostic test, for failure to respond to naloxone suggests a cause other than opioid poisoning

for the comatose state. There is a danger of precipitating a severe withdrawal response with naloxone, because opioid poisoning occurs mainly in illicit opioid users (see **Ch. 50**).

Individual variability

Individuals vary by as much as 10-fold in their sensitivity to opioid analgesics. This can be due to altered metabolism or altered sensitivity of the receptors (for extensive review, see **Rollason et al., 2008**). For morphine, reduced responsiveness may result from mutations in a number of genes including that for the drug transporter, P-glycoprotein (see Chs **9** and **12**), for glucuronyltransferase that metabolises morphine and for the μ receptor itself. Mutations of various cytochrome P450 (CYP) enzymes influence the metabolism of codeine, oxycodone, methadone, tramadol and dextromethorphan. Genotyping could in principle be used to identify opioid-resistant individuals, but first the contribution of genotype to clinical outcome must be confirmed in the population at large.

Other Opioid Analgesics

Diamorphine (heroin) is 3,6-diacetylmorphine; it can be considered as a prodrug because its high analgesic potency is attributable to rapid conversion first to 6-monoacetylmorphine (6-MAM) and then to morphine. Its effects are indistinguishable from those of morphine following oral administration. It is said to be less emetic than morphine, but the evidence for this is limited. It is still available in Britain for use as an analgesic, although it is banned in many countries. Its only advantage over morphine is its greater solubility, which allows smaller volumes to be given orally,

subcutaneously or intrathecally. It exerts the same respiratory depressant effect as morphine and, if given intravenously, is more likely to cause dependence.

Codeine (3-methoxymorphine) is also a prodrug but, unlike heroin, undergoes demethylation by CYP2D6 in the liver to produce morphine. It has 20% or less of the analgesic potency of morphine, as a large proportion of the absorbed drug is not converted to morphine but instead undergoes hepatic glucuronidation and is then excreted. Its analgesic effect does not increase appreciably at higher dose levels, presumably because of limited conversion to morphine, and so it is sometimes referred to as a weak opioid. It is more reliably absorbed by mouth than morphine and is therefore used mainly as an oral analgesic for mild types of pain (headache, acute backache, etc.). About 10% of the population is resistant to the analgesic effect of codeine, because they lack the demethylating enzyme that converts it to morphine. Unlike morphine, it causes little or no euphoria and is rarely addictive. It is often combined with **paracetamol** in proprietary analgesic preparations (see later section on combined use of opioids and NSAIDs). In relation to its analgesic effect, codeine produces the same degree of respiratory depression as morphine, but the limited response, even at high doses, means that it is seldom a problem in practice. It does, however, cause constipation. Codeine has marked antitussive activity and is often used in cough mixtures (see **Ch. 28**). **Dihydrocodeine** is pharmacologically very similar, having no substantial advantages or disadvantages over codeine.

Oxycodone is used in the treatment of acute pain, for example after an operation or a serious injury, and cancer pain. The

suggestion that it acts on a subtype of κ opioid receptor is not generally accepted. Claims that it has less euphoric effect and less abuse potential are unfounded. It is available as a slow-release oral preparation, as is **hydrocodone** which is similar in action. Overprescribing of these drugs led to them becoming a major drug problem especially in North America (see **Ch. 50**).

Tramadol and **tapentadol** are widely used as analgesics for postoperative pain. Tramadol comprises two structural enantiomers – (+)-tramadol inhibits 5-HT reuptake and (–)-tramadol inhibits noradrenaline (NA) reuptake – and the major metabolite of (+)-tramadol, O-desmethyltramadol, activates the μ receptor. Tapentadol inhibits NA reuptake and activates the μ receptor. They are effective analgesics and appear to have a better side-effect profile than most opioids, although psychiatric reactions have been reported. They are given by mouth or by intramuscular or intravenous injection for acute and chronic pain, including musculoskeletal pain and the pain associated with diabetic neuropathy.

Fentanyl, **alfentanil**, **sufentanil** and **remifentanil** are highly potent phenylpiperidine derivatives, with actions similar to those of morphine but with a more rapid onset and shorter duration of action, particularly remifentanil. They are used extensively in anaesthesia, and they may be given intrathecally. Fentanyl, alfentanil and sufentanil are also used in patient-controlled infusion systems or administered via patches applied to the skin. The rapid onset is advantageous in breakthrough pain. Fentanyl has minimal cardiovascular effects and does not release histamine. **Carfentanil** is a highly potent fentanyl analogue used to sedate large animals for

veterinary procedures. In recent years, illicitly produced fentanyl, carfentanil and a range of other analogues have become a major drug problem, especially in North America (see **Ch. 50**). Unlike other opioids, they are easily synthesised, without the need to harvest poppies.

Methadone is orally active and pharmacologically similar to morphine, the main difference being that its duration of action is considerably longer (plasma half-life >24 hours). The increased duration seems to occur because the drug is bound in the extravascular compartment and slowly released. On withdrawal, the physical abstinence syndrome is less acute than with morphine. Methadone is widely used as a heroin substitution treatment (see **Ch. 50**). [13] Methadone also has actions at other sites in the CNS, including block of potassium channels, NMDA receptors and 5-HT receptors, that may explain its CNS side-effect profile. There is interindividual variation in the response to methadone, probably due to genetic variability between individuals in its metabolism.

Pethidine (meperidine) is very similar to morphine in its pharmacological effects, except that it tends to cause restlessness rather than sedation. It was originally investigated as a new antimuscarinic agent but was found to have opioid analgesic activity, its residual antimuscarinic action being responsible for its side effects of dry mouth and blurring of vision. It produces a very similar euphoric effect. Its duration of action is the same or slightly shorter than that of morphine, but the route of metabolic degradation is different. Pethidine is partly *N*-demethylated in the liver to norpethidine, which has hallucinogenic and convulsant effects. These become significant with large oral doses of pethidine,

producing an overdose syndrome rather different from that of morphine. Pethidine is preferred to morphine for analgesia during labour, because it does not reduce the force of uterine contraction. Pethidine is only slowly eliminated in the neonate, and naloxone may be needed to reverse respiratory depression in the newborn (morphine is even more problematic in this regard, because the conjugation reactions on which the excretion of morphine, but not of pethidine, depends are deficient in the newborn). Severe reactions, consisting of excitement, hyperthermia and convulsions, have been reported when pethidine is given to patients receiving monoamine oxidase inhibitors. This seems to be due to inhibition of an alternative metabolic pathway, leading to increased norpethidine formation, but the details are unclear.

Buprenorphine is a partial agonist on μ receptors that produces strong analgesia but there is a ceiling to its respiratory depressant effect. Due to extensive first-pass elimination it is administered sublingually or by injection. Because of its antagonist actions, it can produce mild withdrawal symptoms in patients dependent on other opioids. It dissociates slowly from the receptors and so has a long duration of action. Like methadone, it is also used in substitution treatment for people dependent on opioids (see **Ch. 50**).

Meptazinol is an opioid of unusual chemical structure. It can be given orally or by injection and has a duration of action shorter than that of morphine. It is a μ receptor partial agonist and seems to be relatively free of morphine-like side effects, causing neither euphoria nor dysphoria, nor severe respiratory depression. It does, however, produce nausea, sedation and dizziness, and has atropine-like actions. Because of its short duration of action and lack of

respiratory depression, it may have advantages for obstetric analgesia.

Etorphine is a morphine analogue with a potency more than 1000 times that of morphine, but otherwise very similar in its actions. Its high potency confers no particular human clinical advantage, but it is used in veterinary practice, especially in large animals. It can be used in conjunction with sedative agents (neuroleptanalgesia) to immobilise wild animals. [14]

Nalbuphine is an analgesic that has activity at κ, μ and, to a lesser extent, δ receptors. It acts as an agonist at κ receptors and as a partial agonist at μ receptors. **Pentazocine**, rarely used clinically nowadays, also combines a degree of κ agonist and μ antagonist (or weak partial agonist) activity. These agents are thought to produce less euphoria than μ receptor agonists. **Cebranopadol**, currently awaiting regulatory approval, is an agonist at all four opioid receptors.

Loperamide is a μ receptor agonist that is effectively extruded from the brain by P-glycoprotein and therefore lacks analgesic activity. It inhibits peristalsis, and is used to control diarrhoea (see **Ch. 30**).

Opioid Antagonists

Naloxone was the first pure opioid antagonist, with affinity for all three classic opioid receptors (μ > κ ≥ δ). It blocks the actions of endogenous opioid peptides as well as those of morphine-like drugs and has been extensively used as an experimental tool to determine the physiological role of these peptides, particularly in pain transmission.

Given on its own, naloxone produces very little effect in normal subjects but produces a rapid reversal of the effects of morphine and other opioids. It has little effect on pain threshold under normal conditions but causes hyperalgesia under conditions of stress or inflammation, when endogenous opioids are produced. This occurs, for example, in patients undergoing dental surgery, or in animals subjected to physical stress. Naloxone also inhibits acupuncture analgesia, which is known to be associated with the release of endogenous opioid peptides, but does not reduce meditation-induced analgesia. Analgesia produced by PAG stimulation is also prevented by naloxone.

The main clinical uses of naloxone are to treat respiratory depression caused by opioid overdosage (see **Ch. 50**), and occasionally to reverse the effect of opioid analgesics, used during labour, on the respiration of the newborn baby. It can be administered nasally, intramuscularly or intravenously, and its effects are rapid in onset. It is rapidly metabolised by the liver, and its effect lasts only 2–4 h, which is considerably shorter than that of most morphine-like drugs and therefore it may have to be given repeatedly.

Naloxone has no important unwanted effects of its own but precipitates withdrawal symptoms in opioid users. It can be used to detect opioid dependence.

Naltrexone is very similar to naloxone but with the advantage of a much longer duration of action (half-life about 10 h). It may be of value in opioid users who have been ‘detoxified’, because it nullifies the effect of a subsequent dose of an opioid should the patient’s resolve fail. For this purpose, it is available in a slow-release

subcutaneous implant formulation. It is also effective in reducing alcohol consumption in heavy drinkers (see **Ch. 50**), the rationale being that part of the high from alcohol comes from the release of endogenous opioid peptides. **Nalmefene**, another non-selective opioid antagonist, is also used to treat patients with alcohol use disorder. Naltrexone may also have beneficial effects in septic shock. It is effective in treating chronic itching (pruritus), as occurs in chronic liver disease. Again, this may indicate the involvement of endogenous opioid peptides in the pathophysiology of such itch conditions.

Methylnaltrexone bromide, **alvimopan**, **naloxegol** and **naldemedine** are μ receptor antagonists that do not cross the blood–brain barrier. They can be used in combination with opioid agonists to block unwanted effects, most notably reduced gastrointestinal motility, nausea and vomiting.

Opioid antagonists

- Pure antagonists include **naloxone** (short acting) and **naltrexone** (longer acting). They block μ, δ and κ receptors. Selective antagonists are available as experimental tools.
- **Alvimopan**, **naloxegol** and **naldemedine** are μ receptor antagonists that do not cross the blood–brain barrier. They block opioid-induced constipation, nausea and vomiting.
- **Naloxone** does not affect pain threshold normally but blocks stress-induced analgesia and can exacerbate clinical pain.
- **Naloxone** rapidly reverses opioid-induced analgesia and respiratory depression, and is used mainly to treat opioid

overdose or to improve breathing in newborn babies affected by opioids given to the mother.

- **Naloxone** precipitates withdrawal symptoms in opioid-dependent patients or animals. **Buprenorphine** (a partial agonist) can also precipitate withdrawal due to its antagonist action against higher efficacy opioid agonists.

Paracetamol

NSAIDs (covered in detail in **Ch. 25**) are widely used to treat painful inflammatory conditions and to reduce fever. **Paracetamol** (known as **acetaminophen** in the United States) deserves special mention here. It was first synthesised more than a century ago, and since the 1950s has (alongside aspirin and ibuprofen) been the most widely used over-the-counter remedy for minor aches and pains. Paracetamol differs from other NSAIDs in producing analgesic and antipyretic effects while lacking anti-inflammatory effects. It also lacks the tendency of other NSAIDs to cause gastric ulceration and bleeding. The reason for the difference between paracetamol and other NSAIDs is unclear. Biochemical tests showed it to be only a weak COX inhibitor, with some selectivity for brain COX, possibly because of the unique reducing environment in neurons (see **Ch. 25**). Interestingly, the antinociceptive and antipyretic effects of paracetamol are absent in mice lacking the TRPA1 receptor. These effects appear to be mediated by a metabolite (*N*-acetyl-*p*-benzoquinoneimine), not by paracetamol itself. This activates TRPA1 and thus reduces voltage-gated calcium and sodium currents in primary sensory neurons.

Paracetamol is well absorbed following oral administration, and its plasma half-life is about 3 h. It is metabolised by hydroxylation, conjugated mainly as glucuronide, and excreted in the urine. In therapeutic doses, it has few adverse effects. However, in overdose, paracetamol causes severe liver damage, which is commonly fatal (see Chs **25** and **58**), and the drug is often used in attempted suicide.

Use of Opioids and Nsaids in Combination

The rationale behind co-administration of two drugs that produce analgesia by different mechanisms is that, if the effects are additive, less of each drug can therefore be given but the same degree of analgesia produced. This has the effect of reducing the intensity of the unwanted side effects produced by each drug. In the case of opioids (e.g. codeine) in combination with paracetamol or aspirin, the combination appears to produce synergy rather than simple additivity. The combination of dextropropoxyphene and paracetamol was withdrawn in the United Kingdom due to concerns about overdosing.

Chronic Pain

The International Association for the Study of Pain (IASP) has classified chronic pain (pain that persists for more than three months) into two types (**Treede et al., 2019**):

- chronic secondary pain in which the underlying or initiating cause is known. Common conditions of this type are neuropathic pains (e.g. those that are a consequence of diabetes, shingles or herpes zoster infection, as well as

sciatica and trigeminal neuralgia), posttraumatic and postsurgical pain (e.g. following a stroke, spinal cord injury or phantom limb pain) and musculoskeletal pain.

- chronic primary pain in which there is no obvious cause. Common conditions of this type are nonspecific low back pain and fibromyalgia. [15]

Chronic pain involves not only the processing of nociceptive information but also comprises emotional and psychosocial components (e.g. mood, circumstance, stress, duration, meaning, acceptance, expectation and fear), more so than acute or cancer-related pain (see **Stannard, 2016**). These other components may render most opioid drugs less effective in the long-term treatment of chronic pain. [16] The British Medical Association concluded that 'There is a lack of good-quality evidence to support a strong clinical recommendation for the long-term use of opioids for patients with chronic pain' (see **BMA, 2017**). Psychological treatments such as acceptance and commitment therapy (ACT) and cognitive behavioural therapy (CBT) are useful in reducing the impacts of chronic pain. A number of non-opioid drugs are used to treat chronic pains but for many of them sound evidence for their efficacy or an understanding of the mechanisms underlying their effects in chronic pain is somewhat lacking (see **Dworkin et al., 2010**; **BMA, 2017**). Their use to treat chronic pain results largely from serendipitous observations rather than a rational programme of drug discovery. An important component of pain is its emotional and cognitive effects (**Fig. 43.8**). In acute pain these serve important roles including focusing attention on the cause of the pain and facilitating learning so that future behaviours are adapted

to avoid pain. However, in chronic pain, these effects can be detrimental and are thought to contribute to the high prevalence of depression in patients with chronic pain. It may be that drugs used to treat chronic pain primarily work through targeting these cognitive and emotional symptoms.

FIG. 43.8 Experimental manipulations to take attention away from the painful sensation or to change mood can change a patient's perception of pain.(A) Manipulating attention away from the pain primarily alters the perceived intensity of the pain sensation without significantly altering the perceived unpleasantness of the pain. (B) By contrast, altering the mood state using acute manipulations, e.g. using emotive music or recalling emotional memories, alters the perceived unpleasantness of the pain without altering the intensity of the sensation. These data suggest that the effects of these higher level cognitive and emotional mechanisms alter pain via distinct descending modulatory systems. Although the effects may seem modest, these are likely to be associated with improvements in patient well-being.

Treatment of Chronic Secondary Pain

Musculoskeletal pain affects bones, joints, ligaments, tendons or muscles. Arthritic conditions can be especially painful. Treatment can be targeted at disease modification or at reducing inflammation and pain (described in detail in **Ch. 25**). Inflammation and pain in these conditions respond to NSAIDs.

The pathophysiological mechanisms underlying neuropathic pain are poorly understood, although spontaneous activity in damaged

sensory neurons, due to overexpression or redistribution of voltage-gated sodium channels, is thought to be a factor. In addition, central sensitisation occurs. The sympathetic nervous system also plays a part, because damaged sensory neurons can express α_1 adrenoceptors and develop a sensitivity to noradrenaline that they do not possess under normal conditions. Thus, physiological stimuli that evoke sympathetic responses can produce severe pain, a phenomenon described clinically as sympathetically mediated pain.

Tricyclic antidepressants, particularly **amitriptyline**, **nortriptyline** and **desipramine** (see **Ch. 48**), are widely used. These drugs act centrally by inhibiting noradrenaline and serotonin reuptake and are effective in some, but not all, cases. Drugs such as **duloxetine** and **venlafaxine**, which inhibit serotonin and noradrenaline uptake, are also effective and have a different side-effect profile, but selective serotonin reuptake inhibitors show little or no benefit. Little is known about the mechanisms which contribute to these effects. One theory is that they modulate descending inhibitory control mediated by noradrenaline and maybe serotonin and therefore have a direct effect on the pain pathway. However, they may also work centrally by affecting the emotional effects of chronic pain via mechanisms similar to those associated with their antidepressant and anxiolytic effects. Depression and anxiety are also highly comorbid in patients with chronic pain.

Gabapentin and its congener, **pregabalin**, first introduced as antiepileptic drugs (see **Ch. 46**), have become widely used to treat chronic pains. They reduce the expression of $\alpha_2\delta$ subunits of voltage-activated calcium channels on the nerve membrane (see **Ch. 4**) and reduce neurotransmitter release. The $\alpha_2\delta$ subunits are

up-regulated in damaged sensory neurons, which may explain why these agents may be more effective across a range of pain states associated with nerve damage than in other forms of pain. These drugs are also effective anxiolytics (see **Ch. 45**) and this may also contribute to their overall benefits for these patients.

Carbamazepine, another type of antiepileptic drug, is effective in trigeminal neuralgia but evidence for effectiveness against other neuropathic pains is lacking. Carbamazepine blocks voltage-gated sodium channels (see **Ch. 4**) being slightly more potent in blocking $Na_v1.8$ than $Na_v1.7$ and $Na_v1.3$ channels; all of these channel subtypes are thought to be up-regulated by nerve damage and contribute to the sensation of pain. At higher concentrations, it inhibits voltage-activated calcium channels. **Phenytoin** administered intravenously is sometimes used in cases of severe trigeminal neuralgia. Other antiepileptic agents such as **valproic acid**, **lamotrigine**, **oxcarbazepine**, **topiramate** and **levetiracetam** may have some efficacy in some neuropathic pain states.

Tramadol and **tapentadol** have been reported to have efficacy in treating diabetic peripheral neuropathy, chronic low back pain and sciatica. In addition to their agonist action at μ opioid receptors, their ability to reduce monoamine reuptake (discussed earlier in this chapter) may be important.

Lidocaine (lignocaine), a local anaesthetic drug (see **Ch. 44**), can be used topically to relieve neuropathic pain. It probably acts by blocking spontaneous discharges from damaged sensory nerve terminals. Some antidysrhythmic drugs (e.g. **mexiletine**, **tocainide**, **flecainide**; see **Ch. 20**) are effective orally.

Capsaicin can be applied topically to areas of localised neuropathic and osteoarthritic pain. It activates nociceptors before subsequently desensitising them and so it initially produces short-lived, localised sensations of burning, or pain. A single application can produce relief of pain for up to 3 months.

Although some drug treatments may only partially alleviate chronic secondary pain for sufferers any decrease in pain intensity can be a welcome improvement to their condition. The abundance of drugs and mechanisms deployed to alleviate chronic secondary pain reflects the current lack of drugs that work effectively and reliably in these common and serious conditions.

Drugs used to treat neuropathic pain

- Certain antidepressants (e.g. **amitriptyline**, **duloxetine**) provide therapeutic benefit.
- **Gabapentin** and **pregabalin** are now used more to treat neuropathic pain than as antiepileptic agents.
- **Carbamazepine**, as well as some other antiepileptic agents that block sodium channels, can be effective in treating trigeminal neuralgia.
- **Capsaicin and lidocaine** may provide relief when applied topically.

Treatment of Chronic Primary Pain

The National Institute for Clinical Care (UK) recently concluded that in people suffering from chronic primary pains,

pharmacological treatment with some antidepressants (**amitriptyline, citalopram, duloxetine, fluoxetine, paroxetine** and **sertraline**) can be beneficial (**NICE Guideline, 2021**) but they considered the evidence of efficacy for most other drugs currently used to treat chronic primary pain states to be insufficient.

Fibromyalgia is characterised by widespread musculoskeletal pain, fatigue and insomnia. Its cause is unknown, with no obvious characteristic pathology being apparent. It is associated with allodynia. Classical analgesics (i.e. NSAIDs and opioids) are not very effective in treating this disorder. As with chronic secondary pain, some antidepressant drugs can bring relief. However, while **gabapentin and pregabalin** and benzodiazepines (e.g. **clonazepam**, **zopiclone**; see **Ch. 45**) are currently used to treat fibromyalgia, convincing evidence of their efficacy is still lacking.

Other Drugs Used to Treat Pain

Nefopam, an inhibitor of amine uptake with some sodium channel-blocking properties, is sometimes used in the treatment of persistent pain unresponsive to opioid drugs. It does not depress respiration but does produce sympathomimetic and antimuscarinic side effects.

Ketamine, a dissociative anaesthetic (see **Ch. 41**), **memantine** and **dextromethorphan** work by blocking NMDA receptor channels, and probably reduce the wind-up phenomenon in the dorsal horn (see **Fig. 43.2**). Given intrathecally, ketamine's effects on memory and cognitive function are largely avoided. It is used for acute relief rather than long-term treatment.

Ziconotide, a synthetic analogue of the N-type calcium-channel blocking peptide ω-conotoxin MVIIA, is effective when administered by the intrathecal route. It is used in patients whose pain does not respond to other analgesic agents. Blockers of low voltage-activated T-type calcium channels may also be effective analgesics in some pain states.

Cannabinoids (see **Ch. 18**) acting at CB_1 receptors are effective pain-relieving agents in animal models of pain, including models of acute, antinociceptive, inflammatory and neuropathic pain. There is also mounting evidence that these agents are effective in reducing pain in humans (see **Barnes and Barnes, 2016**). However, good quality, large, long-term randomised controlled trials are required to define their effectiveness in different pain states. The strongest evidence of therapeutic benefit is for central neuropathic pain in multiple sclerosis. Effective cannabinoids include **nabilone** and **dronabinol** (synthetic (−)-trans-Δ^9-tetrahydrocannabinol) as well as natural cannabinoids such as **nabiximols** (formerly known by its trade name **Sativex**). **Nabiximols** is an extract of the cannabis plant containing Δ^9-tetrahydrocannabinol (THC) and cannabidiol that has been suggested to have improved therapeutic efficacy. CB_2 receptor agonists may also be potential analgesic agents.

In addition, cannabinoids and related drugs that lack agonist action at CB_1 receptors have been observed to induce analgesia by potentiating the actions of the inhibitory amino acid glycine at the ionotropic glycine receptor (see **Ch. 38**) in the spinal cord. This may lead to the development of new therapeutic agents lacking the unwanted effects of CB_1 agonism.

Botulinum toxin injections are effective in relieving back pain and the pain associated with spasticity. This effect is due mainly to a relief of muscle spasm (see **Ch. 14**).

Ropinirole, **pramipexole** and **rotigotine**, dopamine-receptor agonists (see **Ch. 39**), are used to treat restless leg syndrome, which can be painful in some individuals.

Clinical uses of analgesic drugs (1)

- Analgesics are used to treat and prevent pain, for example:
  - pre- and postoperatively
  - common painful conditions including headache, dysmenorrhoea, labour, trauma and burns
  - many medical and surgical emergencies (e.g. myocardial infarction and renal colic)
  - terminal disease (especially metastatic cancer)
- Opioid analgesics are used in some non-painful conditions, for example acute heart failure (because of their haemodynamic effects) and terminal chronic heart failure (to relieve distress).
- The choice and route of administration of analgesic drugs depend on the nature and duration of the pain.
- A progressive approach is often used, starting with NSAIDs, supplemented first by weak opioid analgesics and then by strong opioids.
- In general, severe acute pain is treated with strong opioids (e.g. **morphine**, **fentanyl**) given by injection. Mild inflammatory pain (e.g. sprains, mild arthralgia) is treated

with NSAIDs (e.g. **ibuprofen**) or by **paracetamol** supplemented by weak opioids (e.g. **codeine**). Severe pain (e.g. cancer pain) is treated with strong opioids given orally, intrathecally, epidurally or by subcutaneous injection. Patient-controlled infusion systems are useful postoperatively.

- Chronic neuropathic pain is less responsive to NSAIDS or opioids and can be treated with tricyclic antidepressants (e.g. **amitriptyline**) or anticonvulsants (e.g. **carbamazepine**, **gabapentin**).

Clinical uses of analgesic drugs (2)

- NSAIDs (see first clinical box), including **paracetamol**, are useful for musculoskeletal and dental pain and for dysmenorrhoea. They reduce opioid requirements in acute (e.g. postoperative) and chronic (e.g. bone metastasis) pain.
- Weak opioids (e.g. **codeine**) combined with **paracetamol** are useful in moderately severe pain if non-opioids are not sufficient. **Tramadol** and **tapentadol** (a weak opioid with additional action on 5-HT and noradrenaline uptake) are alternatives.
- Strong opioids (e.g. **morphine**) are used for severe pain, particularly of visceral origin.
- Note that:
  - the intravenous route provides rapid relief from pain and distress;

  - the intravenous dose is much lower than the oral dose because of presystemic metabolism;
  - **morphine** is given orally as a solution or as 'immediate-release' tablets every 4 h;
  - dose is titrated; when the daily requirement is apparent, the preparation is changed to a modified-release formulation to allow once- or twice-daily dosing;
  - **morphine** and **oxycodone** can be given orally in slow-release tablet form;
  - transdermal administration (e.g. patches of **fentanyl**) is an alternative, rapid means of pain relief;
  - adverse effects (nausea, constipation) are anticipated and treated pre-emptively;
  - addiction is not an issue in the setting of terminal care.
- Subanaesthetic doses of **nitrous oxide** (see **Ch. 41**) are analgesic, and self-administration of a mixture of **nitrous oxide** with oxygen is widely used during labour, following acute injury or for painful dressing changes.

QUESTIONS

QUESTION 43.1

The neural mechanisms of pain are mediated by a range of afferent nerve fibres and mediators which transmit nociceptive signals.

Which of the following statements about pain transmission is incorrect?

OPTIONS:

A. Glutamate acting on *N*-methyl-D-aspartate (NMDA) receptors is responsible for fast synaptic transmission.

B. Myelinated (Aδ) fibres convey a sensation of sharp, well-localised pain.

C. The cell bodies of spinal nociceptive afferent fibres lie in dorsal root ganglia.

D. The substantia gelatinosa (SG) is rich in opioid receptors.

E. The nociceptive afferent neurons release glutamate at their central synapses in the dorsal horn.

QUESTION 43.2

Hyperalgesia is defined as an increased amount of pain associated with a mild noxious stimulus and involves both sensitisation of peripheral nociceptive nerve terminals and central facilitation of transmission at the level of the dorsal horn and thalamus.

Which of the following would not predispose to hyperalgesia?

OPTIONS:

A. Increased circulating levels of bradykinin

B. Activation of the periaqueductal grey (PAG) region

C. Phosphorylation of NMDA receptors

D. Increased release of nerve growth factor (NGF)

E. Up-regulation of $Na_v1.7$ channels

QUESTION 43.3

The proposal that opioids produce analgesia and their other effects by interacting with specific receptors first arose in the 1950s, based on the strict structural and stereochemical requirements essential for activity and has led to the identification of several receptor subtypes.

Which of the following receptor subtypes is responsible for the tolerance which develops to opioid agents?

OPTIONS:

A. μ receptor

B. κ receptor

C. σ receptor

D. δ receptor

E. ORL_1/NOP receptor

ANSWERS

ANSWER 43.1

RATIONALE:

A.

B. Pain is associated with impulse activity in small-diameter (C and Aδ) primary afferent fibres of peripheral nerves. The majority of non-myelinated (C) fibres are associated with *polymodal nociceptive* endings and convey a dull, diffuse burning pain, whereas myelinated (Aδ) fibres convey a sensation of sharp, well-localised pain.

C. The cell bodies of spinal nociceptive afferent fibres lie in dorsal root ganglia; fibres enter the spinal cord via the dorsal roots, ending in the grey matter of the dorsal horn. Most of the nociceptive afferents terminate in the superficial region of the dorsal horn.

D. The SG is rich in both endogenous opioid peptides and opioid receptors, and may be an important site of action for morphine-like drugs.

E. The nociceptive afferent neurons release glutamate and possibly ATP as the fast neurotransmitters at their central synapses in the dorsal horn.

CORRECT ANSWER WITH EXPLANATION:

A. Glutamate acting on NMDA receptors is responsible for fast synaptic transmission.

Glutamate acting on (*S*)-α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors is responsible for fast synaptic transmission at the first synapse in the dorsal horn. There is also a slower *N*-methyl-D-aspartate (NMDA) receptor-mediated response, which is important in relation to the phenomenon of 'wind-up'.

ANSWER 43.2

RATIONALE:

A. The peripheral component of hyperalgesia is due to the action of mediators such as bradykinin and prostaglandins acting on the nerve terminals.

B.

C. Phosphorylation of the NMDA subunit GluN1 by brain-derived neurotrophic factor (BDNF) activated kinase-linked TrkB receptor sensitises these glutamate receptors, resulting in synaptic facilitation and the potential for hyperalgesia.

D. NGF acts on a kinase-linked receptor (known as TrkA) on nociceptive afferent neurons, increasing their electrical excitability, chemosensitivity and peptide content, and also

promoting the formation of synaptic contacts. Increased NGF production may be an important mechanism by which nociceptive transmission becomes facilitated by tissue damage, leading to hyperalgesia.

E. The expression and/or activity of certain sodium-channel subtypes is increased in sensory neurons in various pathological pain states and their enhanced activity underlies the sensitisation to external stimuli that occurs in inflammatory pain and hyperalgesia.

CORRECT ANSWER WITH EXPLANATION:

B. Activation of the PAG region

Electrical stimulation of the PAG brain area causes analgesia mediated by 5-hydroxytryptamine (5-HT) and endogenous opioid signalling.

ANSWER 43.3

RATIONALE:

A.

B. κ Receptors contribute to analgesia at the spinal level and may elicit sedation, dysphoria and hallucinations.

C. The σ 'receptor' is no longer considered to be an opioid receptor. It was originally postulated in order to account for the dysphoric effects (anxiety, hallucinations, bad dreams, etc.) but these are now attributed to other mechanisms.

D. δ Receptor activation results in analgesia but also can be proconvulsant.

E. Activation results in an antiopioid effect (supraspinal), analgesia (spinal), immobility and impairment of learning.

CORRECT ANSWER WITH EXPLANATION:

A. μ receptor

μ Receptors are responsible for most of the analgesic effects of opioids, and for some major unwanted effects (e.g. respiratory depression, constipation, euphoria, sedation and dependence).

[1] Anyone who has rubbed their eyes after cutting up chilli peppers will know this.

[2] The receptor was originally known as the vanilloid receptor because many capsaicin-like compounds are based on the structure of vanillic acid.

[3] $P2X_3$ knock-out mice are, in contrast, fairly normal in this respect, presumably because other mechanisms take over.

[4] While 'diamorphine' is the recommended International Nonproprietary Name (rINN), this drug is widely known as heroin.

[5] The s 'receptor' is no longer considered to be an opioid receptor. It was originally postulated in order to account for the dysphoric effects (anxiety, hallucinations, bad dreams, etc.) produced by some opioids. It is now accepted that these effects result from drug-induced block of the NMDA receptor channel pore, an effect that is also produced by agents such as ketamine (see Ch. 41). Novel s receptors – s_1 and s_2 subtypes – have now been cloned and characterised. They are not structurally related to other receptor types and little is known about their physiological role, but they have been suggested as novel drug targets for psychiatric disorders.

[6] It may seem obvious today that if there is a receptor then there is likely also to be an endogenous ligand for that receptor but it was

the search for, and subsequent discovery of, the enkephalins that gave credence to this idea.

[7] The opioid receptors are unusual among G protein–coupled receptors. First, in that there are many (20 or more) opioid peptides but only four receptors. In contrast, 5-HT, for example, is a single mediator interacting with many (about 14) receptors, which is the more common pattern. Second, all four receptors couple to the same types of G protein (G_i/G_o) and therefore activate the same spectrum of cellular effector mechanisms. In contrast, other receptor families (e.g. muscarinic receptors) couple to different types of G proteins and therefore give rise to different cellular responses (see Ch. 14).

[8] Claims have been made that 'G protein biased' μ opioid receptor ligands will show a reduced side-effect profile in comparison to morphine which is 'unbiased', but recent research does not support this hypothesis (Gillis et al., 2020, Trends Pharmacol Sci 41, 947–959).

[9] The chemically related compound apomorphine is more strongly emetic than morphine, through its action as a dopamine agonist; despite its name, it is inactive on opioid receptors.

[10] The exception is pethidine, which causes pupillary dilatation because it also blocks muscarinic receptors.

[11] In treating pain, constipation is regarded as an undesirable side effect. However, opiates such as codeine and morphine can be used to treat diarrhoea.

[12] Other symptoms include goose pimples and restless leg syndrome. These are the origin of the terms ‘cold turkey’ and ‘kicking the habit’ often used to describe the effect of opioid withdrawal.

[13] The benefits come mainly from removing the risks of self-injection and the need to finance the drug habit through crime.

[14] The required dose of etorphine, even for an elephant, is small enough to be incorporated into a dart or pellet.

[15] Sciatica, characterized by pain, numbness and tingling in the thigh and leg, is often discussed along with chronic low back pain but its cause can in fact often be defined (e.g. nerve compression by a herniated lumbar disc) and is therefore better described as a chronic secondary pain.

[16] Over the past 30 years, there has been widespread long-term prescribing of opioids for chronic pain in the developed world leading to an alarming increase in addiction to prescription opioids and to overdose deaths (see Ch. 50).

44: Local anaesthetics and other drugs affecting sodium channels

OVERVIEW

As described in **Chapter 4**, the property of electrical excitability is what enables the membranes of nerve and muscle cells to generate propagated action potentials, which are essential for communication in the nervous system and for the initiation of mechanical activity in striated muscle. Initiation of the action potential depends on voltage-gated sodium channels, which open transiently when the membrane is depolarised. Here we discuss local anaesthetics, which act mainly by blocking sodium channels, and mention briefly other drugs that affect sodium-channel function.

There are, broadly speaking, two ways in which channel function may be modified, namely block of the channels and modification of gating behaviour. Blocking sodium channels reduces excitability. On the other hand, different types of drugs can either facilitate channel opening, and thus increase excitability, or inhibit channel opening and reduce excitability.

Local Anaesthetics

Although many drugs can, at high concentrations, block voltage-sensitive sodium channels and inhibit the generation of the action potential, the only drugs used clinically for this effect are the local anaesthetics, various antiepileptic and analgesic drugs (see Chs **42**, **43** and **46**) and class I antidysrhythmic drugs (see **Ch. 20**).

History

Coca leaves have been chewed for their psychotropic effects for thousands of years (see **Ch. 49**) by Native South American tribes, who knew about the numbing effect they produced on the mouth and tongue. **Cocaine** was isolated in 1860 and proposed as a local anaesthetic for surgical procedures. Sigmund Freud, who tried unsuccessfully to make use of its 'psychic energising' power, gave some cocaine to his ophthalmologist friend in Vienna, Carl Köller, who reported in 1884 that reversible corneal anaesthesia could be produced by dropping cocaine on to the eye. The idea was rapidly taken up, and within a few years cocaine anaesthesia was introduced into dentistry and general surgery. A synthetic substitute, **procaine**, was discovered in 1905, and many other useful compounds were later developed.

Chemical Aspects

Local anaesthetic molecules consist of an aromatic part linked by an ester or amide bond to a basic side chain (**Fig. 44.1**). They are weak bases, with pK_a values mainly in the range 8–9, so that they are mainly, but not completely, ionised at physiological pH (see **Ch. 9** for an explanation of how pH influences the ionisation of weak bases). This is important in relation to their ability to penetrate the

nerve sheath and axon membrane; quaternary derivatives such as QX-314, which are fully ionised irrespective of pH, are ineffective as local anaesthetics but have important experimental uses. **Benzocaine**, an atypical local anaesthetic, has no basic group.

The presence of the ester or amide bond in local anaesthetic molecules is important because of its susceptibility to metabolic hydrolysis. The ester-containing compounds are fairly rapidly inactivated in the plasma and tissues (mainly liver) by non-specific esterases. Amides are more stable, and these anaesthetics generally have longer plasma half-lives.

Mechanism of Action

Local anaesthetics block the initiation and propagation of action potentials by preventing the voltage-dependent increase in Na^+ conductance (see **Ch. 4** and **Hille, 2001**; **Strichartz and Ritchie, 1987**). At low concentrations they decrease the rate of rise of the action potential, increasing its duration, and increase the refractory period thus reducing the firing rate. At higher concentrations they prevent action potential firing. Currently available local anaesthetic agents do not, by and large, distinguish between different sodium-channel subtypes, although their potencies vary (see **Ch. 4**). They block sodium channels by physically plugging the transmembrane pore (**Fig 44.2**), interacting with various amino acid residues of the S6 transmembrane helical domains of the channel protein (see **Catterall et al., 2020**).

Local anaesthetic activity is strongly pH dependent, being increased at alkaline extracellular pH (i.e. when the proportion of ionised molecules is low) and reduced at acid pH. This is because

the compound first needs to penetrate the nerve sheath and the axon membrane to gain access to the pore of the sodium channel (where the local anaesthetic-binding site resides). Because the ionised form is not membrane-permeant, penetration is very poor at acid pH. Once inside the pore, it is primarily the ionised form of the local anaesthetic molecule that binds to the channel and blocks it (**Fig. 44.2**), the unionised form having only weak channel-blocking activity. This pH dependence can be clinically important, because the extracellular fluid of inflamed tissues is often relatively acidic and such tissues are thus somewhat resistant to local anaesthetic agents.

Many drugs that block sodium channels do so in a state-dependent manner, depending on the resting membrane potential and the frequency of action potential firing. They exhibit the property of *'use-dependent' block* of sodium channels, as well as affecting, to some extent, the gating of the channels. Use-dependence means that the more the channels are opened, the greater the block becomes. It is a prominent feature of the action of many class I antidysrhythmic drugs (see **Ch. 20**) and antiepileptic drugs (see **Ch. 46**), and occurs because the blocking molecule enters the channel much more readily when the channel is open than when it is closed. Furthermore, for local anaesthetics that rapidly dissociate from the channel, block only occurs at high frequencies of action potential firing when the time between action potentials is too short for drug dissociation from the channel to occur. The channel can exist in three functional states: resting, open and inactivated (see **Ch. 4**). Many local anaesthetics bind most strongly to the inactivated state of the channel. Therefore, at any

given membrane potential, the equilibrium between resting and inactivated channels will, in the presence of a local anaesthetic, be shifted in favour of the inactivated state, and this factor contributes to the overall blocking effect by reducing the number of channels available for opening, and by prolonging the refractory period following an action potential. The passage of a train of action potentials, for example, in response to a painful stimulus, causes the channels to cycle through the open and inactivated states, both of which are more likely to bind local anaesthetic molecules than the resting state; thus both mechanisms contribute to use-dependence, which explains in part why pain transmission may be blocked more effectively than other sensory modalities.

Local anaesthetics

Aromatic region	Ester or amide bond	Basic amine side-chain	
			Procaine
			Cocaine
			Tetracaine (amethocaine)
			Cinchocaine (dibucaine)
			Lidocaine (lignocaine)
			Prilocaine
			Bupivacaine
			Articaine
			Benzocaine
			QX-314

FIG. 44.1 Structures of some local anaesthetics.The general structure of local anaesthetic molecules consists of an aromatic group *(left)*, ester or amide group *(shaded blue)* and amine group *(right)*.

Quaternary amine local anaesthetics only work when applied to the inside of the membrane and the channels must be cycled through their open state a few times before the blocking effect appears. With tertiary amine local anaesthetics, block can develop even if the channels are not open, and it is likely that the blocking molecule (uncharged) can reach the channel either directly from the membrane phase through fenestrations in the channel protein that allow uncharged molecules to access the pore of the channel in the resting (closed) state or from the intracellular side via the open gate (see **Fig. 44.2**). The fenestrations can change size and shape in the inactivated state and this might explain the preferential binding of local anaesthetics and related drugs to inactivated sodium channels. The relative importance of the two blocking pathways – the hydrophobic pathway via the fenestrations and the hydrophilic pathway via the inner mouth of the channel – varies according to the chemical properties of the drug.

In general, local anaesthetics block conduction in small-diameter nerve fibres more readily than in large fibres. Because nociceptive impulses are carried by Aδ and C fibres (see **Ch. 43**), pain sensation is blocked more readily than other sensory modalities (touch, proprioception, etc.). Motor axons, being large in diameter, are also relatively resistant. The differences in sensitivity among different

nerve fibres, although easily measured experimentally, are not of much practical importance, and it is not possible to block pain sensation without affecting other sensory modalities.

Local anaesthetics, as their name implies, are mainly used to produce local nerve block. At low concentrations, they are also able to suppress the spontaneous action potential discharge in sensory neurons that occurs in neuropathic pain (see **Ch. 43**). The properties of individual local anaesthetic drugs are summarised in **Table 44.1**.

Unwanted Effects

When used clinically as local anaesthetics, the main unwanted effects involve the central nervous system (CNS) and the cardiovascular system (see **Table 44.1**). Their action on the heart can also be of use in treating cardiac arrhythmias (see **Ch. 20**). Although local anaesthetics are usually administered in such a way as to minimise their spread to other parts of the body, they are ultimately absorbed into the systemic circulation. They may also be injected into veins or arterioles in error.

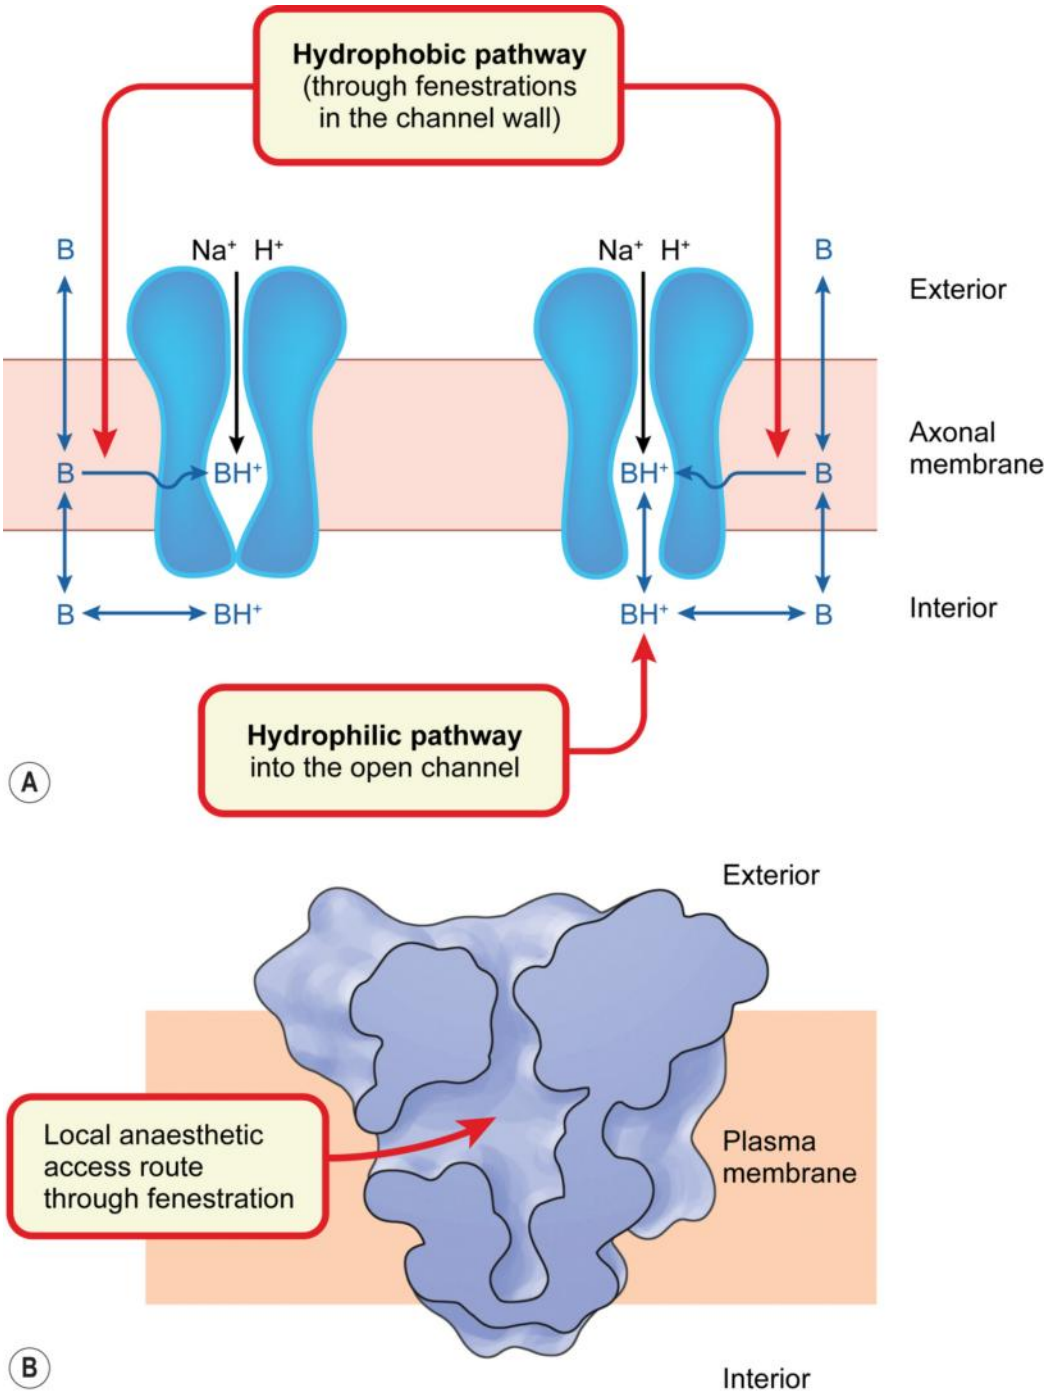

FIG. 44.2 (A) Interaction of local anaesthetics with sodium channels. The blocking site within the channel can be reached via the open channel gate on the inner surface of the membrane by the charged species BH^+ *(hydrophilic pathway)*,

or directly from the membrane through fenestrations in the channel wall by the uncharged species B *(hydrophilic pathway)*. (B) Side view section through the sodium channel crystal structure showing a fenestration in the channel wall through which a local anaesthetic can enter and block the pore. Adapted from Catterall, W.A., Swanson, T.M., 2015. Structural basis for pharmacology of voltage-gated sodium and calcium channels. Mol. Pharmacol. 88, 141–150.

Most local anaesthetics produce a mixture of depressant and stimulant effects on the CNS. Depressant effects predominate at low plasma concentrations, giving way to stimulation at higher concentrations, resulting in restlessness, tremor and sometimes convulsions, accompanied by subjective effects ranging from confusion to extreme agitation. Further increasing the dose produces profound CNS depression and death due to respiratory depression. The only local anaesthetic with markedly different CNS effects is **cocaine** (see **Ch. 49**), which produces euphoria at doses well below those that cause other CNS effects. This relates to its specific effect to inhibit monoamine uptake, an effect not shared by other local anaesthetics. **Procaine** is particularly liable to produce unwanted central effects, and has been superseded in clinical use by agents such as **lidocaine** and **prilocaine**. Studies with **bupivacaine**, a widely used long-acting local anaesthetic prepared as a racemic mixture of two optical isomers, suggested that its CNS

and cardiac effects were mainly due to the *S*(+) isomer. The *R*(–) isomer (**levobupivacaine**) has a better margin of safety.

Actions of local anaesthetics

- Local anaesthetics block action potential generation by blocking sodium channels.
- Local anaesthetics are amphiphilic molecules with a hydrophobic aromatic group and a basic amine group.
- Local anaesthetics are weak bases that act in their cationic form but must reach their site of action by penetrating the nerve sheath and axonal membrane as un-ionised species.
- Many local anaesthetics show use-dependence (depth of block increases with action potential frequency). This arises:
  - because anaesthetic molecules gain access to the channel more readily when the channel is open;
  - because anaesthetic molecules gain access to the channel more readily when the channel is open;
  - because anaesthetic molecules have higher affinity for inactivated than for resting channels.
- Use-dependence is mainly of importance in relation to antidysrhythmic and antiepileptic effects of sodium-channel blockers.
- Local anaesthetics block conduction in peripheral nerves in the following order: small myelinated axons, non-myelinated axons, large myelinated axons. Nociceptive and sympathetic transmission is thus blocked first.

- Sodium-channel block in cardiac muscle and in CNS neurons is exploited in the therapy of cardiac dysrhythmias (see **Ch. 20**) and epilepsy (see **Ch. 46**).

The adverse cardiovascular effects of local anaesthetics are due mainly to myocardial depression, conduction block and vasodilatation. Reduction of myocardial contractility probably results indirectly from an inhibition of the Na^+ current in cardiac muscle (see **Ch. 20**). The resulting decrease of $[Na^+]_i$ in turn reduces intracellular Ca^{2+} stores (see **Ch. 4**), and this reduces the force of contraction. Interference with atrioventricular conduction can result in partial or complete heart block, as well as other types of dysrhythmia. **Ropivacaine** has less cardiotoxicity than bupivacaine.

Vasodilatation, mainly affecting arterioles, is due partly to a direct effect on vascular smooth muscle, and partly to inhibition of the sympathetic nervous system. This leads to a fall in blood pressure, which may be sudden and life-threatening. Cocaine is an exception in respect of its cardiovascular effects, because of its ability to inhibit noradrenaline reuptake (see **Ch. 15**). This enhances sympathetic activity, leading to tachycardia, increased cardiac output, vasoconstriction and increased arterial pressure.

Hypersensitivity reactions sometimes occur with local anaesthetics, usually in the form of allergic dermatitis but rarely as an acute anaphylactic reaction. Other unwanted effects that are specific to particular drugs include mucosal irritation (cocaine) and methaemoglobinaemia (which occurs after large doses of prilocaine, because of the production of a toxic metabolite).

Pharmacokinetic Aspects

Local anaesthetics vary a good deal in the rapidity with which they penetrate tissues, and this affects the rate at which they cause nerve block when injected into tissues, and the rate of onset of, and recovery from, anaesthesia (see **Table 44.1**; see **Becker and Reed, 2012**). It also affects their usefulness as surface anaesthetics for application to mucous membranes. They are sometimes administered along with **hyaluronidase** to break down the intercellular matrix and increase tissue permeation of the local anaesthetic.

Most of the ester-linked local anaesthetics (e.g. **tetracaine**) are rapidly hydrolysed by plasma cholinesterase, so their plasma half-life is short. Procaine – now rarely used – is hydrolysed to *p*-aminobenzoic acid, a folate precursor that interferes with the antibacterial effect of sulfonamides (see **Ch. 52**). The amide-linked drugs (e.g. lidocaine and prilocaine) are metabolised mainly in the liver, usually by *N*-dealkylation rather than cleavage of the amide bond, and the metabolites are often pharmacologically active.

Benzocaine is an unusual local anaesthetic of very low solubility, which is used as a dry powder to dress painful skin ulcers, or as throat lozenges. The drug is slowly released and produces long-lasting surface anaesthesia. [1]

The routes of administration, uses and main adverse effects of local anaesthetics are summarised in **Table 44.2**.

Most local anaesthetics have a direct vasodilator action, which increases the rate at which they are absorbed into the systemic circulation, thus increasing their potential toxicity and reducing their local anaesthetic action. **Adrenaline** (**epinephrine**),

phenylephrine or **felypressin**, a short-acting vasopressin analogue (see **Ch. 33**), may be added to local anaesthetic solutions injected locally to cause vasoconstriction. Adrenaline and phenylephrine absorbed into the circulation may induce unwanted cardiovascular effects such as tachycardia and vasoconstriction, and felypressin may cause coronary artery constriction. Their use in patients with cardiovascular disease is contraindicated.

New Approaches

Blocking specific sodium-channel subtypes is seen as a promising therapeutic strategy for a variety of clinical conditions, including epilepsy (see **Ch. 46**), neurodegenerative diseases and stroke (see **Ch. 40**), neuropathic pain (see **Ch. 43**) and myopathies (see **Ch. 20**). As our understanding of the role of specific sodium-channel subtypes in different pathophysiological situations increases, so too will be the likelihood that selective blocking agents can be developed for use in different clinical situations.

Other Drugs That Affect Sodium Channels

Tetrodotoxin and Saxitoxin

Tetrodotoxin (TTX) is produced by a marine bacterium and accumulates in the tissues of a poisonous Pacific fish, the puffer fish. The puffer fish is regarded in Japan as a special delicacy, partly because of the mild tingling sensation that follows eating its flesh. To serve it in public restaurants, however, the chef must be registered as sufficiently skilled in removing the toxic organs (especially liver and ovaries) to make the flesh safe to eat. Accidental TTX poisoning is quite common, nonetheless. Historical

records of long sea voyages often contained reference to attacks of severe weakness, progressing to complete paralysis and death, caused by eating puffer fish. It was suggested that the powders used by voodoo practitioners to induce zombification may contain TTX but this is disputed.

Unwanted effects and pharmacokinetics of local anaesthetics

- Local anaesthetics are either esters or amides. Esters are rapidly hydrolysed by plasma and tissue esterases, and amides are metabolised in the liver. Plasma half-lives are generally short, about 1–2 h.
- Unwanted effects are due mainly to escape of local anaesthetics into the systemic circulation.
- Main unwanted effects are:
  - CNS effects, namely agitation, confusion, tremors progressing to convulsions and respiratory depression;
  - cardiovascular effects, namely myocardial depression and vasodilatation, leading to a fall in blood pressure;
  - occasional hypersensitivity reactions.
- Local anaesthetics vary in the rapidity with which they penetrate tissues, and in their duration of action. **Lidocaine** (lignocaine) penetrates tissues readily and is suitable for surface application; **bupivacaine** has a particularly long duration of action.

Table 44.1

CNS, Central nervous system.

Table 44.2

LA, Local anaesthetic.

[a] Surface anaesthesia does not work well on the skin, although a non-crystalline mixture of lidocaine and prilocaine (eutectic mixture of local anaesthetics, or EMLA) has been developed for application to the skin, producing complete anaesthesia in about 1 h. Lidocaine is available in a patch preparation that can be applied to the skin to reduce pain in conditions such as post-herpetic neuralgia (shingles).

[b] Use of spinal anaesthesia is declining in favour of epidural administration.

[c] Intrathecal or epidural administration of LA in combination with an opioid (see **Ch. 43**) produces more effective analgesia than can be achieved with the opioid alone. Only a small concentration of LA is needed, insufficient to produce appreciable loss of sensation or other side effects. The mechanism of this synergism is unknown, but the procedure has proved useful in pain treatment.

Saxitoxin (STX) is produced by a marine microorganism that sometimes proliferates in very large numbers and even colours the sea, giving the *red tide* phenomenon. At such times, marine

shellfish can accumulate the toxin and become poisonous to humans.

These toxins, unlike conventional local anaesthetics, act exclusively from the outside of the membrane. Both are complex molecules, bearing a positively charged guanidinium moiety. The guanidinium ion is able to permeate voltage-sensitive sodium channels, and this part of the TTX or STX molecule lodges in the channel, while the rest of the molecule blocks its outer mouth. In the manner of its blockade of sodium channels, TTX can be likened to a champagne cork. In contrast to local anaesthetics, there is no interaction between the gating and blocking reactions with TTX or STX – their association and dissociation are independent of whether the channel is open or closed. Some voltage-sensitive sodium channels expressed in cardiac muscle or up-regulated in sensory neurons in neuropathic pain (i.e. $Na_V1.5$, $Na_V1.8$ and $Na_V1.9$) are relatively insensitive to TTX (see **Ch. 43**).

Both TTX and STX are unsuitable for clinical use as local anaesthetics, being expensive to obtain from their exotic sources and poor at penetrating tissues because of their very low lipid solubility. They have, however, been important as experimental tools for the study of sodium channels (see **Ch. 4**).

Agents That Affect Sodium-Channel Gating

Various substances modify sodium-channel gating in such a way as to *increase* the probability of opening of the channels (see **Hille, 2001**). They include various toxins, mainly from frog skin (e.g. batrachotoxin), scorpion or sea anemone venoms; plant alkaloids such as **veratridine**; and insecticides such as

dichlorodiphenyltrichloroethane (DDT) and the pyrethrins. They facilitate sodium-channel activation so that sodium channels open at more negative potentials close to the normal resting potential; they also inhibit inactivation, so that the channels fail to close if the membrane remains depolarised. The membrane thus becomes hyperexcitable, and the action potential is prolonged. Spontaneous discharges occur at first, but the cells eventually become permanently depolarised and inexcitable. All these substances affect the heart, producing extrasystoles and other dysrhythmias, culminating in fibrillation; they also cause spontaneous discharges in nerve and muscle, leading to twitching and convulsions. The very high lipid solubility of substances like DDT makes them effective as insecticides, for they are readily absorbed through the integument. Drugs in this class are useful as experimental tools for studying sodium channels but have no clinical uses.

Clinical uses of local anaesthetics

- Local anaesthetics may be injected into soft tissue (e.g. of gums) or to block a nerve or nerve plexus.
- Co-administration of a vasoconstrictor (e.g. **adrenaline**) prolongs the local effect.
- Lipid-soluble drugs (e.g. **lidocaine**) are absorbed from mucous membranes and are used as surface anaesthetics.
- **Bupivacaine** has a slow onset but long duration. It is often used for epidural blockade (e.g. to provide continuous epidural blockade during labour) and spinal anaesthesia. Its

isomer **levobupivacaine** is less cardiotoxic if it is inadvertently administered into a blood vessel.

QUESTIONS

QUESTION 44.1

Local anaesthetics block the initiation and propagation of action potentials by affecting sodium-channel function.

Which of the following may reduce the effectiveness of local anaesthetic agents?

OPTIONS:

A. High extracellular pH

B. pK_a values in the range 8–9

C. Inflamed tissue

D. High-frequency action potentials

E. Presence of an amide compared with an ester bond

QUESTION 44.2

Many drugs that block sodium channels do so in a state-dependent manner, depending on the resting membrane potential and the frequency of action potential firing and are influenced by the type of nerve fibre.

Which of the following channels would be most readily blocked by local anaesthetics?

OPTIONS:

A. Resting channels in small diameter nerve fibres

B. Open channels in small diameter nerve fibres

C. Closed channels in motor axons

D. Inactivated channels in small diameter fibres

E. Inactivated channels in motor axons

QUESTION 44.3

Although intended for localised use, absorption of local anaesthetics into the body can result in unwanted systemic and central effects.

Which of the following is NOT a side effect of lidocaine?

OPTIONS:

A. Bradycardia

B. Hypersensitivity

C. Myocardial depression

D. Central nervous system (CNS) effects

E. Increased arterial pressure

ANSWERS

ANSWER 44.1

RATIONALE:

A. Local anaesthetic activity is pH dependent, being higher at alkaline pH when the proportion of ionised molecules is low.

B. Anaesthetics are weak bases, with pK_a values mainly in the range 8–9, so that they are mainly, but not completely, ionised at physiological pH. This is important as the unionised form needs to penetrate the nerve sheath and the axon membrane to gain access to the pore of the sodium channel.

C.

D. Many local anaesthetic agents show 'use-dependent' block, in that the effectiveness of the block increases with increased frequency of channel opening.

E. Ester-linked local anaesthetics are rapidly hydrolysed and so have a short duration, whereas amide-linked anaesthetics are metabolised more slowly and often have active metabolites.

CORRECT ANSWER WITH EXPLANATION:

B. Inflamed tissue

The extracellular fluid in inflamed tissue is often acidic and so results in more ionisation and less penetration of the anaesthetic.

ANSWER 44.2

RATIONALE:

A. Local anaesthetics block conduction in small-diameter nerve fibres more readily than in large fibres but require the channel to be open (active) for effective penetration into the pore.

B. Local anaesthetics block conduction in small-diameter nerve fibres more readily than in large fibres. Drug molecules penetrate the open channels but bind most strongly to the inactivated state of the channel.

C. Local anaesthetics require the channel to be open for effective penetration into the pore also motor axons, being large in diameter, are relatively resistant to the effects of local anaesthetics.

D.

E. Whilst many local anaesthetics bind most strongly to the inactivated state of the channel, motor axons, being large in diameter, are relatively resistant to the effects of local anaesthetics.

CORRECT ANSWER WITH EXPLANATION:

D. Inactivated channels in small diameter fibres

Local anaesthetics block conduction in small-diameter nerve fibres more readily than in large fibres. Because nociceptive impulses are carried by Aδ and C fibres pain sensation is blocked more readily than other sensory modalities (touch, proprioception, etc.). Many local anaesthetics bind most strongly to the inactivated state of the channel. At any given membrane potential, the equilibrium between resting and inactivated channels will, in the presence of a local anaesthetic, be shifted in favour of the

inactivated state, and this factor contributes to the overall blocking effect by reducing the number of channels available for opening, and by prolonging the refractory period following an action potential.

ANSWER 44.3

RATIONALE:

A. Many local anaesthetics cause a decrease in contractility and conduction leading to bradycardia.

B. Hypersensitivity reactions sometimes occur in the form of allergic dermatitis and, rarely, anaphylaxis.

C. A decrease in myocardial contractility probably results indirectly from the block of sodium conductance in cardiac muscle.

D. Most local anaesthetics, if absorbed systemically, can cause CNS depression at low plasma concentrations and stimulant effects at higher concentrations. This is less pronounced with lidocaine, compared with earlier agents such as procaine.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Increased arterial pressure

Most anaesthetics cause vasodilatation due to direct effects on vascular smooth muscle and inhibition of sympathetic transmission.

[1] Benzocaine is also used in ‘endurance’ condoms to delay ejaculation.

45: Anxiolytic and hypnotic drugs

OVERVIEW

In this chapter we discuss the nature of anxiety and the drugs used to treat it (anxiolytic drugs), as well as drugs used to treat insomnia (hypnotic drugs). Historically there was overlap between these two groups, reflecting the fact that older anxiolytic drugs commonly caused a degree of sedation and drowsiness. Newer anxiolytic drugs show much less sedative effect and other hypnotic drugs have been introduced that lack specific anxiolytic effects. Many of the drugs now used to treat anxiety were first developed, and are still used, to treat other disorders such as depression (see **Ch. 48**), epilepsy (see **Ch. 46**) and schizophrenia (see **Ch. 47**). Here we will focus on their use as anxiolytics.

The Nature Of Anxiety And Its Treatment

The normal fear response to threatening stimuli comprises several components, including defensive behaviours, autonomic reflexes, arousal and alertness, corticosteroid secretion and negative emotions. It is also normal to experience these reactions in anticipation of activities which are associated with a fearful or stressful situations, but these should be transient and not adversely

affect normal activities. The distinction between a ‘pathological’ and a ‘normal’ state of anxiety is not clear-cut but to meet the diagnosis of an anxiety disorder the symptoms need to cause significant personal distress and be associated with impairments to everyday function. The term *anxiety* is applied to several distinct disorders. A useful division of anxiety disorders that may help to explain why different types of anxiety respond differently to different drugs is (i) disorders that involve *fear* (panic attacks and phobias) and (ii) those that involve a more general feeling of *anxiety* (often categorised as general anxiety disorder).

Anxiety disorders recognised clinically include the following:

- *generalised anxiety disorder* (an ongoing state of excessive anxiety lacking any clear reason or focus)
- *social anxiety disorder or social phobia* (fear of being with and interacting with other people)
- *phobias* (strong fears of specific objects or situations, e.g. snakes, open spaces, flying)
- *panic disorder* (sudden attacks of overwhelming fear that occur in association with marked somatic symptoms, such as sweating, tachycardia, chest pains, trembling and choking). Such attacks can be induced experimentally in normal individuals by infusion of sodium lactate or exposure to inhalation of 35% CO_2.
- *post-traumatic stress disorder* (PTSD; distress triggered by recall of past stressful experiences)
- *obsessive–compulsive disorder* (recurrent obsessive ruminations, images or impulses, and/or recurrent physical

or mental rituals driven by unfounded and specific anxieties, e.g. fear of contamination).

- *illness anxiety disorder* (a somatic symptom related disorder characterised by excessive or disproportionate preoccupations with having or acquiring a serious illness).

Extensive descriptions of anxiety disorders can be found in *DSM-5*. [1]

Treatment of anxiety disorders requires careful consideration of the individual patient, probable cause and severity of the symptoms (**Fig. 45.1**). Psychological therapies are important as well as drug treatments and, for most patients, drug treatments alone are unlikely to achieve long-term recovery. The traditional approach to treating anxiety was the use of anxiolytic/hypnotic agents (i.e. benzodiazepines and barbiturates). These drugs are referred to as sedative anxiolytics as they produce both anxiolytic effects at low doses and sedation at higher doses. However, the sedative side effects even at low doses, amnesic effects and propensity to induce tolerance and physical dependence limit their value for the long-term treatment of anxiety disorders. Anxiolytic effects have been observed with drugs also used to treat other brain disorders (e.g. some antidepressants, antiepileptic and antipsychotic drugs) or 5-hydroxytryptamine $(5\text{-HT})_{1A}$-receptor agonists (e.g. **buspirone**) that have no hypnotic effects and this has led to a new class of non-sedating anxiolytics which are now first-line treatments for most anxiety disorders. Another important distinction between classes of anxiolytics is their rate of onset of clinical benefit, with benzodiazepines acting within 30 min while the antidepressants and buspirone require several weeks of treatment before a benefit

becomes apparent. Clinically, the choice of drug needs to consider whether acute management of anxiety is required, e.g. for a patient undergoing a stressful procedure or where they are required in acute situations, versus long-term management where the side effects and abuse liability of the benzodiazepines outweigh their short-term benefits. However, there remain situations where, contrary to the widely used <3-week recommendation, poor response to other treatments leads to their longer-term use despite these risks. Anxiety symptoms are also highly comorbid with depression, and for these patients antidepressants are more likely to provide benefits in the long term even though there is an initial delay in the onset of therapeutic effects.

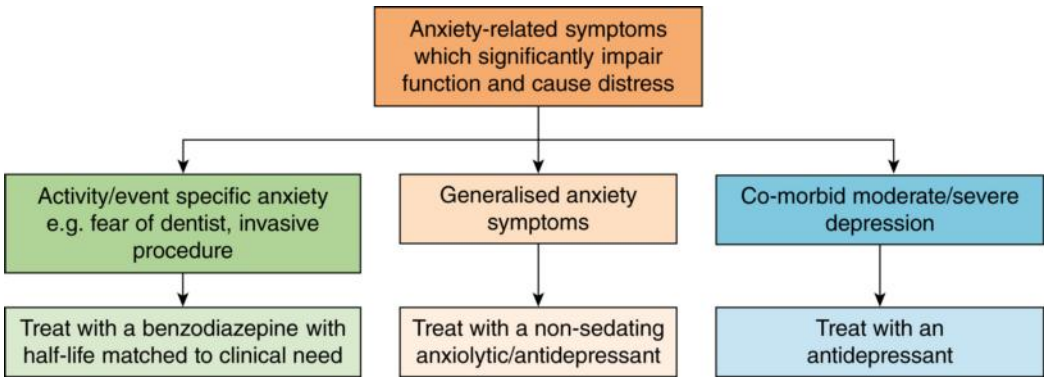

FIG. 45.1 Examples of the different clinical presentations of anxiety disorders and how these may impact on the choice of pharmacological treatment. See British Association for Psychopharmacology guidelines for more detailed discussion, **https://www.bap.org.uk/pdfs/BAP_Guidelines-Anxiety.pdf**

In recent years a number of over-the-counter ‘relaxation’ drinks containing CNS neurotransmitters, their precursors or other hormones and amino acids have been marketed, without any evidence of efficacy. [2]

Measurement Of Anxiolytic Activity

Animal Models Of Anxiety

Anxiety is a state defined by the subjective, self-reported experience of humans and cannot be directly measured in animals; however, many of the behavioural and physiological effects associated with fear or anticipation/expectation of aversive events can be measured in experimental animals. The development of some of the first animal models of anxiety was based on natural behavioural responses which could be modulated by traditional anxiolytic drugs such as benzodiazepines. Methods which capitalised on natural fear behaviours in animals were used to establish pharmacological assays that could be used to predict anxiolytic effects in patients. The ‘elevated plus maze’ and ‘open field test’ were developed to capitalise on this behaviour (**Fig. 45.2**). Rodents spend most of their time in the closed arms or close to the perimeter but administration of benzodiazepine-type anxiolytics reduces time to start exploring and increases the time spent in the open areas but without an increase in motor activity.

An alternative approach is to use learnt behaviours including fear conditioning and conflict tests. Normally, the rat ceases responding or freezes (behavioural inhibition) and an anxiolytic drug reduces this suppressive effect. Other types of psychotropic drug are not effective, nor are analgesic drugs, thus providing some indication of

selective anxiolytic effects. However, these fear-related tests and conflict models are less effective for studying non-sedating anxiolytics. The novelty suppressed feeding test is another conflict-type model and depends on a natural response in rodents to a novel environment, hyponeophagia (suppression of food intake). However it still remains a challenge to the development of new anxiolytic drugs to have animal tests that give a good guide to efficacy in humans, and much ingenuity has gone into developing and validating such tests (for more discussion on animal models for anxiety research see **Campos et al., 2013**, **Ennaceur and Chazot, 2016**).

Quantifying Anxiety In Humans

Diagnosis of anxiety disorders and response to treatment largely depend on subjective self-report questionnaires. Objective methods that directly quantify the physiological and psychological effects of anxiety disorders provide an alternative, and potential more reliable and translational approach. For example, galvanic skin reactions – a measure of sweat secretion – provide a direct measure of autonomic activation in anxiety. Neuropsychological tests, based on computer tasks, have been developed and have revealed that anxiety disorders change a person's responses to certain emotional expressions and words, referred to as affective biases. For example, an anxious patient shows a shift in their attention towards fearful faces referred to as an *attentional bias*. Experimental medicine has also sought to develop human models of anxiety disorders where healthy volunteers are subjected to acute manipulations which generate a transient state of anxiety. An experience akin to a panic attack can

be induced in many subjects by breathing a single inhalation of 35% CO_2 whilst a state more akin to generalised anxiety disorder is triggered by a more prolonged period of inhalation of 7.5% CO_2 (see **Fig. 45.2**).

The challenge remains to develop better human and animal models to study anxiety as well as objective and translational methods to quantify the impacts of anxiety. One example of a translational model is the conflict test described earlier where in humans, substitution of money for food pellets and the use of graded electric shocks as punishment generate similar suppression of responding which is attenuated by administration of the benzodiazepine diazepam although the subjects reported no change in the painfulness of the electric shock.

Drugs Used To Treat Anxiety

The main groups of drugs are as follows:

- Antidepressants (see **Ch. 48** for details). Selective serotonin (5-HT) reuptake inhibitors (SSRIs; e.g. **escitalopram**, **sertraline** and **paroxetine**) and serotonin/noradrenaline reuptake inhibitors (SNRIs; e.g. **venlafaxine and duloxetine**) are effective in the treatment of generalised anxiety disorder, phobias, social anxiety disorder, PTSD and obsessive–compulsive disorder. Older antidepressants (tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs)) are also effective, but a lower side-effect profile favours the use of SSRIs. Some of the newer receptor blocking antidepressants (mirtazapine and

agomelatine) have effects on 5-HT receptors which may contribute to their anxiolytic effects particularly antagonism at 5-HT_2 receptors. These agents have the additional advantage of reducing depression, which is not uncommonly associated with anxiety. The 5-HT_{1A} partial agonist **buspirone**, whilst not an antidepressant, has been used as an anxiolytic and acts via the serotonin system.

- **Benzodiazepines.** Used to treat acute anxiety. Those used to treat anxiety have a long biological half-life (**Table 45.1**). They may be co-administered during stabilisation of a patient on an SSRI and may also be useful in patients who have failed to respond to other treatments.
- **Gabapentin** and **pregabalin (gabapentinoids)** are used to treat general anxiety disorder (**Wensel et al., 2012**), although trial data on gabapentin are limited. Other antiepileptic drugs such as **tiagabine, valproate** and

levetiracetam (see **Ch. 46**) may also be effective in treating generalised anxiety disorder.

- Some atypical antipsychotic agents (see **Ch. 47**) such as **olanzapine**, **risperidone**, **quetiapine** and **ziprasidone** may be effective in generalised anxiety disorder and PTSD.
- β-Adrenoceptor antagonists (e.g. **propranolol**; see **Ch. 15**). These are used to treat some forms of anxiety, particularly where physical symptoms such as sweating, tremor and tachycardia are troublesome. [3] Their effectiveness depends on block of peripheral sympathetic responses rather than on any central effects.

Antidepressants (see **Ch. 48**), antiepileptics (see **Ch. 46**), antipsychotics (see **Ch. 47**) and β-adrenoceptor antagonists (see **Ch. 15**) are described in detail elsewhere in this book. Here we will first focus on how drugs affecting the serotonin system are thought to exert their anxiolytic activity and then discuss in detail the benzodiazepines, the primary use of which is to treat anxiety.

Classes of anxiolytic drugs

- Antidepressant drugs (SSRIs, SNRIs, TCAs and MAOIs, receptor-blocking antidepressants – see **Ch. 48**) are effective anxiolytic agents.
- Benzodiazepines are used for treating acute anxiety and insomnia.
- **Gabapentin** and **pregabalin** drugs have anxiolytic properties.

- **Buspirone** is a 5-hydroxytryptamine $(5\text{-HT})_{1A}$-receptor agonist with anxiolytic activity but little sedative effect.
- Some atypical antipsychotic agents (e.g. **quetiapine**) can be useful to treat some forms of anxiety, but have significant unwanted effects.
- β-Adrenoceptor antagonists (e.g. **propranolol**) are used mainly to reduce physical symptoms of anxiety (tremor, palpitations, etc.); no effect on affective component.

Table 45.1

[a] Another short-acting benzodiazepine, triazolam, has been withdrawn from use in the United Kingdom on account of side effects.

[b] Zolpidem is not a benzodiazepine but acts in a similar manner. Zopiclone and zaleplon are similar.

[c] Due to their long half-life, drowsiness is common on waking.

Delayed Anxiolytic Effect Of Drugs Acting Via Serotonergic Mechanisms

The time course of clinical improvements in anxiety varies for the different classes and this has important implications for their use (see **Fig. 45.1**). The anxiolytic effects of SSRIs (e.g. **escitalopram** and **sertraline**) and, where used, **buspirone** are not immediate but take up to 4 weeks to develop after commencing drug therapy. Recent clinical findings suggest that the main effect of these drugs is to generate an emotional blunting which reduces the subjective

experience of anxiety and this may be linked to their ability to induce an adaptive change in serotonin receptor expression, particularly 5-HT_{1A} receptors.

5-HT_{1A} receptors are expressed on the soma and dendrites of 5-HT-containing neurons, where they function as inhibitory autoreceptors, as well as being expressed on other types of neuron (e.g. noradrenergic locus coeruleus neurons) where, along with other types of 5-HT receptor (see **Ch. 39**), they mediate the postsynaptic actions of 5-HT. Postsynaptic 5-HT_{1A} receptors are highly expressed within the cortico-limbic circuits implicated in emotional behaviour. One theory of how SSRIs and buspirone produce their anxiolytic effect is that over time they induce desensitisation of somatodendritic 5-HT_{1A} autoreceptors, resulting in heightened excitation of serotonergic neurons and enhanced 5-HT release (see **Ch. 48**, **Fig. 48.3**). This might also explain why early in treatment, anxiety can be worsened by these drugs due to the initial activation of 5-HT_{1A} autoreceptors and inhibition of 5-HT release. Drugs with combined 5-HT_{1A} antagonism and SSRI properties have been developed but have not been found to be effective in man, perhaps because they block both 5-HT_{1A} autoreceptors and postsynaptic receptors, the latter effect occluding the beneficial effect of the former. Elevated 5-HT levels may also induce other postsynaptic adaptations. 5-HT_2 receptors have also been implicated, down-regulation of which may be important for anxiolytic action. Drugs with 5-HT_2 and 5-HT_3 receptor antagonist activity are in clinical trials for treating anxiety and the receptor blocking antidepressants mirtazapine and agomelatine (**Ch. 48**) block 5-HT_2 receptors. **Vortioxetine** and **vilazodone** exhibit dual

action inhibiting the serotonin reuptake transporters and acting as agonists at 5-HT_{1A} receptors and therefore may work like an SSRI and buspirone combined.

Antidepressants as anxiolytic drugs

- Anxiolytic effects take days or weeks to develop.
- Antidepressants (selective serotonin reuptake inhibitors (SSRIs), serotonin/noradrenaline reuptake inhibitors SNRIs, tricyclic antidepressants and monoamine oxidase inhibitors (MAOIs) – see **Ch. 48**):
  - effective treatments for generalised anxiety disorder, phobias, social anxiety disorder and post-traumatic stress disorder;
  - may also reduce depression associated with anxiety.

Benzodiazepines And Related Drugs

The first benzodiazepine, **chlordiazepoxide**, was synthesised by accident in 1961, the unusual seven-membered ring having been produced as a result of a reaction that went wrong in the laboratories of Hoffman–La Roche. Its unexpected pharmacological activity was recognised in a routine screening procedure, and benzodiazepines quite soon became the most widely prescribed drugs in the pharmacopoeia.

The basic chemical structure of benzodiazepines consists of a seven-membered ring fused to an aromatic ring, with four main substituent groups that can be modified without loss of activity.

Thousands of compounds have been made and tested, and about 20 are available for clinical use, the most important ones being listed in **Table 45.1**. They are basically similar in their pharmacological actions, although some degree of selectivity has been reported. For example, some, such as **clonazepam**, show anticonvulsant activity with less marked sedative effects. From a clinical point of view, differences in pharmacokinetic behaviour among different benzodiazepines (see **Table 45.1**) are more important than differences in profile of activity. Drugs with a similar structure have been discovered that reverse the effects of the benzodiazepines, for example, **flumazenil** (see later).

The term *benzodiazepine* refers to a distinct chemical structure. Also discussed here are 'Z-drugs' such as **zaleplon**, **zolpidem** and **zopiclone** [4] as well as **abecarnil** – a β-carboline (not licensed for clinical use) – which have different chemical structures but bind to the same sites as the benzodiazepines.

MECHANISM OF ACTION

Benzodiazepines act selectively on $GABA_A$ receptors (see **Ch. 38**), which mediate inhibitory synaptic transmission throughout the CNS. They act as positive allosteric modulators (see **Ch. 2**) to facilitate the opening of γ-aminobutyric acid (GABA)–activated chloride channels thus enhancing the response to GABA (see **Ch. 38**, **Fig. 38.5**). They bind specifically to a modulatory site on the receptor, distinct from the GABA-binding sites, and act allosterically to increase the affinity of GABA for the receptor. Single-channel recordings show an increase in the frequency of channel opening by a given concentration of GABA, but no change in the conductance or

mean open time, consistent with an effect on GABA binding rather than the channel-gating mechanism. Benzodiazepines do not affect receptors for other amino acids, such as glycine or glutamate (see **Fig. 45.3**).

The $GABA_A$ receptor is a ligand-gated ion channel (see **Ch. 3**) consisting of a pentameric assembly of different subunits, the main ones being α, β and γ (see **Ch. 38**). The $GABA_A$ receptor should actually be thought of as a family of receptors as there are six different subtypes of α subunit, three subtypes of β and three subtypes of γ. Although the potential number of combinations is therefore large, certain combinations predominate in the adult brain (see **Ch. 38**). The various combinations occur in different parts of the brain, have different physiological functions and have subtle differences in their pharmacological properties.

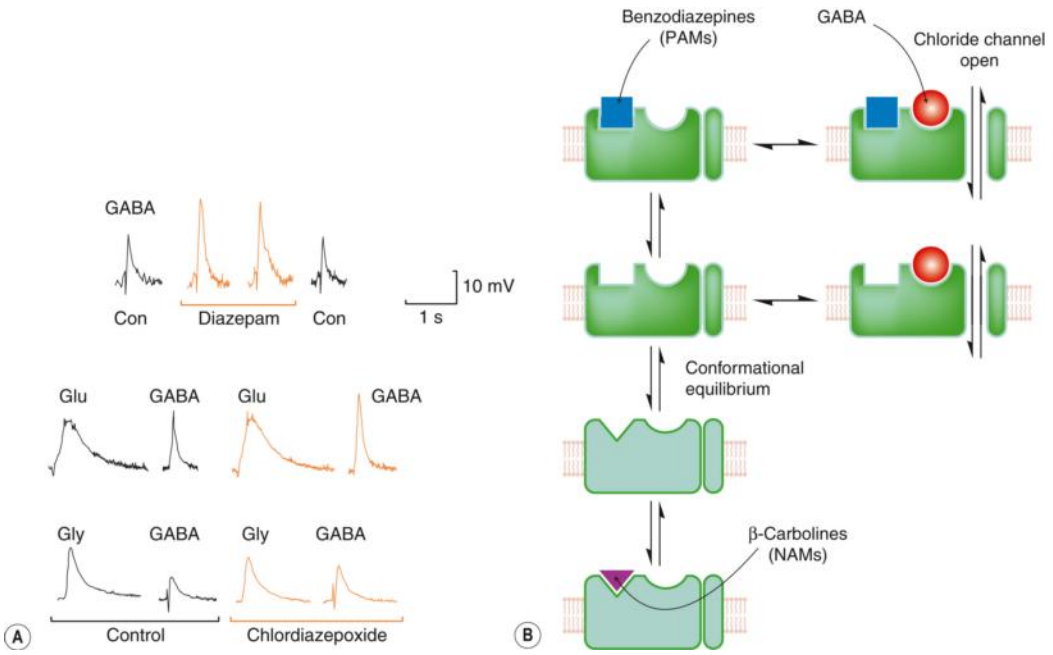

FIG. 45.3 (A) Potentiating effect of benzodiazepines and chlordiazepoxide on the action of GABA.Drugs were applied by iontophoresis to mouse spinal cord neurons grown in tissue culture, from micropipettes placed close to the cells. The membrane was hyperpolarised to −90 mV, and the cells were loaded with Cl^- from the recording microelectrode, so inhibitory amino acids (GABA and glycine (Gly)), as well as excitatory ones (glutamate (Glu)), caused depolarising responses. The potentiating effect of diazepam is restricted to GABA responses, glutamate and glycine responses being unaffected. (B) Model of benzodiazepine/$GABA_A$-receptor interactions. Benzodiazepines and related drugs bind to a modulatory site on the $GABA_A$ receptor distinct

from the GABA-binding site. This mode envisages a conformational equilibrium between states in which the benzodiazepine site binds positive allosteric modulators (PAMs) (i) and negative allosteric modulators (NAMs) (ii). In the latter state, the $GABA_A$ receptor has a much reduced affinity for GABA; consequently the chloride channel remains closed. *Con,* Control; *GABA,* γ-aminobutyric acid.

Benzodiazepines bind across the interface between the α and γ subunits but only to receptors that contain γ2 and α1, α2, α3 or α5 subunits. Genetic approaches have been used to study the roles of different subunits in the different behavioural effects of benzodiazepines. Behavioural analysis of mice with various mutations of the $GABA_A$ receptor subunit indicates that α1-containing receptors mediate the anticonvulsant, sedative/hypnotic and addictive effects but not the anxiolytic effect of benzodiazepines, whereas α2-containing receptors mediate the anxiolytic effect, α2-, α3- and α5-containing receptors mediate muscle relaxation and α1- and α5-containing receptors mediate the amnesic effects (**Tan et al., 2011**).

The obvious next step was to try to develop subunit-selective drugs. Unfortunately, this has proved difficult, due to the structural similarity between the benzodiazepine binding site on different α subunits. The α-subunit selectivity of some benzodiazepines is given in **Table 45.2**. It was hoped that selective efficacy at α2-containing receptors would produce anxiolytic drugs lacking the unwanted effects of sedation and amnesia. However, such

compounds have not translated into human therapeutic agents (**Skolnick, 2012**). **Pagoclone**, reported to be a full agonist at α3 with less efficacy at α1, α2 and α5, has little or no sedative/hypnotic or amnesic actions. Clinical trials of this drug as a treatment for stammering proved unsuccessful; however, it has been suggested that this could form the basis for a new class of social drugs which could deliver the effects of alcohol with less side effects.

Antagonism And Negative Allosteric Modulation

Flumazenil is a benzodiazepine-like compound that competes with benzodiazepines at their binding site on $GABA_A$ receptors but has zero efficacy and so acts as an antagonist. Originally reported to lack effects on behaviour or on drug-induced convulsions when given on its own, subsequent studies found it to possess some 'anxiogenic' and proconvulsant activity which may indicate weak negative allosteric modulatory activity. Flumazenil can be used to reverse the effect of benzodiazepine overdosage (normally used only if respiration is severely depressed), or to reverse the effect of benzodiazepines such as midazolam used for minor surgical procedures. Flumazenil acts quickly and effectively when given by injection, but its action lasts for only about 2 h, so drowsiness tends to return. Convulsions may occur in patients treated with flumazenil, and this is more common in patients receiving TCAs (see **Ch. 48**). Reports that flumazenil improves the mental state of patients with severe liver disease (hepatic encephalopathy) and alcohol intoxication have not been confirmed in controlled trials.

Table 45.2

$GABA_A$-receptor α-subunit selectivity of some therapeutically used benzodiazepines

Drug	Subunit selectivity

Flunitrazepam	α1, α2, α5
Midazolam	α1, α2, α3, α4, α5, α6
Zolpidem	α1
Flumazenil	Antagonist at α1, α2, α3, α4, α5, α6

GABA, γ-aminobutyric acid.

Adapted from **Tan, K.R., Rudolph, U., Lüscher, C., 2011**. Hooked on benzodiazepines: $GABA_A$-receptor subtypes and addiction. Trends Neurosci. 34, 188–197.

Drugs that bind to the benzodiazepine site and exert the opposite effect to that of conventional benzodiazepines (negative allosteric modulators, see **Ch. 2**) produce signs of increased anxiety, panic and convulsions. These include ethyl-β-carboline-3-carboxylate (βCCE) and some benzodiazepine analogues.

Pharmacological Effects And Uses

The main effects of benzodiazepines are:

- reduction of anxiety and aggression;

- induction of sleep (see section on hypnotic drugs);
- reduction of muscle tone;
- anticonvulsant effect;
- anterograde amnesia.

Reduction of anxiety and aggression

Benzodiazepines have rapid anxiolytic effects, reducing anxiety in both humans and animal models following a single dose. With the possible exception of alprazolam (see **Table 45.1**), benzodiazepines do not have antidepressant effects. Benzodiazepines may paradoxically produce an increase in irritability and aggression in some individuals. This appears to be particularly pronounced with the ultrashort-acting drug triazolam (and led to its withdrawal in the United Kingdom and some other countries), and is generally more common with short-acting compounds. It is probably a manifestation of the benzodiazepine withdrawal syndrome, which occurs with all these drugs but is more acute with drugs whose action wears off rapidly.

Benzodiazepines are recommended for treating acute anxiety states, behavioural emergencies and during procedures such as endoscopy. They are also used as premedication before surgery (both medical and dental). Under these circumstances their anxiolytic, sedative and amnesic properties may be beneficial. Intravenous midazolam can be used to induce anaesthesia (see **Ch. 41**).

Reduction of muscle tone

Benzodiazepines reduce muscle tone by a central action on $GABA_A$ receptors, primarily in the spinal cord.

Increased muscle tone is a common feature of anxiety states in humans and may contribute to the aches and pains, including headache, that often trouble anxious patients. The relaxant effect of benzodiazepines may therefore be clinically useful. A reduction of muscle tone appears to be possible without appreciable loss of coordination. However, with intravenous administration in anaesthesia and in overdose when these drugs are being used non-medicinally, airway obstruction may occur. Other clinical uses of muscle relaxants are discussed in **Chapter 14**.

Anticonvulsant effects

All the benzodiazepines have anticonvulsant activity in experimental animal tests. They are highly effective against chemically induced convulsions caused by **pentylenetetrazol**, **bicuculline** and similar drugs that act by blocking $GABA_A$ receptors (see Chs **38** and **46**) but less so against electrically induced convulsions.

Clonazepam (see **Table 45.1**), **diazepam, midazolam** and **lorazepam** are used to treat epilepsy (see **Ch. 46**). They can be given intravenously to control life-threatening seizures in status epilepticus. Diazepam can be administered rectally to children to control acute seizures. Tolerance develops to the anticonvulsant actions of benzodiazepines.

Anterograde amnesia

Benzodiazepines prevent memory of events experienced while under their influence, an effect not seen with other CNS depressants. Minor surgical or invasive procedures can thus be performed without leaving unpleasant memories. **Flunitrazepam**

(better known to the general public by one of its trade names, Rohypnol) is infamous as a date rape drug and victims frequently have difficulty in recalling exactly what took place during the attack.

Amnesia is thought to be due to benzodiazepines binding to $GABA_A$ receptors containing the α5 subunit. α5-Knock-out mice show an enhanced learning and memory phenotype. This raises the possibility that an α5 subunit-selective negative allosteric modulator could be memory enhancing.

Pharmacokinetic aspects

Benzodiazepines are well absorbed when given orally, usually giving a peak plasma concentration in about 1 h. Some (e.g. oxazepam, lorazepam) are absorbed more slowly. They bind strongly to plasma protein, and their high lipid solubility causes many of them to accumulate gradually in body fat. They are normally given by mouth but can be given intravenously (e.g. diazepam in status epilepticus, midazolam in anaesthesia), buccally or rectally. Intramuscular injection often results in slow absorption.

Benzodiazepines are all metabolised and eventually excreted as glucuronide conjugates in the urine. They vary greatly in duration of action and can be roughly divided into short-, medium- and long-acting compounds (see **Table 45.1**). Duration of action influences their use, short-acting compounds being useful hypnotics with reduced hangover effect on wakening, long-acting compounds being more useful for use as anxiolytic and anticonvulsant drugs. Several are converted to active metabolites such as *N*-desmethyldiazepam (**nordazepam**), which has a half-life of about 60 h, and which accounts for the tendency of many benzodiazepines to produce

cumulative effects and long hangovers when they are given repeatedly. The short-acting compounds are those that are metabolised directly by conjugation with glucuronide.

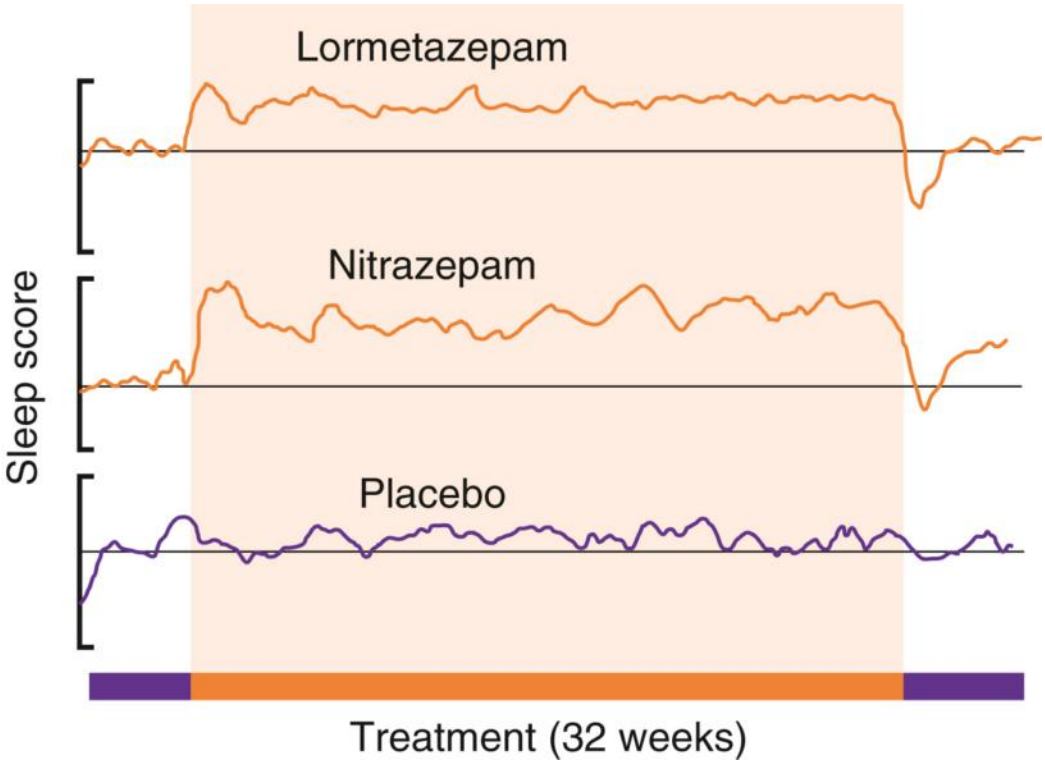

FIG. 45.4 Effects of long-term benzodiazepine treatment on sleep quality.A group of 100 poor sleepers were given, under double-blind conditions, lormetazepam 5 mg, nitrazepam 2 mg or placebo nightly for 24 weeks, the test period being preceded and followed by 4 weeks of placebo treatment. They were asked to assess, on a subjective rating scale, the quality of sleep during each night, and the results are expressed as a 5-day rolling average of these scores. The improvement in sleep quality was maintained during the 24-week test period, and was followed by a 'rebound' worsening of sleep when the test period ended. From Oswald, I., et al., 1982. Br. Med. J. 284, 860–864.

Advancing age affects the rate of oxidative reactions more than that of conjugation reactions. Thus the effect of the long-acting benzodiazepines tends to increase with age, and it is common for drowsiness and confusion to develop insidiously for this reason. [5]

Unwanted Effects

These may be divided into:

- toxic effects resulting from acute overdosage;
- unwanted effects occurring during normal therapeutic use;
- tolerance and dependence.

Acute toxicity

Benzodiazepines in acute overdose are considerably less dangerous than other anxiolytic/hypnotic drugs. Because such agents are often used in attempted suicide, this is an important advantage. In overdose, benzodiazepines cause prolonged sleep, without serious depression of respiration or cardiovascular function. However, in the presence of other CNS depressants, particularly alcohol and opioids, benzodiazepines can cause severe, even life-threatening, respiratory depression. This is a frequent problem when benzodiazepines are used non medicinally (see Chs **50** and **59**). The availability of an effective antagonist, flumazenil, means that the effects of an acute overdose can be counteracted, [6] which is not possible for most CNS depressants.

Side effects during therapeutic use

The main side effects of benzodiazepines are drowsiness, confusion, amnesia and impaired coordination, which considerably impairs

manual skills such as driving performance. Benzodiazepines enhance the depressant effect of other drugs, including alcohol, in a more than additive way. The long and unpredictable duration of action of many benzodiazepines is important in relation to side effects. Long-acting drugs such as nitrazepam are rarely used as hypnotics, and even shorter-acting compounds such as lorazepam can produce a substantial day-after impairment of job performance and driving skill.

Tolerance and dependence

Tolerance (i.e. a gradual escalation of dose needed to produce the required effect) occurs with all benzodiazepines, as does dependence, which is their main drawback. Tolerance appears to represent a change at the receptor level, but the mechanism is not well understood.

At the receptor level, the degree of tolerance will be governed both by the number of sites occupied (i.e. the dose) and the duration of site occupancy (which may vary according to the therapeutic use). Therefore marked tolerance develops when benzodiazepines are used continuously to treat epilepsy, whereas less tolerance occurs to the sleep-inducing effect of short-acting agents when the subject is relatively drug free during the day. It is not clear to what degree tolerance develops to the anxiolytic effect.

Benzodiazepines produce dependence, and this is a major problem and the main reason they are not recommended as a first-line treatment for anxiety disorders. In human subjects and patients, abrupt cessation of benzodiazepine treatment after weeks or months causes a rebound heightened anxiety, together with

tremor, dizziness, tinnitus, weight loss and disturbed sleep due to enhanced rapid eye movement (REM) sleep. It is recommended that benzodiazepines be withdrawn gradually by stepwise lowering of the dose. Withdrawal after chronic administration causes physical symptoms, namely nervousness, tremor, loss of appetite and sometimes convulsions. [7] The withdrawal syndrome is slower in onset than with opioids, probably because of the long plasma half-life of most benzodiazepines. With diazepam, the withdrawal symptoms may take up to 3 weeks to become apparent. Short-acting benzodiazepines cause more abrupt withdrawal effects.

The physical and psychological withdrawal symptoms make it difficult for patients to give up taking benzodiazepines, but craving (i.e. severe psychological dependence that outlasts the physical withdrawal syndrome), which occurs with many drugs of abuse (see **Ch. 50**), is less of an issue.

Non-Medicinal Use

Benzodiazepines are frequently used for non-medicinal purposes, often taken in combination with other drugs such as opioids or alcohol (see **Ch. 50**). Most illicit use comes from diversion of prescribed benzodiazepines although illicitly synthesised etizolam has recently become widely available, especially in Scotland. They induce a feeling of calm and reduced anxiety, with users describing a dream state where they are cushioned from reality. The risk of overdose is greatly increased when used in combination with alcohol. Tolerance and physical dependence occur as described earlier.

Benzodiazepines

- Act by binding to a specific allosteric modulatory site on the $GABA_A$ receptor, thus enhancing the inhibitory effect of GABA. Subtypes of the $GABA_A$ receptor exist in different regions of the brain and differ in their functional effects.
- Anxiolytic benzodiazepines are agonists at this modulatory site. Other benzodiazepines (e.g. **flumazenil**) are antagonists or weak negative allosteric modulators and prevent the actions of the anxiolytic benzodiazepines. Strong negative allosteric modulators (not used clinically) are anxiogenic and proconvulsant.
- Anxiolytic effects are mediated by $GABA_A$ receptors containing the α2 subunit, while sedation occurs through those with the α1 subunit.
- Benzodiazepines cause:
  - reduction of anxiety and aggression
  - sedation, leading to improvement of insomnia
  - muscle relaxation and loss of motor coordination
  - suppression of convulsions (antiepileptic effect)
  - anterograde amnesia
- Differences in the pharmacological profile of different benzodiazepines are minor; **clonazepam** appears to have more anticonvulsant action in relation to its other effects.
- Benzodiazepines are active orally and differ mainly in respect of their duration of action. Short-acting agents (e.g. **lorazepam** and **temazepam**, half-lives 8–12 h) are

metabolised to inactive compounds and are used mainly as sleeping pills. Some long-acting agents (e.g. **diazepam** and **chlordiazepoxide**) are converted to a long-lasting active metabolite (**nordazepam**).

- Some are used intravenously, for example, **diazepam and lorazepam** in status epilepticus, **midazolam** in anaesthesia.
- Benzodiazepines are relatively safe in overdose. Their main disadvantages are interaction with alcohol, long-lasting 'hangover' effects and the development of tolerance and physical dependence – characteristic withdrawal syndrome on cessation of use.

Gabapentinoids

Originally developed as drugs to treat epilepsy the gabapentinoid, **pregabalin** is now a second-line anxiolytic drug used in patients who do not respond to a serotonergic drug or patients who cannot tolerate the side effects of SSRI/SNRIs (**Baldwin et al., 2011**). Their clinical effects develop more quickly than those of the SSRIs and are usually apparent within a week of starting treatment but they are not as rapid as the effects of the benzodiazepines. They also have sedative effects. In patients with generalised anxiety disorder, pregabalin has been found to also improve associated symptoms of depression and reduce sleep disturbance. Pregabalin is generally well tolerated but can cause drowsiness and dizziness although these side effects may be better tolerated than some other treatment options. Abrupt cessation is associated with withdrawal

suggesting adaptive changes develop and there is an increasing awareness of the non-medicinal potential of the gabapentinoids particularly in those with a history of other substance use disorder (see **Ch. 50**). Unlike many other anxiolytics, pregabalin is excreted unchanged which may be advantageous in patients with hepatic impairments but not those with renal disease.

Other Potential Anxiolytic Drugs

PTSD is caused by experiencing stressful, frightening or distressing events. Sufferers often relive the traumatic events through nightmares and flashbacks, and may experience feelings of isolation, irritability and guilt. Symptoms include anxiety, depression and insomnia. If treatment with psychological therapies is unsuccessful then drug therapy with anxiolytic/antidepressant drugs (see **Ch. 48**) (e.g. **paroxetine**, **sertraline** and **mirtazapine)** may be tried. In addition, hypnotic agents (see later) may aid sleeping.

A recent development has been the recognition that the unpleasant, negative memories that underlie fear are not necessarily permanent. When such memories are reactivated (recalled) they return transiently to a labile state that can be disrupted. In humans, propranolol administered before memory reactivation may erase the negative emotions associated with traumatic memories (see **AlOkda et al., 2019**). Ketamine, psilocybin, lysergic acid diethylamide (LSD), dimethyltryptamine (found in ayahuasca) and 3,4-methylenedioxymethamphetamine (MDMA or ecstasy) may have a similar effect (**Glavonic et al.,**

2022). Disrupting unpleasant memories in this way may provide a new treatment for PTSD.

Besides the GABA and 5-HT mechanisms discussed before, many other transmitters and hormones have been implicated in anxiety and panic disorders, particularly noradrenaline, glutamate, melatonin, corticotrophin-releasing factor, cholecystokinin (CCK), substance P, neuropeptide Y, galanin, orexins and neurosteroids. The melatonin agonist agomelatine has been licensed to treat depression (**Ch. 48**), and noradrenaline and serotonin reuptake inhibitors are used as an alternative to SSRIs but other potential targets have yet to yield new treatments

Clinical use of drugs as anxiolytics

- Antidepressants (selective serotonin reuptake inhibitors (SSRIs) or serotonin/noradrenaline reuptake inhibitors (SNRIs)) are now the main drugs used to treat anxiety, especially when this is associated with depression. Their effects are slow in onset (>2 weeks).
- Benzodiazepines are now recommended only as a short-term measure, usually limited to acute relief of severe and disabling anxiety.

Drugs Used To Treat Insomnia (Hypnotic Drugs)

Insomnia can be *transient*, in people who normally sleep well but have to do shift work or have jet lag; *short-term*, usually due to

illness or emotional upset; or *chronic*, where there is an underlying cause such as anxiety, depression, drug use disorder, pain, pruritus or dyspnoea. While in anxiety and depression the underlying psychiatric condition should be treated, improvement of sleep patterns can improve the underlying condition. The drugs used to treat insomnia are:

- Benzodiazepines. Short-acting benzodiazepines (e.g. lorazepam and temazepam) are used for treating insomnia as they have little hangover effect. The short half-life gives more time drug free so reducing the development of tolerance. Diazepam, which is longer-acting, can be used to treat insomnia associated with daytime anxiety.
- Z-drugs (e.g. **zaleplon**, **zolpidem** and **zopiclone**). Although chemically distinct, these short-acting hypnotics act at the benzodiazepine site on $GABA_A$ receptors containing the α1 subunit. They lack appreciable anxiolytic activity. **Eszopiclone** is the active stereoisomer of zopiclone.
- **Clomethiazole.** It acts as a positive allosteric modulator of $GABA_A$ receptors acting at a site distinct from the benzodiazepines.
- Melatonin receptor agonists. **Melatonin**, **ramelteon** and **tasimelteon** are agonists at MT_1 and MT_2 receptors (see **Ch. 39**). They are effective in treating insomnia in the elderly and autistic children as well as in totally blind individuals.
- Orexin receptor antagonist. **Suvorexant** is an antagonist of OX_1 and OX_2 receptors which mediate the actions of the

orexins, peptide transmitters in the CNS that are important in setting diurnal rhythm. Orexin levels are normally high in daylight and low at night, so the drug reduces wakefulness.

- Antihistamines [8] (see **Ch. 25**; e.g. **diphenhydramine** and **promethazine**) can be used to induce sleep. They are included in various over-the-counter preparations. **Mirtazapine** is a receptor blocking antidepressant (see **Ch. 48**) with histamine H_1- and H_2-receptor antagonist properties and many of the older antidepressants (TCAs and MAOIs) as well as some antipsychotic drug (see **Table 47.1**) include H_1 antagonism and can benefit insomnia.
- Miscellaneous other drugs (e.g. **chloral hydrate** and **meprobamate**). They are no longer recommended, but therapeutic habits die hard and they are occasionally used.

Induction Of Sleep By Benzodiazepines

Benzodiazepines decrease the time taken to get to sleep, and increase the total duration of sleep, although the latter effect occurs only in subjects who normally sleep for less than about 6 h each night. With agents that have a short duration of action (e.g. zolpidem or temazepam), a pronounced hangover effect on wakening can be avoided.

On the basis of electroencephalography measurements, several levels of sleep can be recognised. Of particular psychological importance are REM sleep, which is associated with dreaming, and slow-wave sleep, which corresponds to the deepest level of sleep when the metabolic rate and adrenal steroid secretion are at their lowest and the secretion of growth hormone is at its highest (see

Ch. 33). Most hypnotic drugs reduce the proportion of REM sleep, although benzodiazepines affect it less than other hypnotics, and zolpidem least of all. Artificial interruption of REM sleep causes irritability and anxiety, even if the total amount of sleep is not reduced, and the lost REM sleep is made up for at the end of such an experiment by a rebound increase. The same rebound in REM sleep is seen at the end of a period of administration of benzodiazepines or other hypnotics. The proportion of slow-wave sleep is significantly reduced by benzodiazepines, although growth hormone secretion is unaffected.

Fig. 45.4 shows the improvement of subjective ratings of sleep quality produced by a benzodiazepine, and the rebound decrease at the end of a 32-week period of drug treatment. It is notable that, although tolerance to objective effects such as reduced sleep latency occurs within a few days, this is not obvious in the subjective ratings.

Benzodiazepines are now, however, only recommended for short courses of treatment of insomnia. Tolerance develops over 1–2 weeks with continuous use, and on cessation rebound insomnia and withdrawal occur.

Hypnotic drugs

- Drugs that potentiate the action of GABA at $GABA_A$ receptors (e.g. benzodiazepines, **zolpidem**, **zopiclone**, **zaleplon** and **clomethiazole**) are used to induce sleep.
- Drugs with shorter half-lives in the body reduce the incidence of hangover the next morning.

- Drugs with H_1-receptor antagonist properties induce sedation and sleep.
- Drugs with novel mechanisms of action have been developed, e.g. melatonin receptor agonists and orexin receptor antagonists.

Clinical use of hypnotics ('sleeping tablets')

- The cause of insomnia should be established before administering hypnotic drugs. Common causes include alcohol or drug use disorder (see **Ch. 50**) and physical or psychiatric disorders (especially depression).
- Tricyclic antidepressants (see **Ch. 48**) cause drowsiness, so can kill two birds with one stone if taken at night by depressed patients with sleep disturbance.
- Optimal treatment of chronic insomnia is often by changing behaviour (e.g. increasing exercise, staying awake during the day) rather than with drugs.
- Benzodiazepines should be used only for short periods (<4 weeks) and for severe insomnia. They can be useful for a few nights when transient factors such as admission to hospital, jet lag or an impending procedure cause insomnia.
- Drugs used to treat insomnia include:
  - benzodiazepines (e.g. **temazepam**) and related drugs (e.g. **zolpidem**, **zopiclone**, which also act at the benzodiazepine binding site);

– **chloral hydrate** and **triclofos**, which were used formerly in children, but this is seldom justified;
– sedating antihistamines (e.g. **promethazine**), which cause drowsiness (see **Ch. 25**) are less suitable for treating insomnia. They can impair performance the next day.

QUESTIONS

QUESTION 45.1

Benzodiazepines were discovered serendipitously but have proven to be effective anxiolytic agents.

Which of the following statements about the pharmacological actions of benzodiazepines is correct?

OPTIONS:

A. They bind orthosterically to $GABA_A$ receptors to increase the duration of channel opening.

B. The anxiolytic effects of benzodiazepines are largely mediated through binding to α_1 subunits.

C. Negative allosteric modulators can show anxiogenic activity.

D. β-carbolines are endogenous positive allosteric modulators.

E. Benzodiazepines are beneficial as anxiolytics as they have a short half-life.

QUESTION 45.2

Benzodiazepines are used effectively for the treatment of acute anxiety and, compared with other anxiolytic/hypnotic agents, have a good safety profile.

Which of the following statements about potential unwanted effects of benzodiazepines is incorrect?

OPTIONS:

A. Tolerance may occur due to changes in receptor subunit expression.

B. Dependence manifests as physical and psychological withdrawal symptoms.

C. Rapid withdrawal can result in weight loss and sleep disturbance.

D. Benzodiazepines enhance the depressant effects of alcohol.

E. Cardiac dysregulation is associated with overdose.

ANSWERS

ANSWER 45.1

RATIONALE:

A. Benzodiazepines bind to allosteric sites to facilitate the binding of GABA and the opening of the channel but do not affect its conductance or duration.

B. The anxiolytic effects of benzodiazepines are mediated through α_2 subunit binding.

C.

D. Endogenous compounds isolated from the brain include β-carbolines which have been shown to be negative allosteric modulators, increasing anxiety.

E. Benzodiazepines used to treat anxiety have a long biological half-life but are preferentially only used short-term due to side effects and dependence.

CORRECT ANSWER WITH EXPLANATION:

C. Negative allosteric modulators can show anxiogenic activity.

Antagonists that compete for the benzodiazepine binding site act as negative allosteric modulators and can produce signs of increased anxiety and convulsions.

ANSWER 45.2

RATIONALE:

A. The mechanisms of tolerance are not fully understood but may involve a selective loss of membrane expression of α_2 subunit-containing receptors.

B. Rapid withdrawal of long-term benzodiazepine use can lead to a range of physical and psychological symptoms, including rebound anxiety.

C. Rapid withdrawal of long-term benzodiazepine use can lead to a range of physical and psychological symptoms, including weight loss and enhanced rapid eye movement (REM) sleep.

D. The risk of overdose is enhanced with concomitant ingestion of alcohol, particularly respiratory depression.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Cardiac dysregulation is associated with overdose.

In overdose, taken alone, benzodiazepines generally cause prolonged sleep and do not cause severe respiratory depression or cardiac dysregulation.

---

[1] DSM-5: Diagnostic and Statistical Manual of Mental Disorders. fifth ed. American Psychiatric Association, Washington, DC, 2013.

[2] Because 'relaxation' drinks are classified as dietary supplements they are not subject to the same efficacy and safety tests as drugs (see Editorial in Nature Neuroscience, 2012, vol. 15, p. 497).

[3] β-Blockers are sometimes used by actors and musicians to reduce the symptoms of stage fright, but their use by snooker players to minimise tremor is banned as unsportsmanlike.

4 Z-drugs are used primarily to induce sleep and so should perhaps be called ‘Zzzzzz drugs’.

5 At the age of 91 years, the grandmother of one of the authors was growing increasingly forgetful and mildly dotty, having been taking nitrazepam for insomnia regularly for years. To the author’s lasting shame, it took a canny general practitioner to diagnose the problem. Cancellation of the nitrazepam prescription produced a dramatic improvement.

6 In practice, patients are usually left to sleep it off, because there is a risk of seizures with flumazenil; however, flumazenil may be useful diagnostically to rule out coma of other causes.

7 Withdrawal symptoms can be more severe. A relative of one of the authors, advised to stop taking benzodiazepines after 20 years, suffered hallucinations and one day tore down all the curtains, convinced that they were on fire.

8 This is an interesting example of an initial unwanted side effect – sedation is undesired when treating hay fever – subsequently becoming a therapeutic use.

46: Antiepileptic drugs

Overview

In this chapter we describe the nature of epilepsy, the neurobiological mechanisms underlying it and the animal models that can be used to study it. We then proceed to describe the various classes of drugs that are used to treat it, the mechanisms by which they work and their pharmacological characteristics.

Centrally acting muscle relaxants are discussed briefly at the end of the chapter.

Introduction

Epilepsy is a very common disorder, characterised by *seizures*, which take various forms and result from episodic neuronal discharges, with the form of the seizure depending on the part of the brain affected. Epilepsy affects 0.5%–1% of the population, i.e. ~50 million people worldwide. It may be genetic in origin (often referred to as idiopathic) or develop after brain damage, such as trauma, stroke, infection or tumour growth, or other kinds of neurological disease. In many instances the cause is unknown. Epilepsy is treated mainly with drugs, although brain surgery may be used for suitable severe cases. Current antiepileptic drugs are effective in controlling seizures in about 70% of cases, but their use is often limited by side effects. In addition to their use in patients with epilepsy, antiepileptic drugs are used to treat or prevent

convulsions caused by other brain disorders, for example trauma (including following neurosurgery), infection (as an adjunct to antibiotics), brain tumours and stroke. For this reason, they are sometimes termed *anticonvulsants* rather than *antiepileptics*. Increasingly, some antiepileptic drugs have been found to have beneficial effects in non-convulsive disorders such as neuropathic pain (see **Ch. 43**), bipolar depression (see **Ch. 48**) and anxiety (see **Ch. 45**). Many new antiepileptic drugs have been developed over the past 30 years in attempts to improve efficacy and side-effect profiles. Improvements have been steady rather than spectacular, and epilepsy remains a difficult problem.

The Nature of Epilepsy

The term *epilepsy* is used to define a group of neurological disorders, all of which exhibit periodic seizures. Epilepsy may be genetic in origin or result from structural, infectious, metabolic and immune insults. For information on the underlying causes of epilepsy see **Shorvon et al. (2019)**. As explained later, not all seizures involve convulsions. Seizures are associated with episodic high-frequency discharge of impulses by a group of neurons (sometimes referred to as the *focus*) in the brain. What starts as a local abnormal discharge may then spread to other areas of the brain. The site of the primary discharge and the extent of its spread determine the symptoms that are produced, which range from a brief lapse of attention to a full convulsive seizure lasting for several minutes, as well as odd sensations or behaviours. The particular symptoms produced depend on the function of the region of the brain that is affected. Thus, involvement of the motor cortex causes

convulsions, involvement of the hypothalamus causes peripheral autonomic discharge, and involvement of the reticular formation in the upper brain stem leads to loss of consciousness.

Abnormal electrical activity during and following a seizure can be detected by electroencephalography (EEG) recording from electrodes distributed over the surface of the scalp. Various types of seizure can be recognised on the basis of the nature and distribution of the abnormal discharge (**Fig. 46.1**). Modern brain imaging techniques, such as magnetic resonance imaging and positron emission tomography, are now routinely used in the evaluation of patients with seizures (**Fig. 46.2**) (**Bernasconi et al., 2019**).

Types of Epilepsy

The clinical classification of epilepsy is done on the basis of the characteristics of the seizure rather than on the cause or underlying pathology. There are two major seizure categories, namely *partial* (localised to part of the brain) and *generalised* (involving the whole brain).

Partial Seizures

Partial (focal) seizures are those in which the discharge begins locally and often remains localised. The symptoms depend on the brain region or regions involved, and include involuntary muscle contractions, abnormal sensory experiences or autonomic discharge, or the effects on mood and behaviour – often termed *psychomotor epilepsy* – which may arise from a focus within a temporal lobe. The EEG discharge in this type of epilepsy is normally confined to one hemisphere (see **Fig. 46.1D**). Partial seizures can often be attributed to local cerebral lesions, and their

incidence increases with age. In complex partial seizures, loss of consciousness may occur at the outset of the attack, or somewhat later, when the discharge has spread from its site of origin to regions of the brain stem reticular formation. In some individuals, a partial seizure can, during the seizure, become generalised when the abnormal neuronal activity spreads across the whole brain.

An epileptic focus in the motor cortex results in attacks, sometimes called *Jacksonian epilepsy*, [1] consisting of repetitive jerking of a particular muscle group, beginning on one side of the body, often in the thumb, big toe or angle of the mouth, which spreads and may involve much of the body within about 2 min before dying out. The patient loses voluntary control of the affected parts of the body but does not necessarily lose consciousness. In *psychomotor epilepsy* the attack may consist of stereotyped purposive movements such as rubbing or patting movements, or much more complex behaviour such as dressing, walking or hair combing. The seizure usually lasts for a few minutes, after which the patient recovers with no recollection of the event. The behaviour during the seizure can be bizarre and accompanied by a strong emotional response.

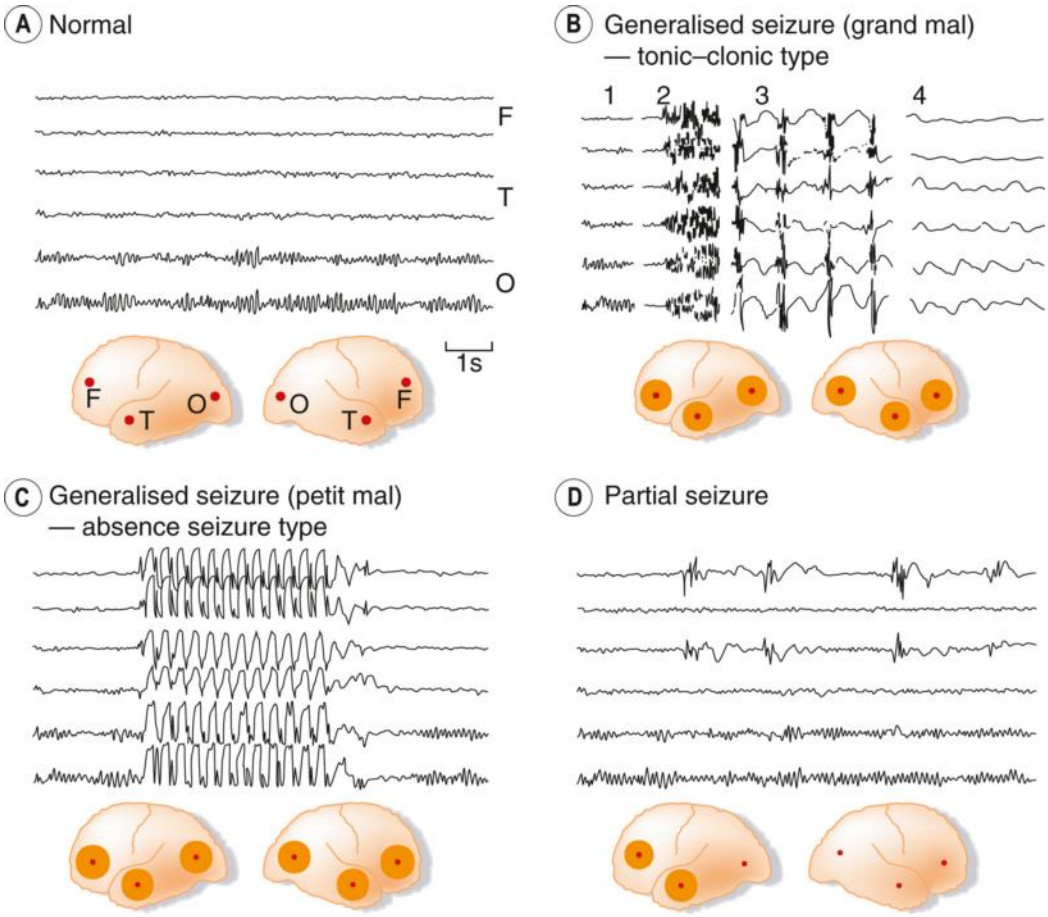

FIG. 46.1 Electroencephalography (EEG) records in epilepsy.(A) Normal EEG recorded from frontal *(F)*, temporal *(T)* and occipital *(O)* sites on both sides, as shown in the inset diagram. The α rhythm (10/s) can be seen in the occipital region. (B) Sections of EEG recorded during a generalised tonic–clonic (grand mal) seizure: *1*, normal record; *2*, onset of tonic phase; *3*, clonic phase; *4*, postconvulsive coma. (C) Generalised absence seizure (petit mal) showing sudden brief episode of 3/s 'spike-and-wave' discharge. (D) Partial seizure with synchronous abnormal discharges in left frontal and temporal

regions. From Eliasson, S.G., et al., 1978. Neurological Pathophysiology, second ed. Oxford University Press, New York.

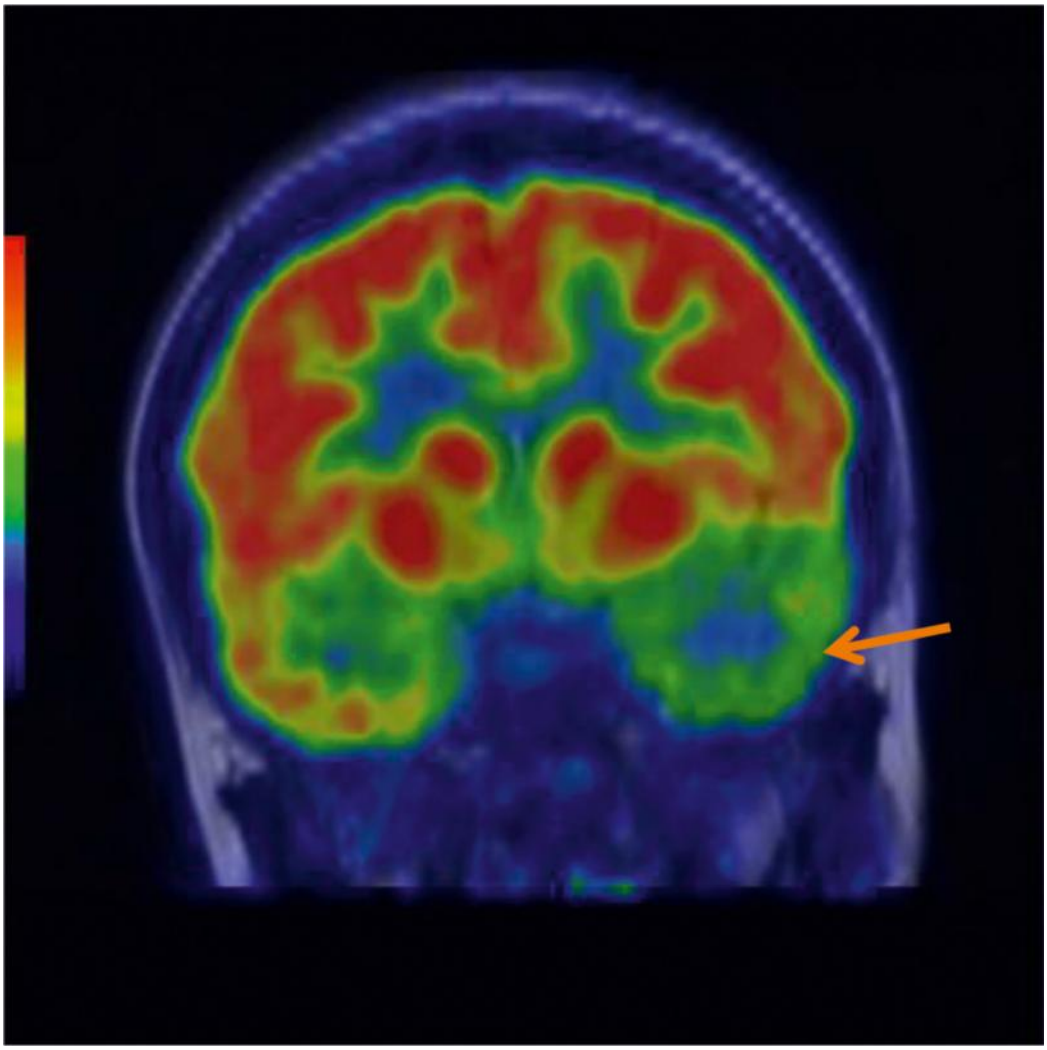

FIG. 46.2 Positron emission tomography (PET) image using [^{18}F]-fluoro-2-deoxyglucose (FDG) of the brain of a female patient suffering from temporal lobe epilepsy.The interictal area of hypometabolism in the left temporal lobe *(arrow)* is suggestive of the site of the epileptic focus. Image kindly provided by Prof. John Duncan and Prof. Peter Ell, UCL Institute of Neurology, London.

Generalised Seizures

Generalised seizures involve the whole brain, including the reticular system, thus producing abnormal electrical activity throughout both hemispheres. Immediate loss of consciousness is characteristic of generalised seizures. There are a number of types of generalised seizure – two important categories are *tonic–clonic* seizures (formerly referred to as grand mal, see **Fig. 46.1B**) and *absence seizures* (petit mal, see **Fig. 46.1C**); others include myoclonic, tonic, atonic and clonic seizures.

A *tonic–clonic seizure* consists of an initial strong contraction of the whole musculature, causing a rigid extensor spasm and an involuntary cry. Respiration stops, and defecation, micturition and salivation often occur. This tonic phase lasts for about 1 min, during which the face is suffused and becomes blue (an important clinical distinction from syncope, the main disorder from which epileptic seizures must be distinguished, where the face is ashen pale), and is followed by a series of violent, synchronous jerks that gradually die out in 2–4 min. The patient stays unconscious for a few more minutes and then gradually recovers, feeling ill and confused. Injury may occur during the convulsive episode. The EEG shows generalised continuous high-frequency activity in the tonic phase and an intermittent discharge in the clonic phase (see **Fig. 46.1B**).

Absence seizures occur in children; they are much less dramatic but may occur more frequently (many seizures each day) than tonic–clonic seizures. The patient abruptly ceases whatever he or she was doing, sometimes stopping speaking in mid-sentence, and stares vacantly for a few seconds, with little or no motor disturbance. Patients are unaware of their surroundings and recover

abruptly with no after-effects. The EEG pattern shows a characteristic rhythmic discharge during the period of the seizure (see **Fig. 46.1C**). The rhythmicity appears to be due to oscillatory feedback between the cortex and the thalamus, the special properties of the thalamic neurons being dependent on the T-type calcium channels that they express. The pattern differs from that of partial seizures, where a high-frequency asynchronous discharge spreads out from a local focus. Accordingly, the drugs used specifically to treat absence seizures act mainly by blocking T-type calcium channels, whereas drugs effective against other types of epilepsy act mainly by blocking sodium channels or enhancing GABA-mediated inhibition.

A particularly severe kind of epilepsy, *Lennox–Gastaut syndrome*, occurs in children and is associated with progressive intellectual disability, possibly a reflection of excitotoxic neurodegeneration (see **Ch. 40**).

As detection techniques have advanced it has become increasingly evident that many forms of epilepsy result from genetic abnormalities (**Perucca et al., 2020**). While some are due to a single genetic mutation, most result from polygenetic mutations. A number of genes associated with familial epilepsies encode neuronal ion channels closely involved in controlling action potential generation (see **Ch. 4**), such as voltage-gated sodium and potassium channels, GABA receptors and nicotinic acetylcholine receptors (see **Weber and Lerche, 2008**). Some other genes encode proteins that interact with ion channels.

Status epilepticus refers to a seizure that lasts longer than 5 min, or having more than one seizure within a 5-min period, without

returning to a normal level of consciousness between episodes. This is a medical emergency that may lead to permanent brain damage or death.

Neural Mechanisms and Animal Models of Epilepsy

The underlying neuronal abnormality in epilepsy is poorly understood. In general, excitation will naturally tend to spread throughout a network of interconnected neurons but is normally prevented from doing so by inhibitory mechanisms. Thus *epileptogenesis* can arise if excitatory transmission is facilitated or inhibitory transmission is reduced (exemplified by $GABA_A$ receptor antagonists causing convulsions; see **Ch. 38**). In certain respects, epileptogenesis resembles long-term potentiation (see **Ch. 38**), and similar types of use-dependent synaptic plasticity may be involved. Neurons from which the epileptic discharge originates display an unusual type of electrical behaviour, termed the paroxysmal depolarising shift (PDS), during which the membrane potential suddenly decreases by about 30 mV and remains depolarised for up to a few seconds before returning to normal. A burst of action potentials often accompanies this depolarisation (**Fig. 46.3**). This event probably results from the abnormally exaggerated and prolonged action of an excitatory transmitter. Activation of *N*-methyl-D-aspartate (NMDA) receptors (see **Ch. 38**) produces 'plateau-shaped' depolarising responses very similar to the PDS.

Because detailed studies are difficult to carry out on epileptic patients, many different animal models of epilepsy have been investigated (see **Bialer and White, 2010**; **Grone and Baraban, 2015**). Genetically altered mouse strains have been

reported that show spontaneous seizures. They include knock-out mutations of various ion channels, receptors and other synaptic proteins. Local application of penicillin crystals to the cerebral cortex results in focal seizures, probably by interfering with inhibitory synaptic transmission. Convulsant drugs (e.g. **pentylenetetrazol** [PTZ]) are often used, as are seizures caused by electrical stimulation of the whole brain. In the *kainate model* a single injection of the glutamate receptor agonist kainic acid into the amygdaloid nucleus of a rat can produce spontaneous seizures 2–4 weeks later that continue indefinitely. This is believed to result from excitotoxic damage to inhibitory neurons.

In the *kindling model*, brief low-intensity electrical stimulation of certain regions of the limbic system, such as the amygdala, normally produces no seizure response but if repeated daily for several days, the response gradually increases until very low levels of stimulation will evoke a full seizure, and eventually seizures occur spontaneously. This kindled state can persist indefinitely but is prevented by NMDA receptor antagonists or deletion of the neurotrophin receptor, TrkB, consistent with a mechanism involving synaptic plasticity.

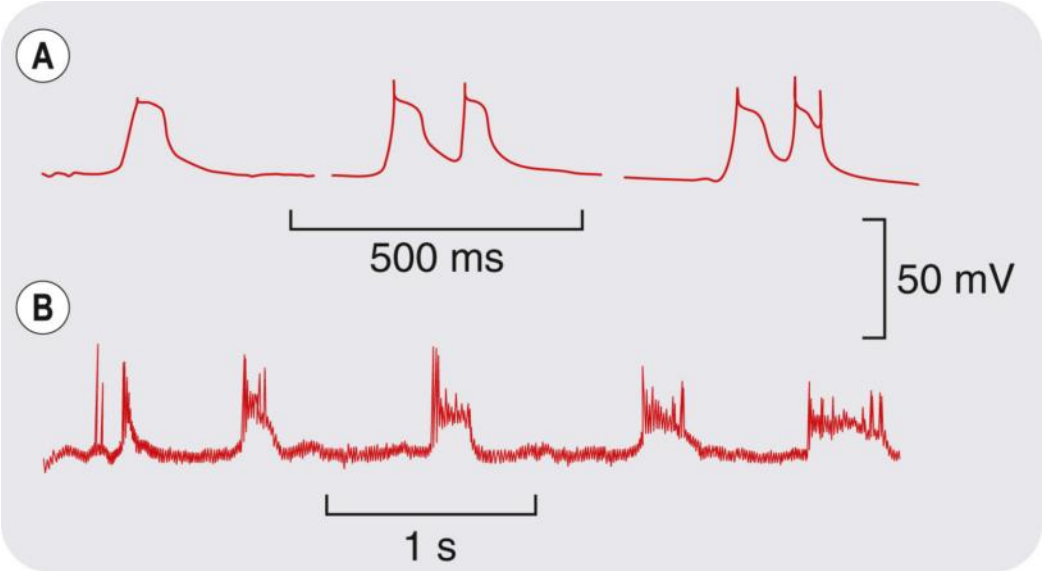

FIG. 46.3 'Paroxysmal depolarising shift' (PDS) compared with experimental activation of glutamate receptors of the *N*-methyl-D-aspartate (NMDA) type.(A) PDS recorded with an intracellular microelectrode from cortical neurons of anaesthetised cats. Seizure activity was induced by topical application of penicillin. (B) Intracellular recording from the caudate nucleus of an anaesthetised cat. The glutamate analogue NMDA was applied by ionophoresis from a nearby micropipette. A from Matsumoto, H., Marsan, C.A., 1964. Exp. Neurol. 9, 286; panel B from Herrling, P.L. et al., 1983. J. Physiol. 339, 207.

In human focal epilepsies, surgical removal of a damaged region of cortex may fail to cure the condition, as though the abnormal discharge from the region of primary damage had somehow produced a secondary hyperexcitability elsewhere in the brain.

Furthermore, following severe head injury, prophylactic treatment with antiepileptic drugs reduces the incidence of post-traumatic epilepsy, which suggests that a phenomenon similar to kindling may underlie this form of epilepsy.

Most recently, zebrafish have been used to study epileptic phenotypes resulting from genetic manipulation, both gene knock-out and knock-in of specific mutations. There is promise for this approach in the screening of drugs with activity against specific forms of genetic epilepsies (**Grone and Baraban, 2015**; **Gawel et al., 2020**).

Nature of epilepsy

- Epilepsy affects about 0.5% of the population.
- The characteristic event is the seizure, which may be associated with convulsions but may take other forms.
- The seizure is caused by an asynchronous high-frequency discharge of a group of neurons, starting locally and spreading to a varying extent to affect other parts of the brain. In absence seizures, the discharge is regular and oscillatory.
- Partial seizures affect localised brain regions, and the attack may involve mainly motor, sensory or behavioural phenomena. Unconsciousness occurs when the reticular formation is involved.
- Generalised seizures affect the whole brain. Two common forms of generalised seizure are the tonic–clonic and the absence seizures. Status epilepticus is a life-threatening condition in which seizure activity is uninterrupted.

- Partial seizures can become secondarily generalised if the localised abnormal neuronal activity subsequently spreads across the whole brain.
- The neurochemical basis of the abnormal discharge is not well understood. It may be associated with enhanced excitatory amino acid transmission, impaired inhibitory transmission or abnormal electrical properties of the affected cells. Several susceptibility genes, mainly encoding neuronal ion channels, have been identified.
- Repeated epileptic discharge can cause neuronal death (excitotoxicity).
- Current drug therapy is effective in 70%–80% of patients.

Antiepileptic Drugs

Antiepileptic (sometimes known as *anticonvulsant*) drugs are used to treat epilepsy as well as non-epileptic convulsive disorders.

When patients fail to respond to single drugs (monotherapy) then combination therapy with two or even three antiepileptic drugs may bring benefit. With optimal drug therapy, epilepsy is controlled completely in about 75% of patients, but about 10% (50,000 in Britain) continue to have seizures at intervals of 1 month or less, which severely disrupts their life and work. There is therefore a need to improve the efficacy of therapy.

Patients with epilepsy usually need to take drugs continuously for many years, so avoidance of side effects and drug interactions (see **Ch. 58**) is particularly important. Nevertheless, some drugs that have considerable adverse effects are still quite widely used even

though they are not drugs of choice for newly diagnosed patients. [2] There is still a need for more effective drugs, and a number of new drugs have been introduced for clinical use. Long-established antiepileptic drugs are listed in **Table 46.1**. Newer drugs (see **Table 46.2**) with similar mechanisms of action to older drugs or novel mechanisms of action may offer advantages in terms of efficacy in drug-resistant epilepsies, better pharmacokinetic profile, improved tolerability, lower potential for interaction with other drugs (see **Ch. 58**) and fewer adverse effects. The appropriate use of drugs from this large available menu depends on many clinical factors (see **Shih et al., 2017**).

Mechanism of Action

Antiepileptic drugs aim to inhibit the abnormal neuronal discharge rather than to correct the underlying cause. Three main mechanisms of action appear to be important:

1. Enhancement of GABA action.
2. Inhibition of sodium channel function.
3. Inhibition of calcium channel function.

More recently, newer drugs with other, novel mechanisms of action have been developed.

Antiepileptic drugs may exert more than one beneficial action, prime examples being **valproate** and **topiramate** (see Tables **46.1** and **46.2**). The relative importance and contribution of each of these actions to the therapeutic effect are somewhat uncertain.

As with drugs used to treat cardiac dysrhythmias (see **Ch. 20**), the aim is to prevent the paroxysmal discharge without affecting

normal transmission. It is clear that properties such as use dependence and voltage dependence of channel-blocking drugs (see **Ch. 4**) are important in achieving this selectivity, but our understanding remains fragmentary.

Enhancement of GABA action

Several antiepileptic drugs (e.g. **phenobarbital, stiripentol** and **benzodiazepines**) enhance the activation of $GABA_A$ receptors, thus facilitating the GABA-mediated opening of chloride channels (see Chs **3** and **45**). [3] **Vigabatrin** acts by irreversibly inhibiting the enzyme GABA transaminase that is responsible for inactivating GABA (see **Ch. 38**) in astrocytes and GABAergic nerve terminals. **Tiagabine** is an inhibitor of the 'neuronal' GABA transporter GAT1 that is expressed on GABAergic nerve terminals, and, to a lesser extent, on neighbouring astrocytes, thus inhibiting the removal of GABA from the synapse. It elevates the extracellular GABA concentration, as measured in microdialysis experiments, and also potentiates and prolongs GABA-mediated synaptic responses in the brain.

Table 46.1

[a] Oxcarbazepine and eslicarbazepine, recently introduced, are similar; claimed to have fewer side effects.

[b] Fosphenytoin is a water-soluble phenytoin prodrug that is safer than phenytoin when given by injection.

[c] Trimethadione is similar to ethosuximide in that it acts selectively against absence seizures but has greater toxicity (especially the risk of severe hypersensitivity reactions and teratogenicity).

[d] Primidone is pharmacologically similar to phenobarbital and is converted to phenobarbital in the body. It has no clear advantages and is more liable to produce hypersensitivity reactions, so is now rarely used.

Table 46.2

AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; *NMDA*, *N*-methyl-D-aspartate; *SV2A*, synaptic vesicle protein 2A.

[a] Brivaracetam is a structural analogue.

Inhibition of sodium channel function

Many antiepileptic drugs (e.g. **carbamazepine, phenytoin**, **lamotrigine** and **cenobamate**; see Tables **46.1** and **46.2**) affect membrane excitability by an action on voltage-dependent sodium channels (see Chs **4** and **44**), which carry the inward membrane current necessary for the generation of an action potential. Their blocking action shows the property of use-dependence; in other words, they block preferentially the excitation of cells that are firing

repetitively, and the higher the frequency of firing, the greater the block produced. This characteristic, which is relevant to the ability of drugs to block the high-frequency discharge that occurs in an epileptic seizure without unduly interfering with the low-frequency firing of neurons in the normal state, arises from the ability of blocking drugs to discriminate between sodium channels in their resting, open and inactivated states (see Chs **4** and **44**). Depolarisation of a neuron (such as occurs in the PDS described previously) increases the proportion of the sodium channels in the inactivated state. Some antiepileptic drugs bind preferentially to channels in this state, preventing them from returning to the resting state, and thus reducing the number of functional channels available to generate subsequent action potentials. **Lacosamide** enhances sodium channel inactivation, but unlike other antiepileptic drugs it appears to affect slow rather than rapid inactivation processes.

Inhibition of calcium channels

Drugs that are used to treat absence seizures (e.g. **ethosuximide** and **valproate**) share the ability to block T-type low-voltage-activated calcium channels (see **Ch. 4**). T-type channel activity is important in determining the rhythmic discharge of thalamic neurons associated with absence seizures (**Khosravani et al., 2004**).

Gabapentin, although designed as a simple analogue of GABA that would be sufficiently lipid soluble to penetrate the blood–brain barrier, owes its antiepileptic effect mainly to an action on P/Q-type calcium channels. By binding to a particular channel subunit (α2δ1),

both gabapentin and **pregabalin** (a related analogue) reduce the trafficking to the plasma membrane of calcium channels containing this subunit, thereby reducing calcium entry into the nerve terminals and reducing the release of various neurotransmitters and modulators.

Other mechanisms

Many of the newer antiepileptic drugs were developed empirically on the basis of activity in animal models. Their mechanism of action at the cellular level is not fully understood.

Levetiracetam is believed to interfere with neurotransmitter release by binding to synaptic vesicle protein 2A (SV2A), which is involved in synaptic vesicle docking and fusion. **Brivaracetam**, a related antiepileptic agent, also binds to SV2A with 10-fold higher affinity.

While a drug may appear to work by one of the major mechanisms described, close scrutiny often reveals other actions that may also be therapeutically relevant. For example, **phenytoin** not only causes use-dependent block of sodium channels but also affects other aspects of membrane function, including calcium channels and post-tetanic potentiation, as well as intracellular protein phosphorylation by calmodulin-activated kinases, which could also interfere with membrane excitability and synaptic function.

Antagonism at ionotropic excitatory amino acid receptors has been a major focus in the search for new antiepileptic drugs. Despite showing efficacy in animal models, by and large they did not prove useful in the clinic, because the margin between the

desired anticonvulsant effect and unacceptable side effects, such as loss of motor coordination, was too narrow. However, **perampanel**, a non-competitive α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-receptor antagonist, has been approved as an add-on treatment for partial seizures.

Mechanism of action of antiepileptic drugs

- The major antiepileptic drugs are thought to act by three main mechanisms:
  - reducing electrical excitability of cell membranes, mainly through use-dependent block of sodium channels;
  - enhancing GABA-mediated synaptic inhibition; this may be achieved by an enhanced postsynaptic action of GABA, by inhibiting GABA transaminase or by inhibiting GABA uptake into neurons and glial cells;
  - inhibiting T-type calcium channels (important in controlling absence seizures).
- Newer drugs act by other mechanisms, some yet to be elucidated.

Carbamazepine

Carbamazepine is chemically related to the tricyclic antidepressant drugs (see **Ch. 48**) and was found in a routine screening test to inhibit electrically evoked seizures in mice. Pharmacologically and clinically, its actions resemble those of phenytoin, although it appears to be particularly effective in treating certain partial

seizures (e.g. psychomotor epilepsy). It is also used to treat other conditions, such as neuropathic pain (see **Ch. 43**) and bipolar disorder (see **Ch. 48**).

Pharmacokinetic aspects

Carbamazepine is slowly but well absorbed after oral administration. Its plasma half-life is about 30 h when it is given as a single dose, but it is a strong inducer of hepatic enzymes, and the plasma half-life shortens to about 15 h when it is given repeatedly. Some of its metabolites have antiepileptic properties. A slow-release preparation is used for patients who experience transient side effects coinciding with plasma concentration peaks following oral dosing.

Unwanted effects

Carbamazepine produces a variety of unwanted effects ranging from drowsiness, dizziness and ataxia to more severe mental and motor disturbances. [4] It can also cause water retention (and hence hyponatraemia; see **Ch. 29**) and a variety of gastrointestinal and cardiovascular side effects. The incidence and severity of these effects are relatively low, however, compared with other drugs. Treatment is usually started with a low dose, which is built up gradually to avoid dose-related toxicity. Severe bone marrow depression, causing neutropenia, and other severe forms of hypersensitivity reaction can occur, especially in people of Asian origin (see **Ch. 12**).

Carbamazepine is a powerful inducer of hepatic microsomal enzymes, and thus accelerates the metabolism of many other drugs, such as phenytoin, oral contraceptives, warfarin and corticosteroids,

as well as of itself. When starting treatment, the opposite of a 'loading dose' strategy is employed: small initial doses are gradually increased, as when dosing is initiated, metabolising enzymes are not induced and so even low doses may give rise to adverse effects (notably ataxia); as enzyme induction occurs, increasing doses are needed to maintain therapeutic plasma concentrations. In general, it is inadvisable to combine it with other antiepileptic drugs, and interactions with other drugs (e.g. warfarin) metabolised by cytochrome P450 (CYP) enzymes are common and clinically important. **Oxcarbazepine** is a prodrug that is metabolised to a compound closely resembling carbamazepine, with similar actions but less tendency to induce drug-metabolising enzymes. Another structurally related drug, **eslicarbazepine**, may have less effect on metabolising enzymes.

Phenytoin

Phenytoin is the most important member of the hydantoin group of compounds, which are structurally related to the barbiturates. It is highly effective in reducing the intensity and duration of electrically induced convulsions in mice, although ineffective against PTZ-induced convulsions. Owing to its many side effects and unpredictable pharmacokinetic behaviour, phenytoin usage is declining. Phenytoin is effective against various forms of partial and generalised seizures, although not against absence seizures, which it may even worsen. **Fosphenytoin** is a phosphorylated, prodrug form of phenytoin that is water soluble and can be administered by intravenous infusion or intramuscular injection in situations where

oral phenytoin administration would be inappropriate, e.g. during status epilepticus or vomiting.

Pharmacokinetic aspects

Phenytoin has certain pharmacokinetic peculiarities that need to be taken into account when it is used clinically. It is well absorbed when given orally, and about 80%–90% of the plasma content is bound to albumin. Other drugs, such as salicylates, phenylbutazone and valproate, inhibit this binding competitively (see **Ch. 58**). This increases the free phenytoin concentration but also increases hepatic clearance of phenytoin, so may enhance or reduce the effect of the phenytoin in an unpredictable way. Phenytoin is metabolised by the hepatic mixed function oxidase system and excreted mainly as glucuronide. It causes enzyme induction, and thus increases the rate of metabolism of other drugs (e.g. oral anticoagulants). The metabolism of phenytoin itself can be either enhanced or competitively inhibited by various other drugs that share the same hepatic enzymes. **Phenobarbital** produces both effects, and because competitive inhibition is immediate whereas induction takes time, it initially enhances and later reduces the pharmacological activity of phenytoin. **Ethanol** has a similar dual effect.

The metabolism of phenytoin shows the characteristic of saturation (see **Ch. 10**), which means that over the therapeutic plasma concentration range the rate of inactivation does not increase in proportion to the plasma concentration. The consequences of this are that:

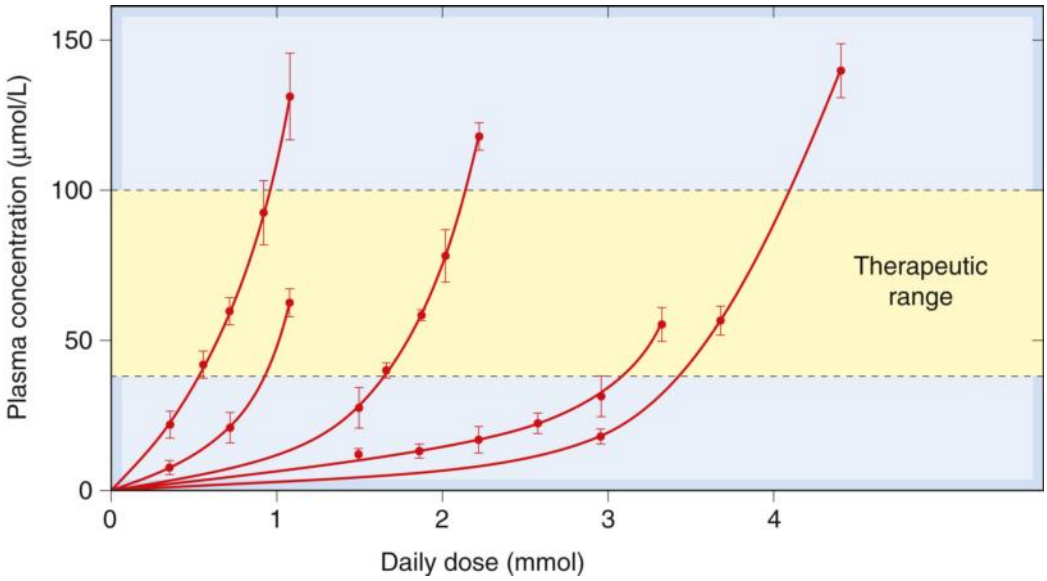

FIG. 46.4 Non-linear relationship between daily dose of phenytoin and steady-state plasma concentration in five individual human subjects.The daily dose required to achieve the therapeutic range of plasma concentrations (40–100 μmol/L) varies greatly between individuals, and for any one individual the dose has to be adjusted rather precisely to keep within the acceptable plasma concentration range. Redrawn from Richens, A., Dunlop, A., 1975. Lancet 2, 247.

- the plasma half-life (approximately 20 h) increases as the dose is increased
- the steady-state mean plasma concentration, achieved when a patient is given a constant daily dose, varies disproportionately with the dose. **Fig. 46.4** shows that, in

one patient, increasing the dose by 50% caused the steady-state plasma concentration to increase more than four-fold.

The range of plasma concentration over which phenytoin is effective without causing excessive unwanted effects is quite narrow (approximately 40–100 μmol/L). The very steep relationship between dose and plasma concentration and the many interacting factors mean that there is considerable individual variation in the plasma concentration achieved with a given dose. Regular monitoring of plasma concentration has helped considerably in achieving an optimal therapeutic effect. The past tendency was to add further drugs in cases where phenytoin alone failed to give adequate control. It is now recognised that much of the unpredictability can be ascribed to pharmacokinetic variability, and regular monitoring of plasma concentration has reduced the use of polypharmacy.

Unwanted effects

Side effects of phenytoin begin to appear at plasma concentrations exceeding 100 μmol/L and may be severe above about 150 μmol/L. The milder side effects include vertigo, ataxia, headache and nystagmus, but not sedation. At higher plasma concentrations, marked confusion with intellectual deterioration occurs; a paradoxical increase in seizure frequency is a particular trap for the unwary prescriber. These effects occur acutely and are quickly reversible. Hyperplasia of the gums often develops gradually, as does hirsutism and coarsening of the features, which probably result from increased androgen secretion. Megaloblastic anaemia, associated with a disorder of folate metabolism, sometimes occurs,

and can be corrected by giving folic acid (see **Ch. 24**). Hypersensitivity reactions, mainly rashes, are quite common. Phenytoin has also been implicated as a cause of the increased incidence of fetal malformations in children born to epileptic mothers, particularly the occurrence of cleft palate, associated with the formation of an epoxide metabolite. Severe idiosyncratic reactions, including hepatitis, skin reactions and neoplastic lymphocyte disorders, occur in a small proportion of patients.

Valproate

Valproate is a simple monocarboxylic acid usually administered as the sodium salt (**sodium valproate**). **Valproic acid** acts similarly to sodium valproate **and semisodium valproate** is equimolar amounts of sodium valproate and valproic acid. Valproate is chemically unrelated to any other class of antiepileptic drug, and in 1963 it was discovered quite accidently to have anticonvulsant properties in mice. It inhibits most kinds of experimentally induced convulsions and is effective in many kinds of epilepsy, being particularly useful in certain types of infantile epilepsy, where its low toxicity and lack of sedative action are important, and in adolescents who exhibit both tonic–clonic or myoclonic seizures in addition to absence seizures, because valproate (unlike most antiepileptic drugs) is effective against each. Like carbamazepine, valproate is also used in psychiatric conditions such as bipolar disorder (see **Ch. 48**).

Valproate works by several mechanisms (see **Table 46.1**), the relative importance of which remains to be clarified. It causes a significant increase in the GABA content of the brain and is a weak

inhibitor of the enzyme system that inactivates GABA, namely GABA transaminase and succinic semialdehyde dehydrogenase (see **Ch. 38**), but in vitro studies suggest that these effects would be very slight at clinical dosage. Other more potent inhibitors of these enzymes (e.g. **vigabatrin**) also increase GABA content and have an anticonvulsant effect in experimental animals. There is some evidence that it enhances the action of GABA by a postsynaptic action, but no clear evidence that it affects inhibitory synaptic responses. It inhibits sodium channels, but less so than phenytoin, and inhibits T-type calcium channels, which might explain why it is effective against absence seizures.

Valproate is well absorbed orally and excreted, mainly as the glucuronide, in the urine, the plasma half-life being about 15 h.

Unwanted effects

Valproate is contraindicated in women of childbearing age because it is a potent teratogen (even more so than other anticonvulsants that tend to share this secondary pharmacology), causing spina bifida and other neural tube defects.

Another serious but rare side effect is hepatotoxicity. An increase in plasma glutamic oxaloacetic transaminase, which signals liver damage of some degree, commonly occurs, but proven cases of valproate-induced hepatitis are rare. The few cases of fatal hepatitis in valproate-treated patients may well have been caused by other factors. More commonly, valproate causes thinning and curling of the hair, in about 10% of patients.

Ethosuximide

Ethosuximide is another drug developed empirically by modifying the barbituric acid ring structure. Pharmacologically and clinically, however, it is different from the drugs so far discussed, in that it is active against PTZ-induced convulsions in animals and against absence seizures in humans, with little or no effect on other types of epilepsy. It supplanted **trimethadione**, the first drug found to be effective in absence seizures, which had major side effects. Ethosuximide is used clinically for its selective effect on absence seizures.

Ethosuximide and trimethadione, unlike other antiepileptic drugs, act mainly by inhibition of T-type calcium channels, which play a role in generating the firing rhythm in thalamic relay neurons that generates the 3/s spike-and-wave EEG pattern characteristic of absence seizures.

Ethosuximide is well absorbed and metabolised and excreted much like phenobarbital, with a plasma half-life of about 60 h. Its main side effects are nausea and anorexia, sometimes lethargy and dizziness, and it is said to precipitate tonic–clonic seizures in susceptible patients. Very rarely, it can cause severe hypersensitivity reactions.

Phenobarbital

Phenobarbital was one of the first barbiturates to be developed but is rarely used nowadays. Its clinical effectiveness closely resembles that of phenytoin; it affects the duration and intensity of artificially induced seizures, rather than the seizure threshold, and is (like phenytoin) ineffective in treating absence seizures. **Primidone** acts by being metabolised to phenobarbital. It may cause

hypersensitivity reactions and is rarely used nowadays to treat epilepsy but is used for the treatment of essential tremor (see **Ch. 40**). The clinical uses of phenobarbital are virtually the same as those of phenytoin, but it is seldom used now because it causes sedation. For some years, phenobarbital was widely used in children, including as prophylaxis following febrile convulsions in infancy, but it can cause behavioural disturbances and hyperkinesias. It is, however, widely used in veterinary practice.

Pharmacokinetic aspects

Phenobarbital is well absorbed, and about 50% of the drug in the blood is bound to plasma albumin. It is eliminated slowly from the plasma (half-life 50–140 h). About 25% is excreted unchanged in the urine. Because phenobarbital is a weak acid, its ionisation and hence renal elimination are increased if the urine is made alkaline (see **Ch. 10**). The remaining 75% is metabolised, mainly by oxidation and conjugation, by hepatic microsomal enzymes. Phenobarbital is a powerful inducer of liver CYP enzymes, and it lowers the plasma concentration of several other drugs (e.g. steroids, oral contraceptives, warfarin, tricyclic antidepressants) to an extent that is clinically important.

Unwanted effects

The main unwanted effect of phenobarbital is sedation, which often occurs at plasma concentrations within the therapeutic range for seizure control. This is a serious drawback, because the drug may have to be used for years on end. Some degree of tolerance to the sedative effect seems to occur, but objective tests of cognition and motor performance show impairment even during long-term

treatment. Other unwanted effects that may occur with clinical dosage include megaloblastic anaemia (similar to that caused by phenytoin), mild hypersensitivity reactions and osteomalacia. Like other barbiturates, it must not be given to patients with porphyria (see **Ch. 12**). In overdose, phenobarbital depresses brain stem function, producing coma and respiratory and circulatory failure, as do all barbiturates.

Benzodiazepines

Benzodiazepines can be used to treat both acute seizures, especially in children – **midazolam** given buccally or **diazepam** being administered rectally – and status epilepticus (a life-threatening condition in which epileptic seizures occur almost without a break) for which agents such as **lorazepam**, diazepam or **clonazepam** are administered intravenously. The advantage in status epilepticus is that they act very rapidly compared with other antiepileptic drugs. With most benzodiazepines (see **Ch. 45**), the sedative effect is too pronounced for them to be used for maintenance therapy and tolerance develops over 1–6 months. **Clonazepam** is unique among the benzodiazepines in that in addition to acting at the $GABA_A$ receptor, it also inhibits T-type calcium channels. Both this and the related compound **clobazam** are claimed to be relatively selective as antiepileptic drugs. Sedation is the main side effect of these compounds, and an added problem is the withdrawal syndrome, which results in an exacerbation of seizures if the drug is stopped abruptly.

Newer Antiepileptic Drugs

Vigabatrin

Vigabatrin, the first ‘designer drug’ in the epilepsy field, is a vinyl-substituted analogue of GABA that was designed as an irreversible inhibitor of the GABA-metabolising enzyme GABA transaminase. In animal studies, vigabatrin increases the GABA content of the brain and also increases the stimulation-evoked release of GABA, implying that GABA transaminase inhibition can increase the releasable pool of GABA and effectively enhance inhibitory transmission. In humans, vigabatrin increases the content of GABA in the cerebrospinal fluid. Although its plasma half-life is short, it produces a long-lasting effect because the enzyme is blocked irreversibly, and the drug can be given by mouth once daily.

Vigabatrin’s licence is restricted to patients with resistant epilepsy who have not responded or tolerated other appropriate drug combinations. A major drawback of vigabatrin is the development of irreversible peripheral visual field defects in a proportion of patients on long-term therapy, thus necessitating systematic screening examinations of the visual fields at regular intervals. Vigabatrin may cause depression, and occasionally psychotic disturbances and hallucinations, in a minority of patients.

Lamotrigine

Lamotrigine, although chemically unrelated, resembles phenytoin and carbamazepine in its pharmacological effects but it appears that, despite its similar mechanism of action, lamotrigine has a broader therapeutic profile than the earlier drugs, with significant efficacy against absence seizures (it is also used to treat unrelated psychiatric disorders). Its main side effects are nausea, dizziness

and ataxia, and hypersensitivity reactions (mainly mild rashes, but occasionally more severe). Its plasma half-life is about 24 h, with no particular pharmacokinetic anomalies, and it is taken orally.

Gabapentin and Pregabalin

Gabapentin and pregabalin are effective against partial seizures. Side effects (drowsiness, headache, fatigue, dizziness and weight gain) are less severe than with many antiepileptic drugs. The absorption of gabapentin from the intestine depends on the L-amino acid carrier system and shows the property of saturability, which means that increasing the dose does not proportionately increase the amount absorbed. Pregabalin is more readily absorbed from the gut. Gabapentin and pregabalin have a plasma half-life of about 6 h, requiring dosing two to three times daily. As these drugs are excreted unchanged in the urine they must be used with care in patients whose renal function is impaired. Both drugs are also used as analgesics to treat neuropathic pain (see **Ch. 43**) and as anxiolytics in the treatment of general anxiety disorders (see **Ch. 45**). Recently gabapentin and pregabalin misuse has become popular, especially amongst heroin users, and may contribute to opioid overdose deaths (see **Ch. 50**).

Tiagabine

Tiagabine is an analogue of GABA that is able to penetrate the blood–brain barrier. It has a short plasma half-life and is mainly used as an add-on therapy for partial seizures. Its main side effects are drowsiness and confusion, dizziness, fatigue, agitation and tremor.

Topiramate

Topiramate is a drug that appears to do a little of everything, blocking sodium and calcium channels, enhancing the action of GABA, blocking AMPA receptors and, for good measure, weakly inhibiting carbonic anhydrase. Its clinical effectiveness resembles that of phenytoin, and it is claimed to produce less severe side effects, as well as being devoid of the pharmacokinetic properties that cause trouble with phenytoin. Currently, it is mainly used as add-on therapy in refractory cases of partial and generalised seizures.

Levetiracetam

Levetiracetam was developed as an analogue of **piracetam**, a drug developed to improve cognitive function, and discovered by accident to have antiepileptic activity in animal models. Unusually, it lacks activity in conventional models such as electroshock and PTZ tests, but is effective in the audiogenic and kindling models. Levetiracetam is excreted unchanged in the urine. Common side effects include headaches, inflammation of the nose and throat, sleepiness, vomiting and irritability. **Brivaracetam** is similar to levetiracetam.

Zonisamide

Zonisamide is a sulfonamide compound originally intended as an antibacterial drug and found accidently to have antiepileptic properties. It is mainly free of major unwanted effects, although it causes drowsiness, and of serious interaction with other drugs. It tends to suppress appetite and cause weight loss and is sometimes

used for this purpose. Zonisamide has a long plasma half-life of 60–80 h, and is partly excreted unchanged and partly converted to a glucuronide metabolite. It is licensed for use as an adjunct treatment of partial and generalised seizures but may be effective as a monotherapy.

Rufinamide

Rufinamide is a triazole derivative structurally unrelated to other antiepileptic drugs. It is licensed for treating Lennox–Gastaut syndrome and may also be effective in partial seizures. It has low plasma protein binding and is not metabolised by CYP enzymes.

Perampanel

Perampanel is effective in refractory partial seizures. Side effects include dizziness, sedation, fatigue, irritability, weight gain and loss of motor coordination. There is a risk of serious psychiatric problems (violent, even homicidal, thoughts and threatening behaviour) in some individuals.

Lacosamide

Lacosamide is a functionalised amino acid used alone or in combination with other drugs to treat partial seizures. Side effects include nausea, dizziness, sedation and fatigue. It produces relief of pain caused by diabetic neuropathy.

Stiripentol

Stiripentol is used as an adjunctive therapy for Dravet's syndrome in children. It enhances GABA release and prolongs GABA-mediated synaptic events in a manner similar to phenobarbital. It also

inhibits lactate dehydrogenase (LDH) which may reduce the metabolic energy production required to maintain seizures. It inhibits cytochrome P450 isoenzymes and so interacts with several antiepileptic drugs as well as other drugs (see **Ch. 58**).

Cenobamate

Cenobamate is used as an adjunct therapy for partial onset seizures. It is well absorbed from the gut and reaches peak plasma concentrations after 1 to 4 h.

Cannabidiol

Cannabidiol, a major phytocannabinoid devoid of the psychoactive properties of **Δ ^{9} -tetrahydrocannabinol (**Δ^{9}- THC; see **Ch. 18**), has been approved for the treatment of Dravet syndrome and Lennox–Gastaut syndrome as well as for seizures associated with tuberous sclerosis complex, a rare genetic condition that causes mainly non-cancerous tumours to develop. The mechanisms underlying its antiepileptic efficacy are unclear as it has low affinity for CB_1 and CB_2 cannabinoid receptors. Other phytocannabinoids may also have anticonvulsant properties.

Felbamate

Felbamate is an analogue of an obsolete anxiolytic drug, **meprobamate**. It is active in many animal seizure models and has a broader clinical spectrum than earlier antiepileptic drugs, but its mechanism of action at the cellular level is uncertain. Its acute side effects are mild, mainly nausea, irritability and insomnia, but it occasionally causes severe reactions resulting in aplastic anaemia or hepatitis. For this reason, its recommended use is limited to

intractable epilepsy (e.g. in children with Lennox–Gastaut syndrome) that is unresponsive to other drugs. Its plasma half-life is about 24 h, and it can enhance the plasma concentration of other antiepileptic drugs given concomitantly.

New Drugs

There are a number of new antiepileptic agents with novel mechanism of action approved or in late stages of clinical trials. [5] **Ganaxolone**, structurally resembling endogenous neurosteroids (see **Ch. 38**), is a positive allosteric modulator of $GABA_A$ receptors containing δ subunits that has recently been approved for the treatment of CDLK5 disorder, a rare form of genetic epilepsy predominantly affecting young girls. It may be effective against other forms of epilepsy especially in children. Side effects include drowsiness, dizziness and fatigue. **Everolimus**, an inhibitor of mammalian target of rapamycin (mTOR, see **Ch. 25**), is in a phase III clinical trial for partial seizures. **Tonabersat** is a novel neuronal gap junction inhibitor that shows early promise.

Other Uses of Antiepileptic Drugs

Antiepileptic drugs have proved to have much wider clinical applications than was originally envisaged, and clinical trials have shown many of them to be effective in the following conditions:

- bipolar disorder (**valproate**, **carbamazepine**, **oxcarbazepine**, **lamotrigine**, **topiramate**; see **Ch. 48**)
- migraine prophylaxis (**valproate**, **gabapentin**, **topiramate**; see **Ch. 42**)
- anxiety disorders (**gabapentin, pregabalin**; see **Ch. 45**)

- neuropathic pain (**gabapentin**, **pregabalin**, **carbamazepine**, **lamotrigine, lacosamide**; see **Ch. 43**)

This surprising multiplicity of clinical indications may reflect the fact that similar neurobiological mechanisms, involving synaptic plasticity and increased excitability of interconnected populations of neurons, underlie each of these disorders.

Antiepileptic Drugs and Pregnancy

There are several important implications for women taking antiepileptic drugs. By inducing hepatic CYP3A4 enzymes, some antiepileptic drugs may increase oral contraceptive metabolism, thus reducing their effectiveness (see **Ch. 35**). Taken during pregnancy, drugs such as phenytoin, carbamazepine, lamotrigine, topiramate and valproate are thought to have some risk of teratogenic effects, although the magnitude of risk appears greatest with valproate. It remains to be clarified if newer agents also have this problem. Induction of CYP enzymes may result in vitamin K deficiency in the newborn (see **Ch. 24**).

Clinical uses of antiepileptic drugs

- Generalised tonic–clonic seizures:
  - **valproate**, **lamotrigine** or **carbamazepine**;
  - use of a single drug is preferred, when possible, to avoid pharmacokinetic interactions;
  - newer agents include **topiramate**, **levetiracetam.**

- Partial (focal) seizures: **carbamazepine**, or **lamotrigine**; alternatives include **valproate**, **levetiracetam**, **clobazam**, **gabapentin**, **topiramate**, **levetiracetam.**
- Absence seizures: **ethosuximide**, **valproate**
  - **valproate** is the first-choice drug when absence seizures coexist with tonic–clonic seizures, because most other drugs used for tonic–clonic seizures can worsen absence seizures.
- Myoclonic seizures: **valproate**, **topiramate**, **levetiracetam.**
- Status epilepticus: **lorazepam** intravenously (or in the absence of accessible veins, intramuscular or oromucosal **midazolam** or **diazepam** rectally).
- Neuropathic pain: for example **carbamazepine**, **gabapentin** (see **Ch. 43**).
- To stabilise mood in mono- or bipolar affective disorder (as an alternative to **lithium**): for example, **carbamazepine**, **valproate** (see **Ch. 48**).

Muscle Spasm and Muscle Relaxants

Many diseases of the brain and spinal cord produce an increase in muscle tone, which can be painful and disabling. Spasticity resulting from birth injury or cerebral vascular disease and the paralysis produced by spinal cord lesions are examples. Multiple sclerosis is a neurodegenerative disease that is triggered by inflammatory attack on the central nervous system (see **Ch. 40**). When the disease has

progressed for some years it can cause muscle stiffness and spasms, as well as other symptoms such as pain, fatigue, difficulty passing urine and tremors. Local injury or inflammation, as in arthritis, can also cause muscle spasm, and chronic back pain is also often associated with local muscle spasm.

Certain centrally acting drugs are available that have the effect of reducing the background tone of the muscle without seriously affecting its ability to contract transiently under voluntary control. The distinction between voluntary movements and 'background tone' is not clear-cut, and the selectivity of those drugs is not complete. Postural control, for example, is usually jeopardised by centrally acting muscle relaxants. Furthermore, drugs that affect motor control generally produce rather widespread effects on the central nervous system, and drowsiness and confusion turn out to be very common side effects of these agents.

Baclofen (see **Ch. 38**) is a chlorophenyl derivative of GABA originally prepared as a lipophilic GABA-like agent in order to assist penetration of the blood–brain barrier, which is impermeable to GABA itself. Baclofen is a selective agonist at $GABA_B$ receptors (see **Ch. 38**). The antispastic action of baclofen is exerted mainly on the spinal cord, where it inhibits both monosynaptic and polysynaptic activation of motor neurons. It is effective when given by mouth and is used in the treatment of spasticity associated with multiple sclerosis or spinal injury. However, it is ineffective in cerebral spasticity caused by birth injury.

Baclofen produces various unwanted effects, particularly drowsiness, motor incoordination and nausea, and it may also have behavioural effects. It is not useful in epilepsy.

Benzodiazepines are discussed in detail in **Chapter 45**. They produce muscle relaxation by an effect in the spinal cord. They are also anxiolytic.

Tizanidine is an α_2-adrenoceptor agonist that relieves spasticity associated with multiple sclerosis and spinal cord injury.

For many years anecdotal evidence suggested that smoking **cannabis** (see **Ch. 18**) relieves the painful muscle spasms associated with multiple sclerosis. **Sativex**, a cannabis extract containing Δ^9-THC (also known as **dronabinol**; see **Ch. 18**) and cannabidiol, is licensed in some countries as a treatment for spasticity in multiple sclerosis. It also has pain-relieving properties (see Chs **18** and **43**).

Methocarbamol is used to treat muscle pain and stiffness. Its mechanism of action is unclear.

Dantrolene acts peripherally rather than centrally to produce muscle relaxation (see **Ch. 4**).

Botulinum toxin (see **Ch. 14**) injected into a muscle inhibits acetylcholine release, causing long-lasting paralysis confined to the site of injection; its use to treat local muscle spasm is increasing. Its non-medicinal use as a 'beauty' treatment has become widespread.

QUESTIONS

QUESTION 46.1

Epilepsy is a very common disorder, characterised by *seizures*, which take various forms and result from episodic neuronal discharges, the form of the seizure depending on the part of the brain affected.

Which type of seizure is characterised by periods of continuous high-frequency activity followed by intermittent discharge?

OPTIONS:

A. Partial

B. Psychomotor

C. Jacksonian

D. Tonic-clonic

E. Absence

QUESTION 46.2

Antiepileptic drugs aim to inhibit the abnormal neuronal discharge rather than to correct the underlying cause. The mechanism of action of the agents varies and different agents are used for the different forms of epilepsy.

Which would be the best choice agent for the treatment of absence seizures?

OPTIONS:

A. Phenobarbital

B. Valproate

C. Vigabatrin

D. Tiagabine

E. Phenytoin

QUESTION 46.3

Carbamazepine is chemically related to the tricyclic antidepressant drugs and was found in a routine screening test to inhibit electrically evoked seizures in mice. It appears to be particularly effective in treating certain partial seizures.

Which of the following treatment regimens would be most appropriate for the treatment of a patient with epilepsy with carbamazepine?

OPTIONS:

A. Low initial dose then increasing

B. High initial loading dose then decreasing

C. Low dose co-administered with phenytoin

D. High loading dose followed by phenytoin

E. Maintenance of low dose

ANSWERS

ANSWER 46.1

RATIONALE:

A. In partial seizures a high-frequency asynchronous discharge spreads out from a local focus. The electroencephalography (EEG) discharge in this type of epilepsy is normally confined to one hemisphere.

B. Psychomotor epilepsy is a form of partial seizure showing a high-frequency asynchronous discharge which may arise from a focus within a temporal lobe and has effects on mood and behaviour.

C. Jacksonian epilepsy is a form of partial seizure which is characterised by a high-frequency asynchronous discharge with an epileptic focus in the motor cortex consisting of repetitive jerking of a particular muscle group, beginning on one side of the body.

D.

E. In absence seizures the EEG pattern shows a characteristic rhythmic discharge during the period of the seizure.

CORRECT ANSWER WITH EXPLANATION:

D. Tonic-clonic

In tonic-clonic seizures the EEG shows generalised continuous high-frequency activity in the tonic phase and an intermittent discharge in the clonic phase.

ANSWER 46.2

RATIONALE:

A. Phenobarbital enhances the activation of $GABA_A$ receptors, thus facilitating the GABA-mediated opening of chloride channels. Absence seizures are often exacerbated by drugs that enhance GABA activity.

B.

C. Vigabatrin acts by irreversibly inhibiting the enzyme GABA transaminase that is responsible for inactivating GABA in astrocytes and GABAergic nerve terminals. Absence seizures are often exacerbated by drugs that enhance GABA activity.

D. Tiagabine is an inhibitor of the 'neuronal' GABA transporter GAT1 that is expressed on GABAergic nerve terminals, and, to a lesser extent, on neighbouring astrocytes, thus inhibiting the removal of GABA from the synapse. Absence seizures are often exacerbated by drugs that enhance GABA activity.

E. Phenytoin affects membrane excitability by an action on voltage-dependent sodium channels which carry the inward membrane current necessary for the generation of an action potential. Absence seizures mainly involve t type calcium channels so phenytoin would have little effect.

CORRECT ANSWER WITH EXPLANATION:

B. Valproate blocks T-type low-voltage-activated calcium channels.

T-type channel activity is important in determining the rhythmic discharge of thalamic neurons associated with absence seizures. Absence seizures, paradoxically, are often exacerbated by drugs that enhance GABA activity.

ANSWER 46.3

RATIONALE:

A.

B. When starting treatment, the opposite of a 'loading dose' strategy is employed: small initial doses are gradually

increased, as when dosing is initiated, metabolising enzymes are not induced and so even low doses may give rise to adverse effects (notably ataxia); as enzyme induction occurs, increasing doses are needed to maintain therapeutic plasma concentrations.

C. Carbamazepine is a powerful inducer of hepatic microsomal enzymes, and thus accelerates the metabolism of many other drugs, such as phenytoin.

D. When starting treatment, the opposite of a 'loading dose' strategy is employed: small initial doses are gradually increased, as when dosing is initiated, metabolising enzymes are not induced and so even low doses may give rise to adverse effects. Enzyme induction accelerates the metabolism of phenytoin.

E. Carbamazepine is a potent inducer of hepatic microsomal enzymes. As enzyme induction occurs, increasing doses are needed to maintain therapeutic plasma concentrations.

CORRECT ANSWER WITH EXPLANATION:

A. Low initial dose then increasing

Treatment is usually started with a low dose, which is built up gradually to avoid dose-related toxicity. Carbamazepine is a potent inducer of hepatic microsomal enzymes. As enzyme induction occurs, increasing doses are needed to maintain therapeutic plasma concentrations.

[1] After Hughlings Jackson, a distinguished 19th-century Yorkshire neurologist who published his outstanding work in the *Annals of the West Riding Lunatic Asylum*.

[2] Bromide was the first antiepileptic agent. Its propensity to induce sedation and other unwanted side effects has resulted in it being largely withdrawn from human medicine, although it is still approved for human use in some countries and may have uses in drug-resistant childhood epilepsies. It is still widely used in veterinary practice to treat epilepsy in dogs and cats.

[3] Absence seizures, paradoxically, are often exacerbated by drugs that enhance GABA activity and better treated by drugs acting by different mechanisms such as T-type calcium-channel inhibition.

[4] One of the authors who was a keen hockey player played in a team with a goalkeeper who sometimes made silly errors early in the match. It turned out that he suffered from epilepsy and had taken his dose of carbamazepine too close to the start of the match.

[5] The Epilepsy Foundation website (http://www.epilepsy.com/accelerating-new-therapies/new-therapies-pipeline#drugs) gives details on the large number of drugs currently in development for the treatment of epilepsies.

47: Antipsychotic drugs

OVERVIEW

Antipsychotic drugs are used to treat disorders associated with psychosis, particularly schizophrenia, which affects about 1% of the population. As with other treatments for psychiatric disorders, the relationship between the mechanisms of action of antipsychotic drugs and the underlying pathology of the disorders is poorly understood. There has also been a similar tendency to relate the pharmacology of the treatments to the cause of the disorder but with relatively limited empirical evidence. We include here discussion of these various neurochemical hypotheses and their relationship to the actions of the main types of antipsychotic drug.

Introduction

Psychotic illnesses include various disorders, but the term *antipsychotic drugs* – previously known as *neuroleptic drugs*, *antischizophrenic drugs* or *major tranquillisers* – conventionally refers to those used to treat schizophrenia. These same drugs are also used to treat mania (see **Ch. 48**) and other acute behavioural disturbances including drug-induced psychosis, e.g. resulting from non-medical use of stimulants or *N*-methyl-D-aspartate (NMDA) receptor antagonists such as phencyclidine (PCP or 'Angel Dust')

(see **Ch. 49**). Pharmacologically, most are dopamine receptor antagonists, although many of them also act on other targets, particularly 5-hydroxytryptamine$_2$ (5-HT$_2$) receptors, which may contribute to their clinical efficacy as well as affecting their side effect profile. Existing drugs still have many drawbacks in terms of their efficacy and side effects. Gradual improvements have been achieved with newer drugs, but radical new approaches will require a better understanding of the causes and underlying pathology of the disease, which are still poorly understood. [1]

The Nature of Schizophrenia

Schizophrenia [2] (see **Stahl, 2021**) affects about 1% of the population. It is one of the most important forms of psychiatric illness, because it affects young people, is often chronic and is usually highly disabling. [3] There is a strong hereditary factor in its aetiology, and evidence suggestive of a fundamental biological disorder. The main clinical features of the disease are as follows.

Positive symptoms

- Delusions (often paranoid in nature).
- Hallucinations (often in the form of voices, which may be exhortatory in their message).
- Thought disorder (comprising wild trains of thought, delusions of grandeur, garbled sentences and irrational conclusions).
- Abnormal, disorganised behaviour (such as stereotyped movements, disorientation and occasionally aggressive behaviours).

- Catatonia (can be apparent as immobility or purposeless motor activity).

Negative symptoms

- Withdrawal from social contacts.
- Flattening of emotional responses.
- Anhedonia (an inability to experience pleasure).
- Reluctance to perform everyday tasks.

Cognition

- Deficits in cognitive function (e.g. cognitive flexibility, attention, memory).

In addition to the more recognised psychotic symptoms, anxiety, guilt, depression and self-punishment are often present, leading to suicide attempts in up to 50% of cases, about 10% of which are successful. The clinical phenotype varies greatly, particularly with respect to the balance between positive and negative symptoms, and this may have a bearing on the efficacy of antipsychotic drugs in individual cases. Schizophrenia can present dramatically, usually in young people, with predominantly positive features such as hallucinations, delusions and uncontrollable behaviour, or more insidiously in older patients with negative features such as flat mood and social withdrawal. The latter may be more debilitated than those with a florid presentation, and the prognosis is generally worse. Cognitive impairment may be evident even before the onset of other symptoms. Schizophrenia can follow a relapsing and remitting course, or be chronic and progressive, particularly in cases

with a later onset. Chronic schizophrenia used to account for most of the patients in long-stay psychiatric hospitals; following the closure of many of these in the United Kingdom, it now accounts for many of society's outcasts.

A characteristic feature of schizophrenia is a defect in 'selective attention'. Whereas most people quickly accommodate to stimuli of a familiar or inconsequential nature, and respond only to stimuli that are unexpected or significant, the ability to discriminate between significant and insignificant stimuli seems to be impaired in people with schizophrenia. Thus the ticking of a clock may command as much attention as the words of a companion; a chance thought, which a normal person would dismiss as inconsequential, may become an irresistible imperative.

Aetiology and Pathogenesis of Schizophrenia

Genetic and Environmental Factors

The causes of schizophrenia remain unclear but involve a combination of genetic and environmental factors. Thus a person may have a genetic predisposition to schizophrenia, but exposure to environmental factors is required for schizophrenia to develop. As with other mental health conditions, stress is a major risk factor for the development of schizophrenia. The different forms that gene–environment interaction can take are discussed in detail in **Ayhan et al. (2016)**.

The disease shows a strong, but incomplete, hereditary tendency. In first-degree relatives, the risk is about 10%, but even in monozygotic (identical) twins, one of whom has schizophrenia, the probability of the other being affected is only about 50%, pointing

towards the importance of environmental factors. Genetic linkage studies have identified more than 100 genetic regions (loci) associated with a risk of schizophrenia (**McCutcheon et al., 2020**). There are significant associations between polymorphisms in individual genes and the likelihood of an individual developing schizophrenia but there appears to be no single gene that has an overriding influence. Some of the genes implicated in schizophrenia are also associated with bipolar disorder (see **Ch. 48**).

The most robust associations are with genes that control neuronal development, synaptic connectivity and glutamatergic neurotransmission. These include *complement component 4A (C4A), neuregulin, dysbindin, DISC-1, TCF4* and *NOTCH4*. Increases in C4A expression result in increased synaptic pruning (the process of synapse elimination that occurs between early childhood and the onset of puberty) and may help explain the reduced numbers of synapses in the brains of patients with schizophrenia. Genetically altered mice that underexpress neuregulin-1, a protein involved in synaptic development and plasticity and which controls NMDA receptor expression, show a phenotype resembling human schizophrenia in certain respects. Dysfunction of NMDA receptors is further implicated by genetic association with the genes for D-amino acid oxidase (DAAO), the enzyme responsible for metabolising D-serine, an allosteric modulator of NMDA receptors (see **Ch. 39**), and for DAAO activator (G72). Dysbindin is located in postsynaptic density domains and may be involved in tethering receptors including NMDA receptors. DISC-1 – which stands for **d**isrupted **i**n **sc**hizophrenia-**1** – is a protein that associates with cytoskeletal proteins and is involved

with cell migration, neurite outgrowth and receptor trafficking. Population genetic studies have suggested that *NOTCH4*, a developmentally expressed gene, and TCF-4, a gene also associated with intellectual disability, are strongly associated with susceptibility for schizophrenia-like symptoms but their precise roles in its aetiology remain to be elucidated. Among other suggested susceptibility genes, some (such as the genes for monoamine oxidase A (MAO-A), tyrosine hydroxylase and the D_2 dopamine receptor) are involved in monoamine transmission in the central nervous system. However, the weight of current evidence seems to suggest that schizophrenia results from neurodevelopmental consequences of both genetic and environmental factors. These affect the way the neuronal circuits develop and the connections between different regions of the brain and it is these abnormal brain networks that cause the disorder rather than a deficit in any one transmitter system.

Some environmental influences early in development have been identified as possible predisposing factors, particularly maternal virus infections, leading to changes in the cerebral cortex which occur in the first few months of prenatal development. These developmental changes seem to then manifest in adolescence as the brain undergoes synaptic pruning during this important stage in brain development. It is also when key regions such as the prefrontal cortex undergo maturation. This view is supported by brain imaging studies showing neuroanatomical changes in the early course of the disease which may increase with time and correlate with the progression of the disorder (**Fusar-Poli et al.,**

2012). Functional whole-brain network architecture is also altered (**Kambeitz et al., 2016**).

The Neuroanatomical and Neurochemical Basis of the Symptoms of Schizophrenia

The symptoms of schizophrenia appear to result from dysfunction in neuronal circuits which regulate behaviour; however, there is a lack of reliable evidence of gross anatomical or neurochemical changes in any one brain region or neurotransmitter system. Instead, neurodevelopmental changes in the cerebral cortex are thought to lead to altered regulation of subcortical regions leading to positive symptoms whilst also contributing to emotional and cognitive impairments and hence the negative and cognitive symptoms in schizophrenia. The behavioural manifestation of the positive symptoms of schizophrenia is similar to that seen in healthy subjects following ingestion of drugs which induce neurochemical changes in either subcortical dopamine (e.g. amphetamine, cocaine) or cortical glutamatergic pathways (e.g. NMDA receptor antagonists, 5-HT_{2A} agonists). These observations, alongside identification of the main drug targets for antipsychotic drugs, have led to different neurochemical hypotheses of schizophrenia although with inconclusive clinical evidence. More recent studies have shifted the focus to theories based on changes in neural connectivity including synaptic pruning, excitatory-inhibitory balance in regions such as the prefrontal cortex and also immune-mediated mechanisms but no specific pathology has yet been established.

Dopamine

The original dopamine theory of schizophrenia was proposed by Carlson [4] on the basis of indirect pharmacological evidence in humans and experimental animals. **Amphetamine** releases dopamine in the brain and can produce in humans a behavioural syndrome reminiscent of an acute schizophrenic episode. Also, hallucinations are a side effect of **levodopa** and dopamine agonists used for Parkinson's disease (see **Ch. 40**). In animals, dopamine release causes a specific pattern of stereotyped behaviour that resembles the repetitive behaviours sometimes seen in patients with schizophrenia. Potent D_2 receptor agonists, such as **bromocriptine**, produce similar effects in animals, and these drugs, like amphetamine, exacerbate the symptoms of patients with schizophrenia. Furthermore, dopamine antagonists and drugs that block neuronal dopamine storage (e.g. **reserpine**) are effective in controlling the positive symptoms of schizophrenia, and in preventing amphetamine-induced behavioural changes.

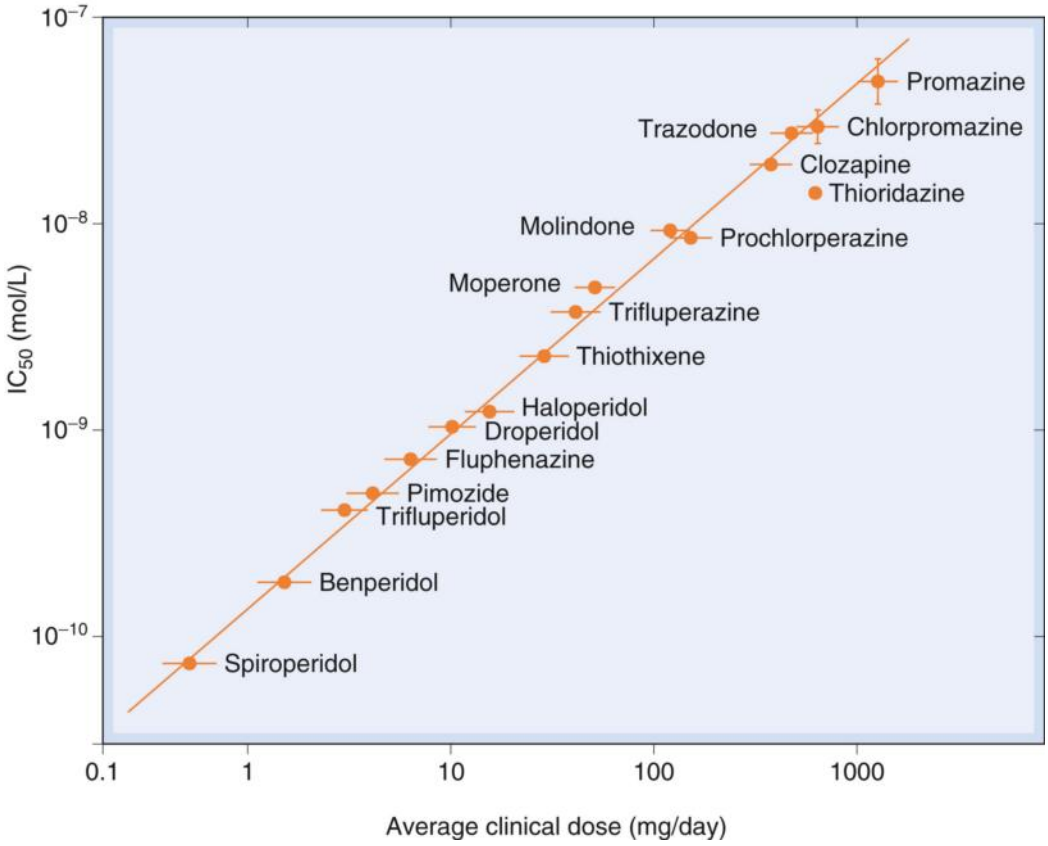

FIG. 47.1 Correlation between the clinical potency and affinity for dopamine D_2 receptors among antipsychotic drugs.Clinical potency is expressed as the daily dose used in treating schizophrenia, and binding activity is expressed as the concentration needed to produce 50% inhibition of haloperidol binding. From Seeman, P., et al., 1976. Nature 361, 717.

There is a strong correlation between antipsychotic potency in reducing positive symptoms and activity in blocking D_2 receptors (**Fig. 47.1**) and receptor imaging studies have shown that clinical efficacy of antipsychotic drugs is achieved when D_2 receptor occupancy reaches 65%–80% with first-generation antipsychotics

but can be lower with second-generation antipsychotics (**Fig. 47.2**).[5]

An increase in dopamine receptor density in schizophrenia has been reported in some studies, but not consistently. There have also been mixed findings in terms of evidence of increased mesolimbic dopamine levels or altered regulation of dopamine release, and the interpretation is complicated by the fact that chronic antipsychotic drug treatment is known to increase dopamine receptor expression. In fact, a side effect of antipsychotic treatment is the increased risk of rebound psychosis if patients are taken off medication.

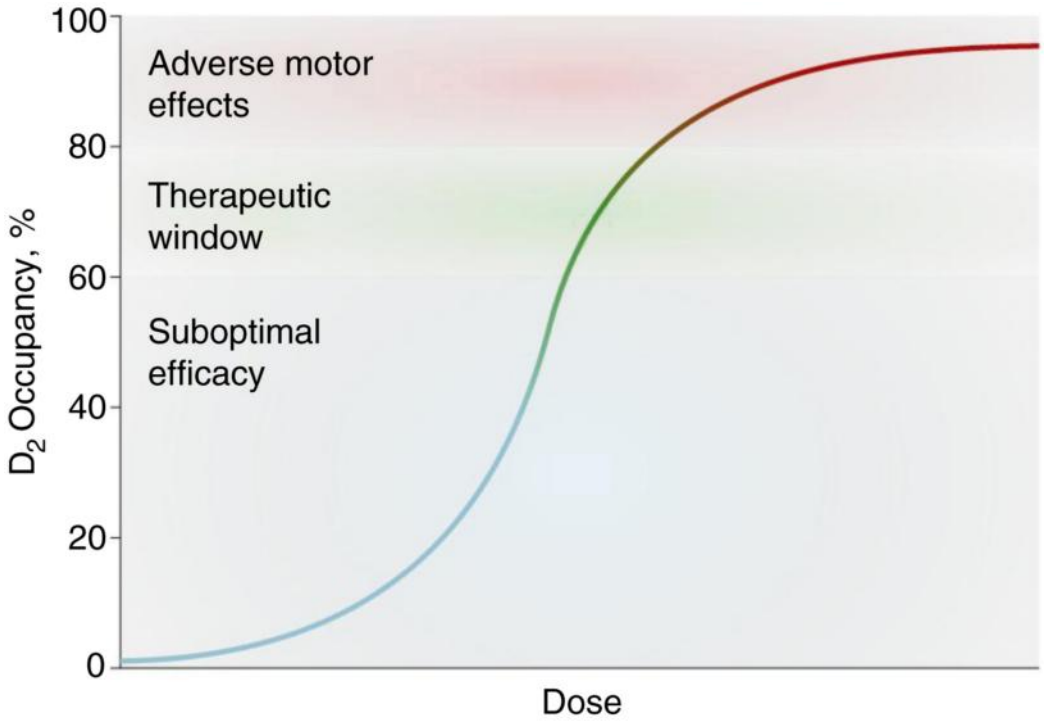

FIG. 47.2 Striatal D2 receptor occupancy greater than 60% is needed for the therapeutic effects of antipsychotics but more than 80% occupancy results in motor side effects.Studies using positron emission tomography of D2-antagonist antipsychotic drugs suggest that there is a therapeutic window between 60% and 80% D2-receptor occupancy. This is associated with beneficial effects in terms of the positive symptoms but with reduced risk of extrapyramidal side effects. This is true for most D2 antagonists but there are exceptions with clozapine achieving therapeutic effects at lower levels of D2 occupancy and partial agonists require higher occupancy.

Glutamate

In humans, NMDA receptor antagonists such as **PCP**, **ketamine** and **dizocilpine** (see **Ch. 39**) can reproduce symptoms characteristic of the positive, negative and cognitive deficit symptoms – in contrast to amphetamine, which produces only positive symptoms. Many of the genes linked to schizophrenia are involved in synapse formation which play a critical role in the development of neuronal networks particularly during adolescent brain development and it has been postulated that these manifest in altered glutamatergic neurotransmission. An interesting insight into the possible role of altered glutamate signalling in schizophrenia comes from a rare autoimmune disorder, anti-NMDA receptor encephalitis, where patients often present with symptoms very similar to schizophrenia but which result from impaired NMDA receptor function.

Another class of drugs which induce altered glutamatergic signalling and can also affect subcortical dopamine are the 5-HT_{2A} receptor antagonists. Highly enriched in cortical regions and particularly associated with effects in the prefrontal cortex, 5-HT_{2A} receptors modulate intracortical and cortical-subcortical glutamatergic neurotransmission, and agonists and partial agonists induce potent psychedelic effects which include altered perception, hallucinations and changes in cognitive and emotional processing.

Glutamatergic neurons and GABAergic neurons play complex roles in controlling the level of activity in neuronal pathways involved in schizophrenia. NMDA receptor hypofunction is thought to *reduce* the level of activity in mesocortical dopaminergic neurons. This would result in a decrease in dopamine release in the

prefrontal cortex and could thus give rise to negative symptoms of schizophrenia. NMDA receptor hypofunction in the cortex may affect GABAergic interneurons and alter cortical processing, giving rise to cognitive impairment. In addition, NMDA receptor hypofunction on GABAergic neurons would reduce inhibition of the excitatory cortical input to the ventral tegmental area (VTA) and thus *enhance* activity in the mesolimbic dopaminergic pathway. Thus NMDA receptor hypofunction could give rise to enhanced dopamine release in limbic areas such as the nucleus accumbens, resulting in the production of positive symptoms.

Given the evidence that schizophrenic symptoms may be due to a reduction in NMDA receptor function, efforts have been made to develop new drugs to enhance NMDA-mediated signalling but not to a level where it becomes neurotoxic (see **Ch. 40**), e.g. by activating the facilitatory glycine site on the NMDA receptor (see **Ch. 38**) with an agonist or by raising extracellular glycine levels by inhibiting the GlyT1 transporter. However, **bitopertin**, a GlyT1 inhibitor, failed as an antipsychotic drug in clinical trials. An alternative approach to modulating glutamate signalling is to target autoreceptors, however clinical trials of mGlu2/3 (**Ch. 38**) agonists failed in clinical trials despite showing promising effects in animal models.

Other glutamate pathways thought to be involved in schizophrenia are the corticostriatal, thalamocortical, corticothalamic and cortico-brain stem pathways. The thalamus normally functions as a sensory filter to limit unnecessary sensory input to the cortex. Disruption of the normal inputs to the thalamus, for example from a reduction in glutamatergic or

GABAergic transmission, disables this 'sensory gate' function, allowing uninhibited input to reach the cortex. The role of the thalamus in schizophrenia is reviewed by **Pergola et al. (2015)**.

Animal models

Traditional pharmacological models of schizophrenia by and large reflect behaviours resulting from heightened dopaminergic transmission in the brain and provide a useful screen for drugs which have dopamine receptor-antagonist activity. Models based on inhibition of NMDA function by PCP or 5-HT_{2A} agonist–induced behaviours such as the head twitch response also provide a useful screen but do not reflect the underlying aetiology of schizophrenia. With increasing understanding of genetic and environmental risk factors, various genetic and developmental models have been evaluated to try to provide a more relevant phenotype. However, it is difficult to fully recapitulate the multifactorial genetic and environmental factors which contribute to the human disorder, many of which are not yet fully understood, in an animal model and laboratory setting. Models of cognitive deficits and negative symptoms are also lacking. For further details of behavioural tasks used for evaluating schizophrenia-like symptoms and an overview of animal models of schizophrenia see **Ang et al. (2021)** and **Winship et al. (2019)**.

The nature of schizophrenia

- Psychotic illness characterised by delusions, hallucinations and thought disorder (positive symptoms), together with

social withdrawal and flattening of emotional responses (negative symptoms), and cognitive impairment.

- Acute episodes (mainly positive symptoms) frequently recur and may develop into chronic schizophrenia, with predominantly negative symptoms.
- Incidence is about 1% of the population, with a significant hereditary component. Genetic linkage studies suggest involvement of multiple genes, but no single 'schizophrenia gene'.
- Neurodevelopmental changes linked to both genetic risk and environmental factors resulting in increased grey matter loss and aberrant network organisation seem the most likely cause of schizophrenia, but no single gene, brain region or neurotransmitter system has consistently been found to underlie the disorder.

Antipsychotic Drugs

Classification of Antipsychotic Drugs

More than 80 different antipsychotic drugs are available for clinical use. These have been divided into two groups – those drugs that were originally developed (e.g. **chlorpromazine**, **haloperidol** and many similar compounds), often referred to as *first-generation*, *typical* or *conventional antipsychotic drugs*, and more recently developed agents (e.g. **clozapine**, **risperidone**), which are termed *second-generation* or *atypical antipsychotic drugs*. **Table 47.1** summarises the main drugs that are in clinical use. [6]

The term *atypical* refers to the diminished tendency to cause unwanted motor side effects, but it is also used to describe compounds with a different pharmacological profile from first-generation compounds. In practice, however, it often serves – not very usefully – to distinguish the large group of similar first-generation dopamine antagonists from the more diverse group of later compounds.

The therapeutic activity of the prototype drug, chlorpromazine, in patients with schizophrenia was discovered through the acute observations of a French surgeon, Laborit, in 1947. He tested various substances, including **promethazine**, for their ability to alleviate signs of stress in patients undergoing surgery, and concluded that promethazine had a calming effect that was different from mere sedation. Elaboration of the phenothiazine structure led to chlorpromazine, the antipsychotic effect of which was demonstrated in man, at Laborit's instigation, by Delay and Deniker in 1953. This drug was unique in controlling the symptoms of patients with psychotic disorders. The clinical efficacy of phenothiazines was discovered long before their mechanism was guessed at, let alone understood.

Pharmacological investigation showed that phenothiazines, the first-generation antipsychotic agents, block many different mediators, including dopamine, histamine, catecholamines, acetylcholine and 5-HT, and this multiplicity of actions led to the trade name Largactil for chlorpromazine.

Classification of antipsychotic drugs

- Main categories are:
  - first-generation ('typical', 'classical' or 'conventional') antipsychotics (e.g. **chlorpromazine**, **haloperidol**, **fluphenazine**, **flupentixol**, **zuclopenthixol**);
  - second-generation ('atypical') antipsychotics (e.g. **clozapine**, **risperidone**, **quetiapine**, **amisulpride**, **aripiprazole**, **ziprasidone**).
- The distinction between first- and second-generation drugs is not clearly defined but rests on:
  - receptor profile;
  - incidence of extrapyramidal side effects (EPSs) (less in second-generation group);
  - efficacy (specifically of **clozapine**) in 'treatment-resistant' patients;
  - efficacy against negative and cognitive symptoms although whether this is due to specific beneficial effects or rather reduced side effects compared with first-generation drugs is still debated.

Clinical Efficacy in Treatment of Schizophrenia

The clinical efficacy of antipsychotic drugs in enabling patients with schizophrenia to lead more normal lives has been demonstrated in many controlled trials (see **Leucht et al., 2013**). The inpatient population (mainly patients with chronic schizophrenia) of psychiatric hospitals declined sharply in the 1950s and 1960s. The introduction of antipsychotic drugs was a significant enabling

factor, as well as the changing public and professional attitudes towards hospitalisation of people with psychiatric disorders.

Antipsychotic drugs have severe drawbacks that include:

- Not all patients with schizophrenia respond to drug therapy. It is recommended to try clozapine in patients who are resistant to other antipsychotic drugs. The 30% of patients who do not respond are classed as 'treatment resistant' and present a major therapeutic problem. The reason for the difference between responsive and unresponsive patients is unknown at present.
- While they control the positive symptoms (thought disorder, hallucinations, delusions, etc.) effectively, most are ineffective in relieving the negative symptoms (emotional flattening, social isolation) and cognitive impairment and some antipsychotics may worsen these symptoms.
- They induce a range of side effects that include extrapyramidal motor, endocrine and sedative effects (see **Table 47.1**) that can be severe and limit patient compliance.
- They may produce unwanted cardiac (proarrhythmic) effects (see **Ch. 21**).

Second-generation antipsychotic drugs were believed to overcome these shortcomings to some degree. However, a meta-analysis (**Leucht et al., 2013**) concluded that only some of the second-generation antipsychotic drugs examined showed better overall efficacy. An important consideration in this discussion is the extent to which a reduced side effect burden, particularly in relation to

cognitive and emotional side effects, may improve overall outcomes but this is not directly linked to drug-induced efficacy.

Abrupt cessation of antipsychotic drug administration may lead to a rapid-onset psychotic episode linked to the adaptive changes induced by the antipsychotic drug treatment and is distinct from the underlying illness.

Other Uses of Antipsychotic Drugs

A common emerging theme with centrally acting drugs is that while they were initially developed to treat one brain disorder they have been subsequently found to be effective in treating other disorders. This is also the case with antipsychotic drugs, which are now used to manage behavioural symptoms associated with a range of disorders, including:

- bipolar disorder, mania and depression (see **Ch. 48**)
- psychomotor agitation and severe anxiety (**chlorpromazine** and **haloperidol**)
- agitation and restlessness in the elderly including patients with dementia (**risperidone**), although this is discouraged due to the potential for adverse long term outcomes
- psychosis associated with Parkinson's disease (**pimavanserin**) (see **Ch. 41**)
- restlessness and pain in palliative care (**levomepromazine**)
- nausea and vomiting (e.g. **chlorpromazine** and **haloperidol**) reflecting antagonism at dopamine, muscarinic, histamine and possibly 5-HT receptors
- motor tics and intractable hiccup (**chlorpromazine** and **haloperidol**)

- antisocial sexual behaviour (**benperidol**)
- involuntary movements caused by Huntington's disease (mainly **haloperidol**; see **Ch. 40**)

Pharmacological Properties

Dopamine Receptors

The classification of dopamine receptors in the central nervous system is discussed in **Chapter 39** (see **Table 39.1**). There are five subtypes, which fall into two functional classes: the D_1 type, comprising D_1 and D_5, and the D_2 type, comprising D_2, D_3 and D_4. Antipsychotic drugs owe their therapeutic effects mainly to blockade of D_2 receptors. [7] As stated previously, antipsychotic effects develop when occupancy reaches between 65% and 80% whilst occupancy over 80% has been linked to motor side effects (see **Fig. 47.2**). The first-generation compounds show some preference for D_2 over D_1 receptors, whereas some of the later agents (e.g. **sulpiride**, **amisulpride**) are highly selective for D_2 receptors. D_2 antagonists that dissociate rapidly from the receptor (e.g. **quetiapine**) and D_2 partial agonists (e.g. **aripiprazole**) were introduced in an attempt to reduce extrapyramidal motor side effects. **Cariprazine**, a new antipsychotic drug, is a D_2 and D_3 partial agonist with higher affinity for D_3 than D_2 receptors.

Table 47.1

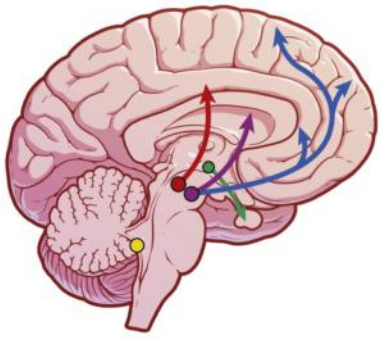
Table based on data contained in Guide to Pharmacology (**http://www.guidetopharmacology.org/**) and NIMH Psychoactive Drug Screening Program database (**http://pdsp.med.unc.edu/**). Where available, data obtained on human receptors are given.

It is the antagonism of D_2 receptors in the mesolimbic pathway that is believed to reduce the positive symptoms of schizophrenia (**Fig. 47.3**). Unfortunately, systemically administered antipsychotic drugs do not discriminate between D_2 receptors in distinct brain regions and D_2 receptors in other brain pathways will also be blocked. Thus antipsychotic drugs produce unwanted motor effects (block of D_2 receptors in the nigrostriatal pathway), enhance prolactin secretion (block of D_2 receptors in the tuberoinfundibular pathway), produce emotional blunting and anhedonia (block of D_2 receptors in the reward component of the mesolimbic pathway) and perhaps even worsen the cognitive and negative symptoms of schizophrenia (**Fig. 47.3**). Expression of D_2 receptors in the prefrontal cortex is low but D_1 receptors are in greater abundance.

This is particularly relevant for the first-generation antipsychotics which are also potent $D_{1\neg}$ antagonists. While all first-generation antipsychotic drugs block D_2 receptors and should therefore in theory induce all of these unwanted effects, some have additional pharmacological activity (e.g. mACh receptor antagonism and 5-HT_{2A} receptor antagonism) that, to varying degrees, ameliorate some of the unwanted effects.

Antipsychotic drugs have classically been thought to have a delayed onset to their therapeutic actions, even though their dopamine receptor-blocking action is immediate. This view has, however, been called into question (**Kapur et al., 2005**; **Leucht et al., 2005**). In animal studies, chronic antipsychotic drug administration does produce compensatory changes in the brain, for example, a reduction in the activity of dopaminergic neurons and proliferation of dopamine receptors, detectable as an increase in haloperidol binding, with a pharmacological supersensitivity to dopamine reminiscent of the phenomenon of denervation supersensitivity (see **Ch. 13**). The mechanism(s) of these delayed effects are poorly understood. They are likely to contribute to the development of unwanted *tardive dyskinesias* and also contribute to acute rebound psychosis if the antipsychotic is stopped abruptly. The sedating effect of some antipsychotic drugs is immediate, making them useful in acute behavioural emergencies.



Dopamine$_2$-receptor antagonism and dopamine pathways

- Mesolimbic – antipsychotic
- Mesocortical – cognitive, emotional impairment
- Nigrostriatal – extrapyramidal side effects
- Tuberohypophyseal – hyperprolactinaemia
- Chemoreceptor trigger zone – antiemetic

Key receptors linked to efficacy and side effects of typical and atypical antipsychotics

RECEPTOR TARGET	ROLE IN EFFICACY	ROLE IN SIDE EFFECTS
D_2-receptor antagonism	Antipsychotic	EPS, hyperprolactinaemia, emotional blunting, cognitive impairment
5-HT_{2A} receptor antagonism	Antipsychotic	Reduced EPS, reduces akathisia induced by D2 antagonism
5-HT_{2C} receptor antagonism	?	Increased appetite, metabolic effects
Muscarinic$_1$ receptor antagonism	?	Constipation, dry mouth, blurred vision Reduced EPS
Histamine$_1$ receptor antagonism	Sedation*	Sedation*
α-adrenoceptor antagonism	?	Postural hypotension
SERT/NAT	Antidepressant	?

*Depending on the circumstances sedation may contribute to efficacy or side effects i.e. in acute psychosis, sedation may be beneficial

FIG. 47.3 Receptors affected by antipsychotic drugs and their relationship to efficacy and side effects.The figure illustrates the effects of D2 antagonism in the different dopamine pathways in the brain whilst the table details some of the receptors commonly affected at therapeutic doses. The beneficial effects and side effects associated with individual antipsychotics depend on their specific receptor profile. *EPS,* Extrapyramidal side effects; *5-HT,* 5-hydroxytryptamine; *NAT,* noradrenaline transporter; *SERT,* serotonin transporter.

Mechanism of action of antipsychotic drugs

- Most antipsychotic drugs are antagonists or partial agonists at D_2 dopamine receptors, but they vary in their potency and also block a variety of other receptors.
- Efficacy in treating positive symptoms generally runs parallel to activity on D_2 receptors, but activities at 5-HT_{2A} receptors are thought to contribute to efficacy whilst interactions with other receptors (e.g. 5-HT_{2A} and muscarinic) may reduce extrapyramidal side effects (EPS).
- Activity at muscarinic, H_1 and α receptors may determine unwanted side effect profile.
- Imaging studies suggest that therapeutic effects typically require 65%–80% occupancy of D_2 receptors with occupancy >80% linked to EPSs.

5-Hydroxytryptamine Receptors

The idea that 5-HT dysfunction could be involved in schizophrenia has drifted in and out of favour many times. It was originally based on the fact that LSD, a partial agonist at 5-HT_{2A} receptors (see Chs **16** and **49**), can induce psychosis with some similarities to the symptoms of schizophrenia. Most of the newer atypical antipsychotics have affinity for 5-HT receptors and antagonism at the 5-HT_{2A} receptor, and to a lesser extent the 5-HT_{1A} receptor, is linked to both therapeutic effects and reduced EPSs. Pharmacological manipulation of 5-HT receptor activity, combined with D_2 receptor antagonism, has resulted in drugs with improved therapeutic profiles (see **Table 47.1**). [8] There is a plethora of 5-HT receptors (see Chs **16** and **39**), with disparate functions in the body.

Interestingly, antagonism at the 5-HT_{2A} receptor is not only a feature of some antipsychotics but also some antidepressants (see **Ch. 48**) and has been associated with anxiolytic, antidepressant and antipsychotic effects. It remains unknown exactly why the 5-HT_{2A} receptor is a common target for many of these drugs but this receptor is an important therapeutic target in psychiatry. 5-HT_{2A} receptors can induce pleiotropic effects dependent on their associated intracellular signalling. The most common intracellular mechanism is to increase calcium signalling via Gq-mediated stimulation of phospholipase C and inositol triphosphate production but other mechanisms have also been reported depending on the brain region and cell type being studied. Drugs with 5-HT_{2A} antagonist properties (e.g. olanzapine and risperidone) are able to enhance dopamine release in the striatum by reducing the inhibitory effect of 5-HT. This may reduce EPSs (see later). In contrast, in the mesolimbic pathway, the combined effects of D_2 and 5-HT_{2A} antagonism are thought to have beneficial effects on the positive symptoms of schizophrenia. Further, enhancing both dopamine and glutamate release in the mesocortical circuit, 5-HT_{2A} receptor antagonism may improve the negative symptoms of schizophrenia (**Stahl, 2021**). Pimavanserin, a drug recently introduced for the treatment of psychosis associated with Parkinson's disease (see **Ch. 40**) and which may be beneficial as an adjunct to other antipsychotic drugs in the treatment of schizophrenia, is an inverse agonist at the 5-HT_{2A} receptor and has no activity at dopaminergic receptors.

5-HT_{1A} receptors are found post-synaptically as well as functioning as somatodendritic autoreceptors that inhibit 5-HT

release (see **Ch. 39**). Antipsychotic drugs that are agonists or partial agonists at 5-HT_{1A} receptors (e.g. quetiapine; see **Table 47.1**) may work by decreasing 5-HT release, thus enhancing dopamine release in the striatum and prefrontal cortex.

Muscarinic Acetylcholine Receptors

Some phenothiazine antipsychotic drugs (e.g. **pericyazine**) have been reported to produce fewer EPSs than others, and this was thought to correlate with their muscarinic antagonist actions. Also, some second-generation drugs possess muscarinic antagonist properties (e.g. olanzapine). In the striatum, dopaminergic nerve terminals are thought to innervate cholinergic interneurons that express inhibitory D_2 receptors (**Pisani et al., 2007**). It is suggested that there is normally a balance between D_2 receptor activation and muscarinic receptor activation. Blocking D_2 receptors in the striatum with an antipsychotic agent will result in enhanced acetylcholine release on to muscarinic receptors, thus producing EPSs, which are counteracted if the antipsychotic also has muscarinic antagonist activity. Maintaining the dopamine/acetylcholine balance was also the rationale for the use of the muscarinic antagonist **benztropine** to reduce extrapyramidal effects of antipsychotic drugs. Muscarinic antagonist activity does, however, induce side effects such as constipation, dry mouth and blurred vision.

Unwanted Effects

Extrapyramidal Motor Disturbances

Antipsychotic drugs produce two main kinds of motor disturbance in humans: *acute dystonias* and *akathisia,* and *tardive dyskinesias*, collectively termed *extrapyramidal side effects (EPSs)*. These all result directly or indirectly from D_2 receptor blockade in the nigrostriatal pathway. EPSs constitute one of the main disadvantages of first-generation antipsychotic drugs. Second-generation drugs were defined based on their ability to induce lower incidence of EPSs at doses which were effective against positive symptoms of schizophrenia. Whilst there may be a reduction in EPS, second-generation antipsychotics are not devoid of these motor side effects and a long-term study of olanzapine, risperidone, quetiapine and **ziprasidone** concluded that they too can induce EPSs (see **Lieberman and Stroup, 2011**). Even aripiprazole, which is a D_2 partial agonist, has been reported to produce this unwanted effect.

Acute dystonias

are involuntary movements (restlessness, muscle spasms, protruding tongue, fixed upward gaze, neck muscle spasm), and ***akathisia,*** an urge to move that you can't control, are symptoms of Parkinson's disease (see **Ch. 40**). They occur commonly in the first few weeks, often declining with time, and are reversible on stopping drug treatment. The timing is consistent with block of the dopaminergic nigrostriatal pathway. Concomitant block of muscarinic receptors and 5-HT_{2A} receptors may mitigate the motor effects of dopamine receptor antagonists (see earlier).

Tardive dyskinesia

(see **Klawans et al., 1988**) develops after months or years (hence 'tardive') in 20%–40% of patients treated with first-generation antipsychotic drugs and is one of the main problems of antipsychotic therapy. Its seriousness lies in the fact that it is a disabling and often irreversible condition, which often gets worse when antipsychotic therapy is stopped and is resistant to treatment. The syndrome consists of involuntary movements, often of the face and tongue, but also of the trunk and limbs, which can be severely disabling. It resembles that seen after prolonged treatment of Parkinson's disease with levodopa (see **Ch. 40**). The incidence depends greatly on drug, dose and age (being commonest in patients who are over 50 years of age).

There are several theories about the mechanism of tardive dyskinesia (see **Casey, 1995**). One is that it is associated with a gradual increase in the number of D_2 receptors in the striatum, which is less marked during treatment with second-generation than with first-generation antipsychotic drugs. Another possibility is that chronic block of inhibitory dopamine receptors enhances catecholamine and/or glutamate release in the striatum, leading to excitotoxic neurodegeneration (see **Ch. 41**).

Drugs that rapidly dissociate from D_2 receptors (e.g. clozapine, olanzapine) induce less severe EPSs. A possible explanation for this (see **Kapur and Seeman, 2001**) is that with a rapidly dissociating compound, a brief surge of dopamine can effectively overcome the block by competition (see **Ch. 2**), whereas with a slowly dissociating compound, the level of block takes a long time to respond to the presence of endogenous dopamine, and is in practice non-competitive. Adverse motor effects may be avoided if fractional

receptor occupation by the antagonist falls during physiological surges of dopamine. An extension of this idea is that perhaps a little D_2 receptor activation may be beneficial. This could be produced, for example, by drugs that are D_2 partial agonists (e.g. aripiprazole) in contrast to simple antagonists. It is thought that partial agonists reduce D_2 hyperactivation in the mesolimbic pathway, thus alleviating positive symptoms of schizophrenia, but provide enough D_2 receptor stimulation in the mesocortical pathway to prevent negative symptoms, and in the nigrostriatal pathway to lower the incidence of EPSs.

Antipsychotic-induced motor disturbances

- Major problem of antipsychotic drug treatment.
- Two main types of disturbance occur:
  - acute, reversible dystonias, akathesis and Parkinson-like symptoms (indeed, antipsychotic drugs generally worsen Parkinson's disease and block the actions of drugs used to treat the disorder);
  - slowly developing tardive dyskinesia, often irreversible.
- Acute symptoms comprise involuntary movements, tremor and rigidity, and are probably the direct consequence of block of nigrostriatal dopamine receptors.
- Tardive dyskinesia comprises mainly involuntary movements of the face and limbs, appearing after months or years of antipsychotic treatment. It may be associated with proliferation of dopamine receptors in the corpus striatum. Treatment is generally unsuccessful.

- The incidence of acute dystonias and tardive dyskinesia is less with newer, second-generation antipsychotics, and particularly low with **clozapine**, **aripiprazole** and **zotepine.**

Theories for reduced EPS with second-generation antipsychotics include antagonism at 5-HT_{2A} receptors as well as rapid dissociation from the D_2 receptor and improved pharmacokinetic profile that enable D_2 receptor occupancy to be more easily maintained between levels which are antipsychotic but do not cause EPS.

Endocrine Effects

Dopamine, released in the median eminence by neurons of the tuberohypophyseal pathway (see Chs **33** and **39**), acts physiologically via D_2 receptors to inhibit prolactin secretion. Blocking D_2 receptors by antipsychotic drugs can therefore increase the plasma prolactin concentration (**Fig. 47.4**), resulting in breast swelling, pain and lactation (known as 'galactorrhoea'), which can occur in men as well as in women. As can be seen from **Fig. 47.4**, the effect is maintained during chronic antipsychotic administration, without any habituation. Other less pronounced endocrine changes have also been reported, including a decrease of growth hormone secretion, but these, unlike the prolactin response, are believed to be relatively unimportant clinically. Because of its D_2 receptor partial agonist action aripiprazole, unlike other antipsychotic drugs, reduces prolactin secretion.

Other Unwanted Effects

Most antipsychotic drugs block a variety of receptors, particularly acetylcholine (muscarinic), histamine (H_1), noradrenaline (α) and 5-HT receptors (see **Table 47.1**). This gives rise to a wide range of side effects (**Fig. 47.3**).

They can produce sexual dysfunction – decreased libido and decreased arousal as well as erection and ejaculation difficulties in men – through block of dopamine, muscarinic and α_1 receptors.

Drowsiness and sedation, which tend to decrease with continued use, occur with many antipsychotic drugs. Antihistamine (H_1) activity is a property of some phenothiazine antipsychotics (e.g. chlorpromazine and **methotrimeprazine**) and contributes to their sedative and antiemetic properties (see **Ch. 30**), but not to their antipsychotic action.

While block of muscarinic receptors produces a variety of peripheral effects, including blurring of vision and increased intraocular pressure, dry mouth and eyes, constipation and urinary retention (see **Ch. 14**), it may, however, also be beneficial in relation to EPSs.

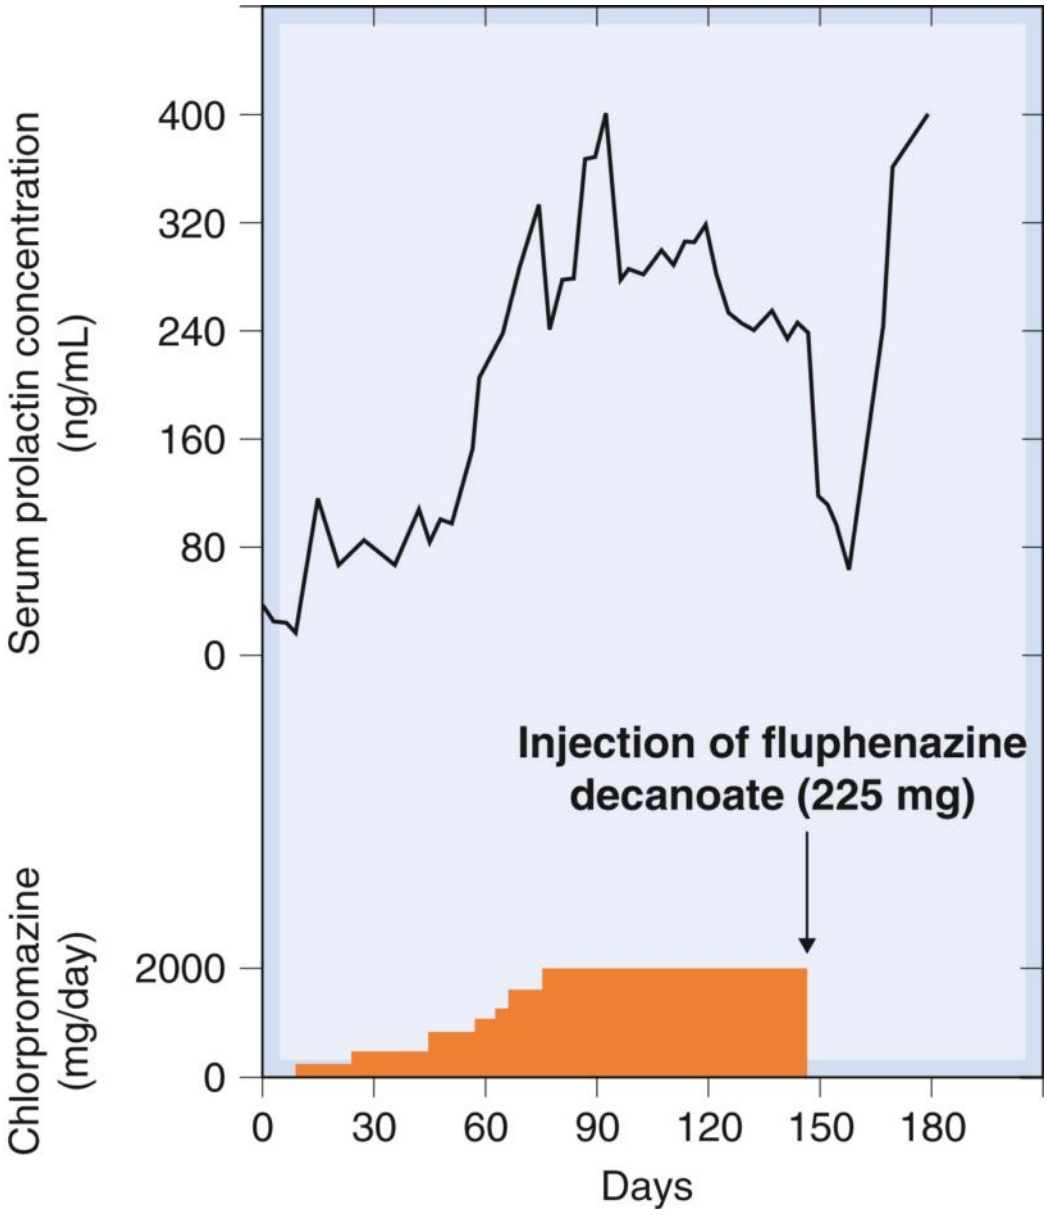


FIG. 47.4 Effects of antipsychotic drugs on prolactin secretion in a patient with schizophrenia.When daily dosage with chlorpromazine was replaced with a depot injection of fluphenazine, the plasma prolactin initially dropped, because of the delay in absorption, and then returned to a high level. From Meltzer, H.Y., et al., 1978. In: Lipton

et al. (Eds). Psychopharmacology: A Generation in Progress. Raven Press, New York.

Blocking α adrenoceptors causes *orthostatic hypotension* (see **Ch. 15**) but does not seem to be important for their antipsychotic action.

Weight gain is a common and serious side effect particularly associated with second-generation antipsychotics and is linked to antagonism at the 5-HT_{2C} receptor leading to effects on both appetite and metabolism. Increased risk of diabetes and cardiovascular disease occurs with several second-generation antipsychotic drugs. Antagonist actions at H_1 and muscarinic receptors may also contribute to these effects.

Antipsychotic drugs can prolong the QT interval in the heart (see **Ch. 20**) giving rise to arrhythmia and risk of sudden death (**Jolly et al., 2009**). As such, a range of baseline measurements are usually recommended prior to starting antipsychotic drugs; these include weight, blood pressure, blood glucose, and electrocardiogram.

Various idiosyncratic and hypersensitivity reactions can occur, the most important being the following:

- *Jaundice*, which occurs with older phenothiazines such as chlorpromazine. The jaundice is usually mild, associated with elevated serum alkaline phosphatase activity (an 'obstructive' pattern), and disappears quickly when the drug is stopped or substituted by a chemically unrelated antipsychotic.

- *Leukopenia* and *agranulocytosis* are rare but potentially fatal, and occur in the first few weeks of treatment. The incidence of leukopenia (usually reversible) is less than 1 in 10,000 for most antipsychotic drugs, but much higher (1%–2%) with clozapine, whose use therefore requires regular monitoring of blood cell counts. Provided the drug is stopped at the first sign of leukopenia or anaemia, the effect is reversible. Olanzapine appears to be free of this disadvantage.
- *Urticarial skin reactions* are common but usually mild. Excessive sensitivity to ultraviolet light may also occur.
- *Antipsychotic malignant syndrome* is a rare but serious complication similar to the malignant hyperthermia syndrome seen with certain anaesthetics (see **Ch. 41**). Muscle rigidity is accompanied by a rapid rise in body temperature and mental confusion. It is usually reversible, but death from renal or cardiovascular failure occurs in 10%–20% of cases.

Unwanted effects of antipsychotic drugs

- Important side effects common to many drugs are:
  - motor disturbances (see Antipsychotic-induced motor disturbances box);
  - endocrine disturbances (increased prolactin release);
  - these are secondary to dopamine receptor block.
- Sedation, hypotension and weight gain are common.
- Obstructive jaundice sometimes occurs with phenothiazines.

- Other side effects (dry mouth, blurred vision, hypotension, etc.) are due to block of other receptors, particularly muscarinic receptors and α adrenoceptors.
- Some antipsychotic drugs cause agranulocytosis as a rare and serious idiosyncratic reaction. With **clozapine**, leukopenia is common and requires routine monitoring.
- Antipsychotic malignant syndrome is a rare but potentially dangerous idiosyncratic reaction.

Pharmacokinetic Aspects

Chlorpromazine, in common with other phenothiazines, is erratically absorbed after oral administration. **Fig. 47.5** shows the wide range of variation of the peak plasma concentration as a function of dosage in 14 patients. Among four patients treated at the high dosage level of 6–8 mg/kg, the variation in peak plasma concentration was nearly 90-fold; two showed marked side effects, one was well controlled and one showed no clinical response.

The relationship between the plasma concentration and the clinical effect of antipsychotic drugs is highly variable, and the dosage has to be adjusted on a trial-and-error basis. This is made even more difficult by the fact that at least 40% of patients with schizophrenia fail to take drugs as prescribed. It is remarkably fortunate that the acute toxicity of antipsychotic drugs is slight, given the unpredictability of the clinical response.

The plasma half-life of most antipsychotic drugs is 15–30 h, clearance depending entirely on hepatic transformation by a combination of oxidative and conjugative reactions.

Most antipsychotic drugs can be given orally or in urgent situations by intramuscular injection. Slow-release (depot) preparations of many are available, in which the active drug is esterified with heptanoic or decanoic acid and dissolved in oil. Given as an intramuscular injection, the drug acts for 2–4 weeks, but initially may produce acute side effects. These preparations are widely used to minimise compliance problems.

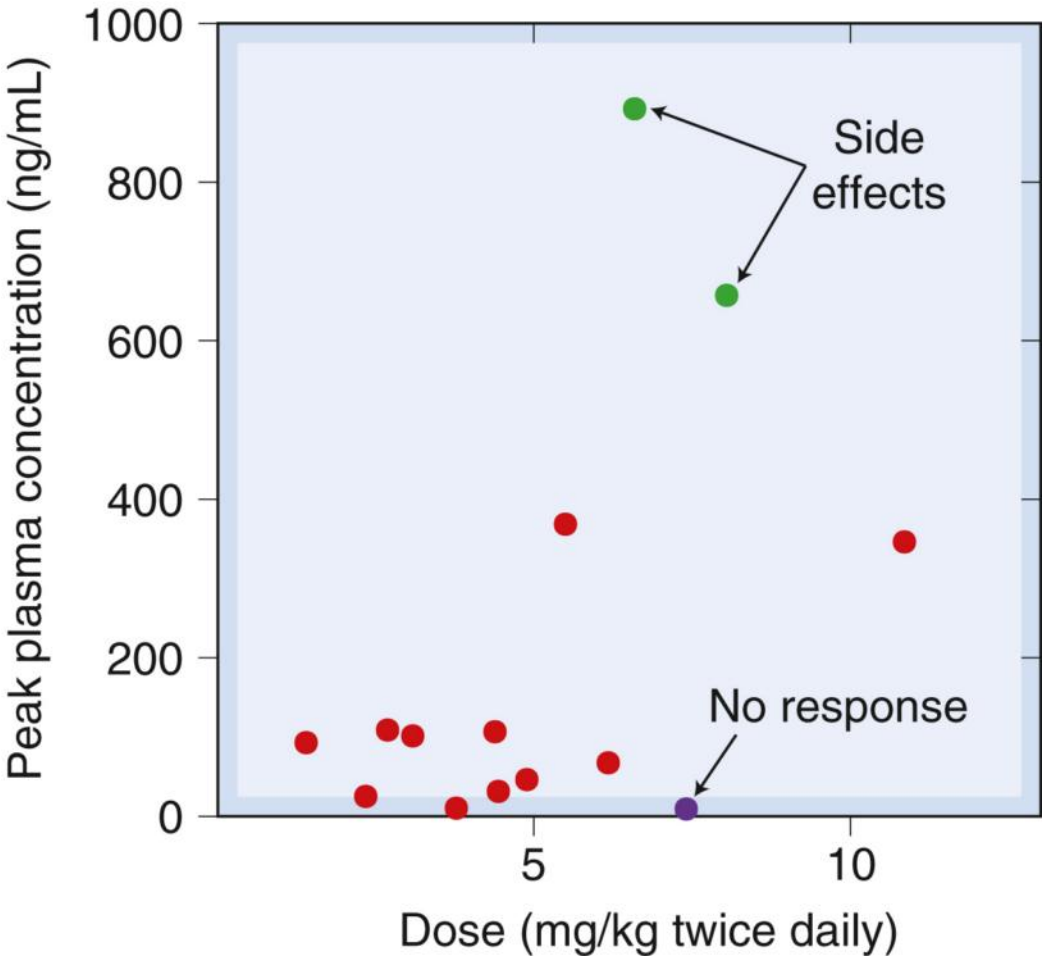

FIG. 47.5 Individual variation in the relation between dose and plasma concentration of chlorpromazine in a group of patients with schizophrenia. Data from Curry, S.H., et al., 1970. Arch. Gen. Psychiatry 22, 289.

The more predictable pharmacokinetic profile of the second-generation antipsychotics as well as their more dynamic interactions with the D_2 receptor may be a factor in their improved EPS profile. Imaging studies suggest that >80% occupancy of D_2 receptors in the nigrostriatal pathway leads to EPS. The pharmacology of first-generation antipsychotics can make it

difficult to achieve the optimal dose but it is easier with many of the second-generation drugs because of their more predictable pharmacokinetics and more rapid association and dissociation from the D2 receptor.

Clinical uses of antipsychotic drugs

- *Behavioural emergencies* (e.g. violent patients with a range of psychopathologies including *mania*, *toxic delirium*, *schizophrenia* and others):
  - Antipsychotic drugs (e.g. **chlorpromazine**, **haloperidol**, **olanzapine**, **risperidone**) can rapidly control hyperactive psychotic states.
  - Note that the intramuscular dose is lower than the oral dose of the same drug because of presystemic metabolism.
- Schizophrenia:
  - Second-generation antipsychotics are recommended as a first-line treatment for chronic treatment due to their reduced side effect burden; however, first-generation drugs are still used for patients who fail to respond or achieve adequate symptomatic control. Depot injections (e.g. **flupentixol decanoate**) may be useful for maintenance treatment when compliance with oral treatment is a problem.
  - **Flupentixol** has antidepressant properties distinct from its antipsychotic action.

– **Clozapine** can cause *agranulocytosis* and is reserved for patients whose condition remains inadequately controlled despite previous use of two or more antipsychotic drugs, of which at least one is a second-generation drug. Blood count is monitored weekly for the first 18 weeks, and less frequently thereafter.

Future Developments

Progress in the development of new antipsychotics has been disappointing with much of the enthusiasm around glutamate-based treatments being crushed when drugs designed to modify glutamatergic transmission failed in clinical trials despite showing promise in both animal models and early trials in humans. This includes the orthosteric and allosteric agonists of $mGluR_2$ and $mGluR_3$ metabotropic glutamate receptors and $mGluR_5$ receptor agonists (see **Ch. 38**). An alternative approach to modulating glutamatergic function is positive allosteric modulation at the AMPA receptor, one such drug, BIIB-104, is currently under development for the treatment of cognitive symptoms in schizophrenia.

Roluperidone is a 5-HT_{2A} and σ_2 receptor antagonist and has an active metabolite with some affinity at H_1 receptors. However, after initial promise, the most recent phase III data are disappointing. Other drugs currently undergoing clinical trial include those with more novel mechanisms of action including, muscarinic M_1 and M_4 agonists such as **xanomeline** which have been shown to have potential as antipsychotic and pro-cognitive drugs but their

peripheral side effects (see **Ch. 14**) have limited progress. A combination of xanomeline and the peripherally restricted muscarinic antagonist **trospium** is currently undergoing clinical trials in schizophrenia. It may also be useful to treat cognitive impairments in other disorders such as Alzheimer's disease. A novel phosphodiesterase10A inhibitor, TAK-063, is also in stage II clinical trial.

Using a different approach to classical drug development methods (see **Ch. 60**), a non-D_2 psychotropic drug was identified based on a novel high-throughput, high-content, mouse-behaviour phenotyping platform, in combination with in vitro screening. The mechanism(s) of action of the arising lead molecule, ulotaront (SEP-363856), has yet to be fully elucidated but includes trace amine-associated receptor-1 and 5-HT_{1A} receptor agonism. Its path through clinical trials will be interesting to follow and, if successful, could provide an example of a different approach to identify new molecules and targets for complex psychiatric disorders – a sort of 'targeted serendipity'.

QUESTIONS

QUESTION 47.1

Schizophrenia is a psychotic disorder, often affecting the young. It has a strong genetic component and there is evidence for underlying biological dysregulation.

Which of the following changes could potentially give rise to the negative symptoms of schizophrenia?

OPTIONS:

A. Overactivation of the mesolimbic pathway involving D_2 receptors

B. Overactivation of the mesolimbic pathway involving D_1 receptors

C. *N*-methyl-D-aspartate (NMDA) receptor hypofunction in the mesocortical pathway

D. NMDA receptor hypofunction in the nucleus accumbens

E. Enhanced 5-hydroxytryptamine $(5\text{-HT})_{2A}$ signalling in the cortex

QUESTION 47.2

A range of first (conventional) and second (atypical) generation agents has been developed for the treatment of psychotic illness with a wide range of pharmacological profiles.

Which pharmacological approach would NOT be beneficial in the treatment of schizophrenia?

OPTIONS:

A. 5-HT_{1A} receptor agonists

B. D_2 receptor antagonists

C. Muscarinic receptor agonists

D. 5-HT_{2A} receptor antagonists

E. D_2 receptor partial agonists

QUESTION 47.3

Like many pharmacological agents, the use of antipsychotic drugs can be limited by unwanted side effects.

Which is NOT a major side effect of antipsychotic drugs?

OPTIONS:

A. Sedation

B. Galactorrhoea

C. Tardive dyskinesia

D. Erectile dysfunction

E. Weight loss

ANSWERS

ANSWER 47.1

RATIONALE:

A. The positive symptoms are potentially caused by overactivation of the mesolimbic pathway involving D_2 receptors.

B. The negative symptoms are potentially caused by decreased activation of the mesocortical pathway involving D_1 receptors.

C.

D. NMDA receptor hypofunction could give rise to enhanced dopamine release in limbic areas such as the nucleus accumbens, resulting in the production of positive symptoms.

E. 5-HT_{2A} receptors modulate intracortical and cortical-subcortical glutamatergic neurotransmission, and agonists and partial agonists induce potent psychedelic effects (similar to the positive symptoms of schizophrenia) which include altered perception, hallucinations and changes in cognitive and emotional processing.

CORRECT ANSWER WITH EXPLANATION:

C. NMDA receptor hypofunction in the mesocortical pathway

NMDA receptor hypofunction is thought to reduce the level of activity in mesocortical dopaminergic neurons. This would result in a decrease in dopamine release in the prefrontal cortex and could thus give rise to negative symptoms of schizophrenia.

ANSWER 47.2

RATIONALE:

A. 5-HT_{1A} receptors are somatodendritic autoreceptors that, when activated, inhibit 5-HT release. Agonists thus enhance dopamine release in the prefrontal cortex, which is beneficial in addressing the negative symptoms of schizophrenia.

B. Antagonism of D_2 receptors in the mesolimbic pathway relieves some of the positive symptoms but can cause unwanted motor effects.

C.

D. In the mesolimbic pathway, 5-HT_{2A} antagonism is thought to have beneficial effects on the positive symptoms of schizophrenia whilst in the mesocortical circuit, 5-HT_{2A} receptor antagonism enhancement of both dopamine and glutamate release may improve the negative symptoms of schizophrenia.

E. D_2 receptor partial agonists, which reduce mesolimbic D_2 receptor activation, were developed in an attempt to reduce the unwanted motor effects of full D_2 receptor antagonists.

CORRECT ANSWER WITH EXPLANATION:

C. Muscarinic receptor agonists

Blocking D_2 receptors in the striatum enhances acetylcholine release, causing unwanted extrapyramidal effects. This would be further exacerbated with the use of muscarinic agonists but inhibited by agents with muscarinic antagonist activity.

ANSWER 47.3

RATIONALE:

A. Drowsiness and sedation are common, possibly due to effects on H_1 receptors.

B. Dopaminergic inhibition leads to increased prolactin secretion and the consequences of breast swelling, pain and lactation (galactorrhoea).

C. This condition, which occurs over months/years, is characterised by involuntary movements that can be disabling and are usually irreversible. This may be due to a gradual increase in the number of D_2 receptors in the striatum, or that chronic block of inhibitory dopamine receptors enhances catecholamine and/or glutamate release in the striatum, leading to excitotoxic neurodegeneration.

D. Many agents cause a decrease in sexual function and libido. This is caused by the block of dopamine, muscarinic and α_1 receptors.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Weight loss

Weight gain is a common and serious side effect particularly associated with second-generation antipsychotics and is linked to antagonism at the 5-HT_{2C} receptor leading to effects on both appetite and metabolism.

[1] In this respect, the study of schizophrenia lags some years behind that of Alzheimer's disease (Ch. 40), where understanding of the pathogenesis has progressed rapidly to the point where promising drug targets have been identified. On the other hand, pragmatists can argue that drugs against Alzheimer's disease are so far only marginally effective, whereas current antipsychotic drugs deliver great benefits even though we do not quite know how they work.

[2] Schizophrenia is a condition where the patient exhibits symptoms of psychosis (e.g. delusions, hallucinations and disorganised behaviour). Psychotic episodes may also occur as a result of taking certain drugs for non-medicinal reasons (see Ch. 49); as an adverse effect of drug treatment, for example steroid-induced psychoses; or in disorders such as mania, bipolar disorder, depression (see Ch. 48) and dementias (see Ch. 40).

[3] A compelling account of what it is like to suffer from schizophrenia is contained in Kean (2009), *Schizophrenia Bulletin* 35, 1034–1036. The author is a pharmacology graduate and now a lecturer in mental health.

[4] Carlson was awarded a Nobel Prize in 2000 for this work.

[5] There are, however, exceptions to this simple rule. Up to one-third of patients with schizophrenia fail to respond even when D_2 receptor blockade exceeds 90%, and clozapine (see Table 47.1) can be effective at much lower levels of block.

[6] Wikipedia (https://en.wikipedia.org/wiki/List_of_antipsychotics) lists no fewer than 49 first-generation and 33 second-generation agents approved for clinical use. Despite this huge investment by the pharmaceutical industry and plethora of me-too compounds, clinical benefits remain modest.

[7] The D_4 receptor attracted attention on account of the high degree of genetic polymorphism that it shows in human subjects, and because some of the newer antipsychotic drugs (e.g. clozapine) have a high affinity for this receptor subtype. However, a specific D_4 receptor antagonist proved ineffective in clinical trials.

8 Early antipsychotic drugs (e.g. chlorpromazine) had actions at various receptors but also had unwanted side effects that resulted from activity at other receptors. Towards the end of the 20th century, drug development, not just of antipsychotic drugs, was focused largely on developing agents with a single action with the intention of reducing unwanted side effects. This philosophy drove the search for selective D_4 receptor antagonists, which proved ineffective. What is now apparent is that drugs with selected multiple actions (e.g. a combination of D_2 antagonism and 5-HT_{2A} antagonism) may have a better therapeutic profile.

48: Antidepressant drugs

OVERVIEW

Depression is an extremely common psychiatric condition but with limited understanding of the underlying neurobiology or how antidepressants reduce symptoms. Bipolar disorder is less common but equally poorly understood. It is a field in which therapeutic empiricism has led the way, with mechanistic understanding tending to lag behind, part of the problem being that it has been difficult to develop animal models that replicate the characteristics that define the human condition. In this chapter, we discuss the current understanding of the nature of the disorder, and describe the major drugs that are used to treat it.

The Nature of Depression

Depression and anxiety are the most common psychiatric disorders and are highly comorbid. Symptoms of depression may range from a very mild condition, bordering on normality, to severe (psychotic) depression accompanied by hallucinations and delusions. Worldwide, depression is a major cause of disability and premature death. In addition to the significant suicide risk, individuals with depression are more likely to die from other causes, such as heart disease or cancer. Depression is a heterogeneous disorder, with patients presenting with one or more core symptoms, and depression is often

associated with other psychiatric conditions, including anxiety, eating disorders, schizophrenia, Parkinson's disease and drug use disorder.

The symptoms of depression include emotional and biological components. Emotional symptoms include:

- low mood, excessive rumination of negative thought, misery, apathy and pessimism
- low self-esteem: feelings of guilt, inadequacy and ugliness
- indecisiveness, loss of motivation
- anhedonia, loss of interest in previously rewarding activities

Biological symptoms include:

- retardation of thought and action
- loss of libido
- sleep disturbance and loss of appetite

There are two distinct types of depressive syndrome, namely *unipolar depression*, in which the mood changes are always in the same direction, and *bipolar disorder*, in which depression alternates with mania. Mania is in most respects exactly the opposite, with excessive exuberance, enthusiasm and self-confidence, accompanied by impulsive actions, these signs often being combined with irritability, impatience and aggression, and sometimes with grandiose delusions. As with depression, the mood and actions are inappropriate to the circumstances.

Unipolar depression is commonly (about 75% of cases) non-familial, clearly associated with stressful life events, and usually accompanied by symptoms of anxiety and agitation; this type is sometimes termed *reactive depression*. Other cases (about 25%,

sometimes termed *endogenous depression*) show a familial pattern, less obviously related to external stresses and with a somewhat different symptomatology. This distinction is made clinically, but there is little evidence that antidepressant drugs show significant selectivity between these conditions. After an inauspicious start, population genetic studies have begun to identify novel genetic variations associated with depression, but depression is probably a polygenic disorder where a number of individual genetic variations as well as environmental factors contribute to the disorder. As illustrated in **Fig 48.1**, depression is linked to both genetic and environmental risk factors which increase vulnerability with precipitating factors related to adolescent and adult stress. These stressors can be psychological and/or physiological with depression a common feature of patients with other chronic illnesses. Some interesting theories have also emerged relating to the role of inflammation and the role of the gut microbiome and the benefit of these microflora on mental health (for those interested in exploring these further see **Bastiaanssen et al., 2020**; **Duman et al., 2021**; **Gonda et al., 2019**; **Pariante, 2017**; **Saavedra and Salazar, 2021**).

Depression cannot be attributed to altered neuronal activity within a single brain region; rather, the circuitry linking different parts of the brain is likely to be more important. Brain imaging studies have indicated that the prefrontal cortex, amygdala and hippocampus may all be involved in components of these disorders. These regions play a critical role in cognitive and emotional behaviour and it is likely that psychological factors are also important but understanding how these biological and experience-dependent factors interact is not straightforward.

Bipolar disorder, which usually appears in early adult life, is less common and results in oscillating depression and mania over a period of weeks/months. It can be difficult to differentiate between mild bipolar disorder and unipolar depression. Also, bipolar manic episodes can be confused with episodes of schizophrenic psychosis (see **Ch. 47**). There is a stronger hereditary tendency for bipolar disorder, and gene-wide association studies (GWASs) have identified a number of new susceptibility genes that may have an effect on the brain functions affected in bipolar disorder but to date these have not impacted on drug therapy of the disorder.

Theories of Depression

Several theories have been proposed to explain the causes of depression although with limited clinical evidence and mainly inferred from the pharmacological effects of antidepressant treatments, e.g. the monoamine hypothesis which arose from the observation that monoamine transmitters were the primary target for antidepressant drugs, and studies in animal models. None fully explain all of the observations and no biological marker has been identified to date. Much of what has been established in the last 70 years has recently had to be re-evaluated in light of the discovery that some drugs, e.g. **ketamine**, have both rapid and sustained antidepressant effects. This is contrary to what had been seen previously with classical antidepressant drugs, now referred to as conventional antidepressants or delayed-onset antidepressants reflecting the widely observed 4–6-week delay from onset of drug treatment before clinical improvement in symptoms is observed. Any theory of depression must now take account of the fact that the direct neurochemical effects of most antidepressant drugs appear very

rapidly (minutes to hours), whereas the therapeutic benefits of conventional antidepressant take weeks to fully develop. They also need to incorporate the developments of the last 20 years following the discovery that low doses of the *N*-methyl-D-aspartate (NMDA) receptor antagonist ketamine has rapid and sustained antidepressant effects. The discovery of ketamine's antidepressant effects has also led to a new class of antidepressants referred to as rapid-acting antidepressants (RAADs).

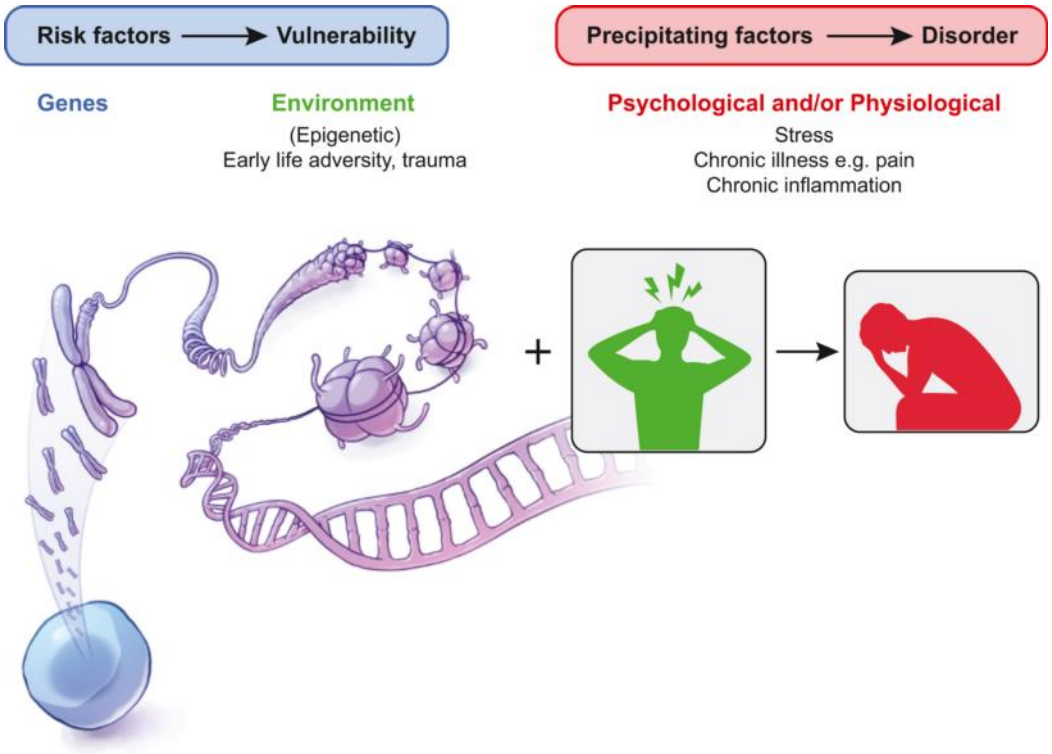

FIG. 48.1 Genetic and environmental factors which contribute to the risks of developing depression.The causes of depression are complex and poorly understood but this diagram illustrates the different risk factors which have been linked to the development of mood disorders. Genetic factors and early life events, e.g. childhood abuse, neglect or trauma, lead to increased vulnerability possibly due to a sensitisation of the stress system. Precipitating factors in adolescence and adulthood then lead to the development of depression. Stress, particularly uncontrollable stress and social stress, as well as other chronic illnesses and chronic inflammatory disorders have all been linked to precipitating an episode of depression. More vulnerable individuals may

> develop depression more readily when exposed to chronic stress but even those who have low vulnerability may experience events in adulthood which can lead to the development of depression. Decades of research have failed to find a specific biological impairment or biomarker which can be attributed to causing depression.

To explain the delayed-onset phenomenon, proponents of the monoamine theory have suggested that secondary, slow adaptive changes in monoamine receptors, rather than the primary drug effect, are responsible for the clinical improvement. Others have favoured a neurotrophic hypothesis where the effects on brain monoamine systems result in longer-term trophic effects including neurogenesis, increases in dendritic arborisation and synapses, the time course of which is paralleled by mood changes. More recently, a neuropsychological model of antidepressant efficacy has been proposed which links the biological effects of the antidepressant with psychological effects. Here we summarise the main theories as they relate to the mechanisms of action of current drug therapies. A more comprehensive review and analysis of these theories are provided by **Harmer et al. (2017)** and **Duman et al. (2021)**.

The Monoamine Theory

The monoamine theory of depression, first proposed by Schildkraut in 1965, states that depression is caused by a functional deficit of the monoamine transmitters, noradrenaline and 5-hydroxytryptamine (5-HT) at certain sites in the brain, while mania results from a functional excess.

The monoamine hypothesis grew originally out of associations between the clinical effects of various drugs that cause or alleviate symptoms of depression and their known neurochemical effects on monoaminergic transmission in the brain. This pharmacological evidence, which is summarised in **Table 48.1**, gives general support to the role of monoamine in the modulation of mood. It provides a potential explanation for how drugs which alter monoamine levels in the brain can alter mood but evidence of a deficit in patients has not been established. Studies into monoamine metabolism in patients with depression or by measuring changes in the number of monoamine receptors in postmortem brain tissue have been inconsistent and the interpretation is often problematic, because the changes described are not specific to depression.

Table 48.1

Pharmacological evidence supporting the role of monoamines in the regulation of mood

Drug(s)	Principal action	Effect in patients with depression
Tricyclic antidepressants	Block noradrenaline and 5-HT reuptake	Mood ↑
MAO inhibitors	Increase stores of noradrenaline and 5-HT	Mood ↑
Tetrabenazine	Reversibly inhibits vesicular monoamine transporter 2 leading to depletion of monoamine storage	Mood ↓
α-Methyltyrosine	Inhibits noradrenaline synthesis	Mood ↓ (calming of manic patients)
Methyldopa	Inhibits noradrenaline synthesis	Mood ↓

Drug(s)	Principal action	Effect in patients with depression
Electroconvulsive therapy	? Increases central nervous system responses to noradrenaline and 5-HT	Mood ↑
Tryptophan (5-hydroxytryptophan)	Increases 5-HT synthesis	Mood ? ↑ in some studies
Tryptophan depletion	Decreases brain 5-HT synthesis	Induces relapse in SSRI-treated patients [a]

5-HT, 5-Hydroxytryptamine; *MAO,* monoamine oxidase; *SSRI,* selective serotonin reuptake inhibitor.

[a] Although initially seen as evidence supporting a monoamine hypothesis of depression, these effects may be more related to the adaptive changes induced by SSRIs which are also linked to emotional blunting and symptoms of withdrawal (see **Fig 48.3**).

Clinically, it seems that inhibitors of noradrenaline reuptake and of 5-HT reuptake are similarly effective as antidepressants, although

individual patients may respond better to one or the other. Given the close interactions between these two transmitter systems, this may not be that surprising.

Neuroendocrine Mechanisms

Various attempts have been made to test for a functional deficit of monoamine pathways in depression linked to neuroendocrine responses, particularly relating to stress hormones. Hypothalamic neurons controlling pituitary function receive noradrenergic and 5-HT inputs, which control the discharge of these cells. Hypothalamic cells release corticotrophin-releasing factor (CRF; also known as *corticotrophin-releasing hormone*), which stimulates pituitary cells to secrete adrenocorticotrophic hormone (ACTH), leading in turn to release of the stress hormone, cortisol (see **Ch. 33**). The plasma cortisol concentration is sometimes higher in patients with depression. Other hormones in plasma are also sometimes affected; for example, growth hormone concentration is reduced and prolactin is increased in some studies. While these changes are consistent with deficiencies in monoamine transmission, they are not specific to depressive syndromes or found reliably across patients.

Neurotrophic Effects and Neuroplasticity

It has been suggested that lowered levels of brain-derived neurotrophic factor (BDNF) or dysfunction of its receptor, TrkB, plays a significant role in the pathology of depression. There has been some evidence of a reduction in BDNF expression in patients, and treatment with antidepressants elevates BDNF levels as well as potentiating downstream signalling via mammalian target of rapamycin (mTOR) or glycogen synthase kinase 3 beta (GSK3β).

Changes in glutamatergic neurotransmission have been linked to this loss of neurons and atrophy in the hippocampus and prefrontal cortex. As with other theories of depression, most studies have focused on the actions of antidepressants and animal studies and then generated hypotheses from this about a possible pathological process which the drugs are able to reverse. This is likely to be too simplistic given the complex biological, psychological and environmental factors which contribute to depression. However, preclinical studies have shown that both conventional and RAADs induce positive effects on both neuroplasticity and neurogenesis. [1] The RAAD ketamine has been found to increase synaptogenesis, the development of new synapses, whilst conventional antidepressants increase BDNF and associated down-stream effects including neurogenesis, possibly via effects on monoamine transmitters. The mood stabiliser, lithium, has also been shown to interact with GSK3β and has been linked to neuroprotective and neurotrophic effects (**Won and Kim, 2017**). Key evidence supporting a role for neuroplastic and neurotrophic mechanism in depression and antidepressant efficacy include:

- Brain imaging and postmortem studies show reductions in volume of the hippocampus and prefrontal cortex of patients with depression, with loss of neurons and glia. Functional imaging reveals altered brain activity in emotional circuits possibly linked to this neuronal loss.
- In animals, the same effect is produced by chronic stress of various kinds, or by administration of glucocorticoids, mimicking the increased cortisol secretion in human

depression. Excessive glucocorticoid secretion in humans (Cushing's syndrome; see **Ch. 33**) often causes depression.

- In experimental animals, antidepressant drugs, or other treatments such as electroconvulsions (see later section on *Brain Stimulation Therapies*), promote neurogenesis in the hippocampus, and (as in humans) restore functional activity. Preventing hippocampal neurogenesis prevents the behavioural effects of antidepressants in rats.
- 5-HT and noradrenaline, whose actions are enhanced by many antidepressants, promote neurogenesis, probably through activation of 5-HT_{1A} receptors and α_2 adrenoceptors, respectively. This effect may be mediated by BDNF.
- Exercise has been shown to promote neurogenesis in animals and to be effective in some patients with mild to moderate depression.
- Ketamine and other putative RAAD increase the development of new synapses on glutamatergic neurons in the prefrontal cortex (**Krystal et al., 2019**; **Vargas et al., 2021**).

Neuropsychological Hypothesis

People suffering from depression tend to perceive events in a negative way, focus on negative information and recall information in a negative rather than positive manner – a behaviour pattern that psychologists term *negative affective biases*. Studies in healthy volunteers and patients with depression suggest that antidepressant drugs may indeed exert acute effects on the way information is processed (cognitive processing), leading to a positive effect on emotional behaviour. For example, when presented with a series of pictures showing facial expressions of different levels of happiness or

sadness, patients with depression consider fewer of the faces to be happy than do healthy volunteers presented with the same faces. But after a single dose of an antidepressant both healthy volunteers and patients now consider more of the same faces to be happy (i.e. their perception of what is happy (positive) has changed) (**Fig 48.2**). It is suggested that patients with depression may not initially be consciously aware of the effect the antidepressant drug has produced, but with prolonged drug administration, these neuropsychological effects positively bias new learning which, over time, leads to a subjective improvement in mood. Using translational animal models of affective biases, similar acute neuropsychological effects have been observed in animals and humans performing memory tasks (**Fig 48.2**).

Theories of depression

- The *monoamine theory*, first proposed in 1965, suggests that depression results from functionally deficient monoaminergic (noradrenaline and/or 5-hydroxytryptamine) transmission in the central nervous system (CNS).
- The theory is based on the ability of most antidepressant drugs (tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs)) to facilitate monoaminergic transmission, and of drugs which deplete monoamines such as **tetrabenazine and reserpine** to cause depression.
- Although the *monoamine hypothesis* in its simple form is insufficient as an explanation of depression, pharmacological

manipulation of monoamine transmission remains the most successful therapeutic approach.

- The *neuropsychological hypothesis* of antidepressant efficacy suggests that drugs may produce immediate psychological effects but patients receiving the drugs need time for these to bias new learning before they become aware of the improvements in their mood.
    - Depression may be associated with neurodegeneration in brain regions regulating emotional behaviour and reduced neurogenesis in the hippocampus, effects which can be reversed by both conventional delayed onset and rapid acting antidepressants (RAADs).
      Biochemical studies in patients with depression do not clearly support any single hypothesis with no biological marker identified which shows reliable changes in all patients.
    - The discovery of RAADs such as ketamine requires us to re-evaluate many of these hypotheses but research to date has provided evidence of both neurotrophic and neuropsychological effects associated with RAADs.

Antidepressant Drugs

Types of Antidepressant Drug

With the emergence of a new class of RAADs, types of antidepressants can be divided into two main types based on the rate of onset of therapeutic effects. *Conventional antidepressants* is a term often now used to describe drugs which have a delayed onset

and target monoamine systems whilst those which have immediate and sustained antidepressant effects are referred to as RAADs. Antidepressant drugs fall into the following pharmacological categories:

Inhibitors of monoamine reuptake

- Selective serotonin (5-HT) reuptake inhibitors (SSRIs) (e.g. fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, escitalopram, vilazodone).
- Classic TCAs (e.g. imipramine, desipramine, amitriptyline, nortriptyline, clomipramine). These vary in their activity and selectivity with respect to inhibition of noradrenaline and 5-HT reuptake.
- Mixed 5-HT and noradrenaline reuptake inhibitors (e.g. venlafaxine (somewhat selective for 5-HT, although less so than SSRIs), desvenlafaxine, duloxetine).
- Noradrenaline reuptake inhibitors (e.g. **reboxetine, atomoxetine**, **bupropion** (also a dopamine reuptake inhibitor)).

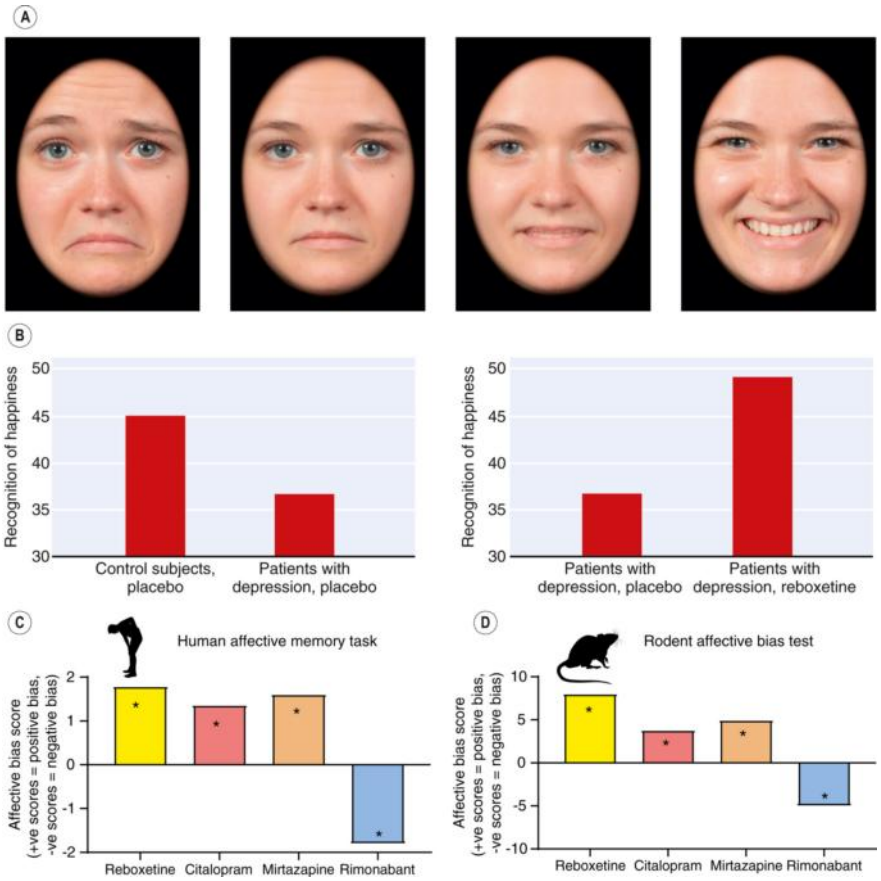

FIG. 48.2 Acute neuropsychological effects of different pharmacological treatments on affective biases in humans and rodents.Affective biases describe how information processing can be altered by the emotional state of the subject and can be measured in humans or animals. (A) illustrates the happy and sad facial expressions used to assess how well patients with depression recognise happy faces. When presented with an array of faces, such as those in (A), patients with depression considered fewer faces to be happy than did control

subjects. After an acute dose of reetine, patients with depression considered more of the facial expressions to be happy. (B) Using tasks which measure affective biases associated with learning and memory has also revealed that acute treatment with antidepressant drugs induces positive memory bias while the pro-depressant cannabinoid$_1$-receptor antagonist, rimonabant, induces a negative memory bias with similar effects seen in humans (C) and rats (D). Faces in (A) are reprinted from the P1vital Oxford Emotional Test Battery, P1vital Products Ltd. Data in (B) are adapted from Harmer, et al., 2009. Am. J. Psychiatry 166, 1178–1184.) (C and D) created using data from Harmer, C.J., Shelley, N.C., Cowen, P.J., et al., 2004. Am. J. Psychiatry 161, 1586–1592; Harmer et al., 2013; Harmer, C.J., Shelley, N.C., Cowen, P.J., et al., 2004. Am. J. Psychiatry 161, 1256–1263; Pringle, A., Browning, M., Cowen, P.J., et al., 2011. Prog. Neuropsychopharmacol. Biol. Psychiatry 35, 1586–1592; Horder, J., Browning, M., Di Simplicio, M., et al., 2012. J. Psychopharmacol. 26, 125–32; Arnone, D., Horder, J., Cwen, P.J. et al.,

2009. Psychopharmacology (Berl) 203, 685–691; and Stuart, S.A., Butler, P., Munafo, M.R., et al., 2013. Neuropsychopharmacology 38, 1625–1635.

- The herbal preparation St John's wort, the main active ingredient of which is hyperforin: it has similar clinical efficacy to most of the prescribed antidepressants. It is a weak monoamine uptake inhibitor but also has other actions. [2]

Receptor blocking antidepressants

- Drugs such as **mirtazapine** and **mianserin** inhibit a range of amine receptors including α_2 adrenoceptors and 5-HT_2 receptors. **Trazodone** has a mixture of agonist and antagonist effects at a range of monoamine receptors and weak effects on monoamine uptake.

Monoamine oxidase inhibitors (MAOIs)

- Irreversible, non-competitive inhibitors (e.g. **phenelzine**, **tranylcypromine**), which are non-selective with respect to the monoamine oxidase (MAO)-A and -B subtypes.
- Reversible, MAO-A-selective inhibitors (e.g. **moclobemide**).

Melatonin receptor agonist

- **Agomelatine** is an agonist at MT_1 and MT_2 melatonin receptors, and a weak 5-HT_{2C} antagonist.

Rapid-acting antidepressants

- **Ketamine** is a non-competitive NMDA receptor channel blocker and has rapid and sustained antidepressant effects at low doses.

Table 48.2 summarises the main features of these types of drug. Mention should also be made of electroconvulsive therapy (ECT), electromagnetic therapy, deep brain stimulation and vagus stimulation, which can be effective in patients who have failed to respond to drug therapy and usually act more rapidly than conventional antidepressant drugs.

To some extent, the term *antidepressant drug* is misleading, as many of these drugs are now also used to treat disorders other than depression. These include:

- neuropathic pain (e.g. amitriptyline, nortriptyline, duloxetine; see **Ch. 43**)
- anxiety disorders (e.g. SSRIs, venlafaxine, duloxetine; see **Ch. 45**)
- fibromyalgia (e.g. duloxetine, venlafaxine, SSRIs, TCAs; see **Ch. 43**)
- bipolar disorder (e.g. fluoxetine in conjunction with **olanzapine**; see later)
- smoking cessation (e.g. bupropion; see **Ch. 50**)
- attention deficit/hyperactivity disorder (e.g. atomoxetine; see **Ch. 49**)

Types of antidepressant drugs

- Main types are:
  - monoamine uptake inhibitors (tricyclic antidepressants, selective serotonin reuptake inhibitors, newer inhibitors of noradrenaline and 5-HT reuptake);
  - monoamine receptor antagonists;
  - monoamine oxidase (MAO) inhibitors.
- Monoamine uptake inhibitors act by inhibiting uptake of noradrenaline and/or 5-HT by monoaminergic nerve terminals.
- α_2-Adrenoceptor antagonists can indirectly elevate 5-HT release (**Fig 48.3**).
- MAOIs inhibit one or both forms of brain MAO, thus increasing the cytosolic stores of noradrenaline and 5-HT in nerve terminals. Inhibition of type A MAO correlates with antidepressant activity. Most are non-selective; **moclobemide** is specific for MAO-A.
- Most antidepressant drugs appear to take at least 2 weeks to produce any perceived beneficial effects.
- Esketamine, one of the stereoisomers of ketamine, is delivered as a nasal spray whilst ketamine is also used as an intravenous infusion (off license) and produces a rapid response lasting for up to 2 weeks.

Testing of Antidepressant Drugs

Animal Models

Progress in unravelling the neurochemical mechanisms is, as in so many areas of psychopharmacology, limited by the lack of good animal models of the clinical condition. Investigating complex psychiatric disorders in animals poses at least two significant challenges. A model of the disorder is needed to understand the underlying pathophysiology and readouts which are relevant to human symptoms of depression to test the effects of novel treatments. Methods which expose animals to stress can generate behavioural despair (e.g. forced swim test, learned helplessness) and these behaviours are sensitive to the original monoaminergic antidepressants but interpretation of these models in the context of underlying disease processes or non-monoaminergic drugs is limited. Somewhat more success has been achieved using different types of stress to induce a depression-like phenotype including early life adversity and experience of chronic social and/environmental stressors. Detecting changes in the animal's emotional behaviour mostly focuses on changes in reward-related behaviours akin to the anhedonia seen in many patients. More recently, attempts to improve the translation between human and animal studies have led to novel neuropsychological models based on negative affective biases. For a more detailed discussion around the limitations of current animal models of depression and future prospects see **Gururajan et al. (2019)**.

Tests on Humans

Clinically, the effect of antidepressant drugs is usually measured by a subjective rating scale such as the Hamilton Rating Scale or the Beck Depression Inventory. Clinical depression takes many forms, and the symptoms vary between patients and over time. Quantitation is

therefore difficult, and the many clinical trials of antidepressants have generally shown rather weak effects, after allowance for quite large placebo responses. There is also a high degree of individual variation, with 30%–40% of patients failing to show any improvement, possibly due to genetic factors (see later section on Clinical Effectiveness). Objective methods based on computerised tasks have been developed for experimental medicine research and are now starting to be used alongside traditional rating scales in early clinical studies.

Table 48.2

5-HT, 5-Hydroxytryptamine; *ADHD,* attention deficit/hyperactivity disorder; *CNS,* central nervous system; *GI,* gastrointestinal; *IV,* intravenous; *MAO,* monoamine oxidase; *NA,* noradrenaline; *NMDA, N*-methyl-D-aspartate; *SSRI,* selective serotonin reuptake inhibitor; *TCA,* tricyclic antidepressant.

[a] Other TCAs include dosulepin, doxepin, lofepramine, trimipramine.

[b] Other 5-HT/NA uptake inhibitors include milnacipran and levomilnacipran.

Mechanism of Action of Conventional Antidepressant Drugs

Chronic Adaptive Changes

There is a discrepancy between the immediate neurochemical effects of conventional antidepressants and the patient's subjective experience of their mood with therapeutic benefits not usually seen for several weeks after the start of treatment. There has been little

evidence that different types of conventional antidepressant are effective over different timescales although early studies with imipramine did report more rapid onset of effects than seen in studies with the second-generation antidepressants.

The initial focus of research into the delayed onset was the adaptive changes which arise in certain monoamine receptors e.g. 5-HT_{1A}, α_2 adrenoceptors, α_1 adrenoceptors, following chronic treatment. Similar effects have also been seen following ECT.

Receptor down-regulation has been shown to occur experimentally in human and animals and can involve both pre- and post-synaptic receptors. Changes in autoreceptor density, which provide negative feedback and regulate further neurotransmitter release, have been of particular interest.

On acute administration, one would expect inhibition of 5-HT uptake (e.g. by SSRIs) to increase the level of 5-HT at the synapse by inhibiting reuptake into the nerve terminals. However, the increase in synaptic 5-HT levels has been observed to be less than expected. This is because the increased activation of 5-HT_{1A} receptors on the soma and dendrites of 5-HT-containing raphe neurons (**Fig. 48.3A**) inhibits these neurons and thus reduces 5-HT release, thus cancelling out to some extent the effect of inhibiting reuptake into the terminals. On prolonged drug treatment, the elevated level of 5-HT in the somatodendritic region desensitises the 5-HT_{1A} receptors, reducing their inhibitory effect on 5-HT release from the nerve terminals. Similar effects may also explain the down-regulation of α_2 adrenoceptors observed when chronic noradrenaline re-uptake inhibitors or mixed re-uptake inhibitors are given chronically.

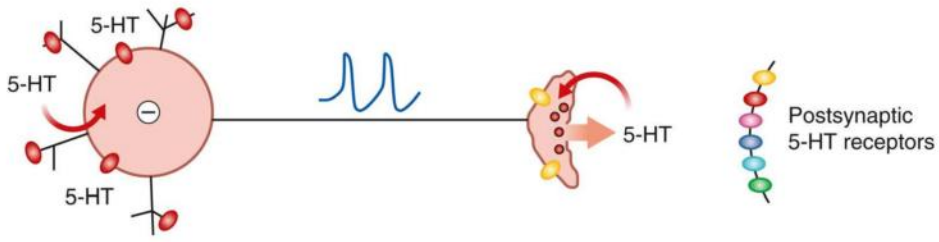
If autoreceptor activation is the major cause of the delayed onset then co-administration of a 5-HT_{1A} or α_2 adrenoceptor antagonist

might lead to a more rapid onset of clinical effects. Attempts with 5-HT_{1A} antagonists have largely failed to find beneficial effects but α_2 adrenoceptor antagonists such as mirtazapine and mianserin have proved to be effective antidepressants although not with more rapid clinical benefits.

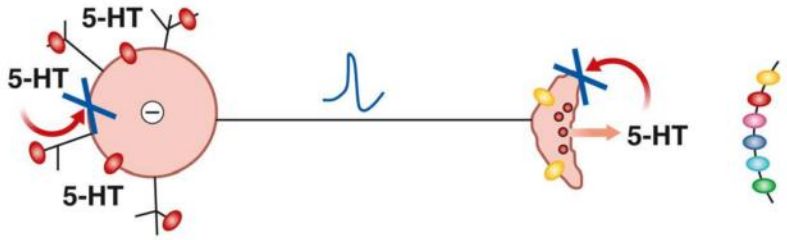
Block of presynaptic α_2 autoreceptors on noradrenergic nerve terminals throughout the CNS will reduce the negative feedback from released noradrenaline and thus enhance further noradrenaline release (see Chs **15** and **37**). In addition, α_2 adrenoceptor antagonists can indirectly enhance 5-HT release through enhanced activation of α_1 adrenoceptors which are found on the raphe nuclei cell bodies and increase firing rate.

Ⓐ

Absence



Acute 5-HT reuptake inhibition



Chronic 5-HT reuptake inhibition

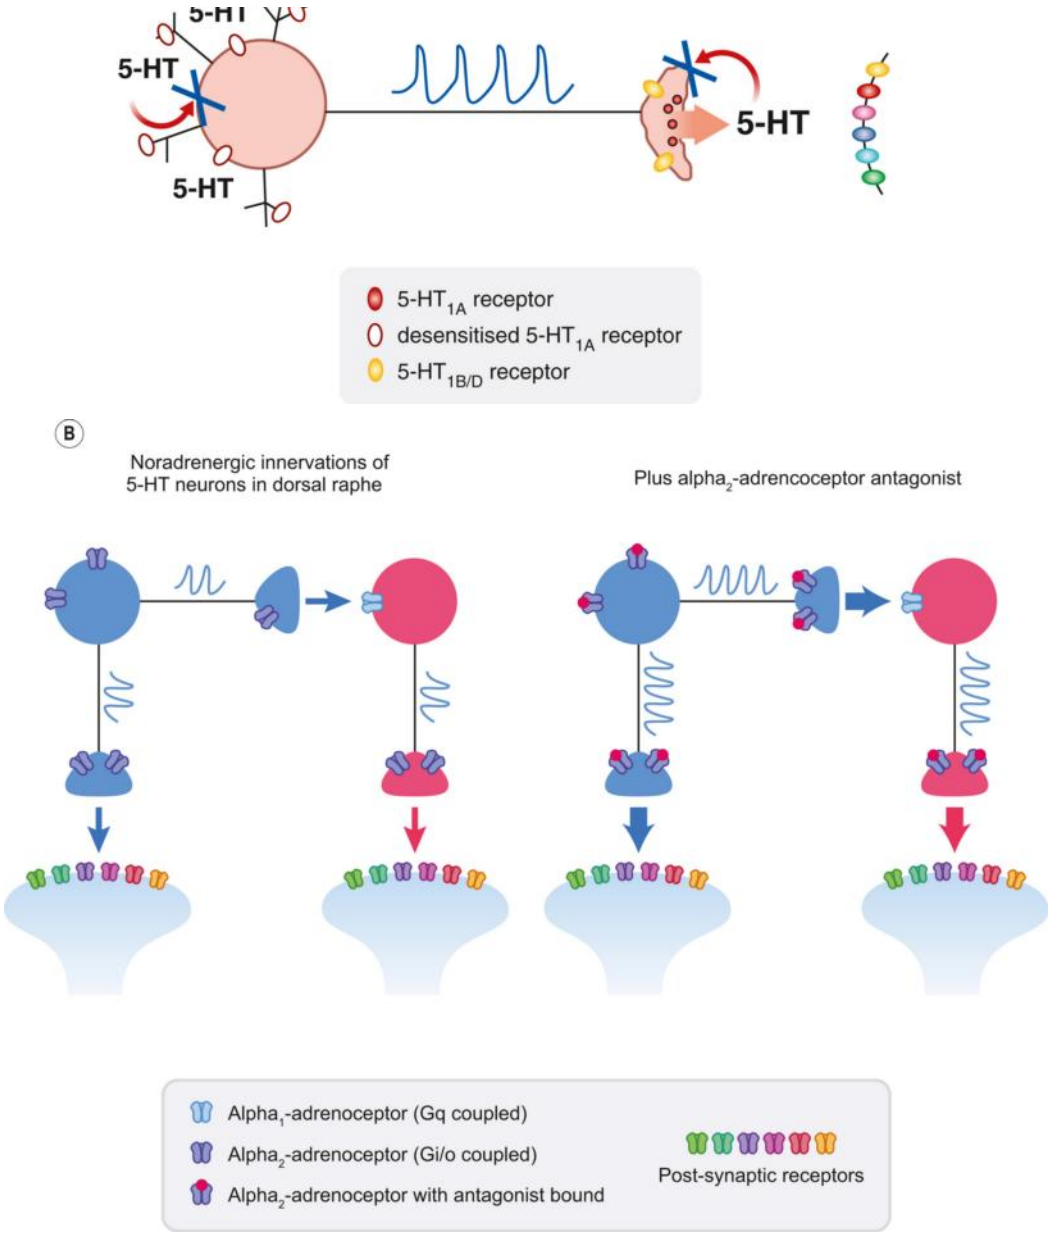


FIG. 48.3 cont'd (B) 5-HT release is controlled by both an excitatory action of noradrenaline (NA) on somatodendritic α_1 adrenoceptors and an inhibitory action on α_2 adrenoceptors on serotonergic nerve terminals. Block of α_2 adrenoceptors located on noradrenergic neurons enhances noradrenaline release resulting in further excitation of serotonergic neurons, while

block of α_2 adrenoceptors on serotonergic neurons removes presynaptic inhibition and thus 5-HT release is enhanced. NA can therefore function as both an accelerator and brake on the 5-HT neurons.Fig. 48.3Control of 5-hydroxytryptamine (5-HT) release and the impact of chronic treatment with selective serotonin reuptake inhibitors (SSRIs). (A) 5-HT release is controlled by the inhibitory action of 5-HT on somatodendritic 5-HT_{1A} receptors. Acute inhibition of 5-HT reuptake results in increased extracellular levels of 5-HT but this increases somatodendritic 5-HT_{1A} receptor–mediated inhibition, hence synaptic 5-HT levels do not rise as much as expected. 5-HT_{1A} receptors eventually desensitise, resulting in reduced inhibition and thus greater 5-HT release. These adaptive changes may contribute to the effects of SSRIs on mood and are also likely to contribute to the withdrawal effects experienced by patients when they stop taking their medication.

Gene Expression and Neurogenesis

An alternative perspective is that the adaptive changes are not directly related to efficacy and the delayed onset is linked to downstream activation of neurotrophic factors which mediate a slow reversal of the stress-induced neuronal loss. As described earlier, several antidepressant drugs appear to promote neurogenesis in the

hippocampus, a mechanism that could account for the slow development of the therapeutic effect. This offers the potential to target directly these mechanisms but if neurogenesis is the primary mediator of the antidepressant effects, then rapid changes in depression would not be expected even with more direct modulation of these pathways.

Impact of the discovery of rapid-acting antidepressants

A major challenge to receptor adaptation and neurotrophic theories about delayed onset came with the publication of a landmark paper in 2000 which showed that a single, low-dose intravenous infusion of the NMDA receptor antagonist, ketamine, induced a rapid (<24 h) and sustained (~7 days) antidepressant effect. Subsequent studies also found ketamine induced an immediate and sustained attenuation of suicidal ideation in bipolar disorder. Receptor adaptation was very unlikely to account for these effects but studies in animals revealed that low-dose ketamine induced rapid changes in synapse formation in the prefrontal cortex. These synaptogenic effects have yet to be studied in humans but there is a growing literature from animal studies, including imaging studies, showing how synapses which are lost due to chronic stress can be reinstated following acute ketamine or esketamine treatment.

Based on a series of clinical trials, it has emerged that not only ketamine has rapid and sustained antidepressant effects, but also similar effects are seen with the muscarinic antagonist scopolamine and the psychedelic 5-HT agonist, psilocybin (see **Ch. 49**). These drugs all act on different primary targets but have all been shown to result in enhancement of glutamate transmission in prefrontal cortex which has been suggested to lead to enhanced BDNF signalling which

acts via downstream mediators such as mTOR to induce rapid changes in synaptic plasticity and synaptogenesis. There is now growing interest in these drugs as a possible new class of 'psychoplastogens' which can promote synaptic plasticity and rapidly reverse maladaptive changes which have led to depression (**Vargas et al., 2021**).

Neuropsychological effects of conventional and rapid-acting antidepressants

An important but often overlooked factor contributing to depression is the psychological experience of the patient. Mood arises from a complex integration of past experiences (memories), current circumstances and future expectations, and a purely biochemical explanation of depression does not consider these psychological factors. The neuropsychological hypothesis of antidepressant efficacy posits that conventional antidepressants generate a neurochemical state which facilitates more positive emotional learning and memory, but the patient needs to form new memories to outweigh the accumulated negatively biased memories. Preclinical studies also suggest that RAAD antidepressants contrast with conventional antidepressants and do not depend on new learning but can modify biases associated with previously learnt memories. For more detailed discussion of this emerging hypothesis see **Godlewska and Harmer (2021)** and **Harmer et al. (2017)** for a discussion of an integration of both the neurotrophic and neuropsychological hypotheses.

SUMMARY

The mechanisms which underlie antidepressant effects remain poorly understood and hampered by the challenges of the limitations of animal models, complexity of psychological and biological factors and disease heterogeneity. The emergence of the RAAD is an exciting development for the field but presents new challenges to established theories and is leading to a rapid reappraisal. It is also feasible that the complexity of emotional regulation and mood disorders means that more than one mechanism may be involved and aspects of all these different hypotheses may yet emerge as contributing to the symptoms seen in patients.

Monoamine Uptake Inhibitors

Selective 5-Hydroxytryptamine Uptake Inhibitors

These are the most commonly prescribed group of antidepressants. Examples include **fluoxetine**, **fluvoxamine**, **paroxetine**, **citalopram**, **escitalopram** and **sertraline** (see **Table 48.2**). As well as showing selectivity with respect to 5-HT over noradrenaline uptake (**Fig. 48.4**), they are less likely than TCAs to cause anticholinergic side effects and are less dangerous in overdose. In contrast to MAOIs, they do not cause 'cheese reactions'. They are also used to treat anxiety disorders (see **Ch. 45**) and premature ejaculation. **Vortioxetine** is a novel SSRI that is an agonist at 5-HT_{1A}, a partial agonist at 5-HT_{1B} receptors and an antagonist at other 5-HT receptors including 5-HT_{3A} receptors.

Individual patients may respond more favourably to one SSRI than another. This may reflect other pharmacological properties of each individual drug as none is devoid of other actions. Fluoxetine has 5-HT_{2C} antagonist activity, a property it shares with other non-SSRI antidepressants such as **mirtazapine**. Sertraline is a weak inhibitor

of dopamine uptake. Escitalopram is the *S* isomer of racemic citalopram. It lacks the antihistamine and CYP2D6 inhibitory properties of the *R* isomer.

Pharmacokinetic aspects

The SSRIs are well absorbed when given orally, and most have plasma half-lives of 18–24 h (fluoxetine is longer acting: 24–96 h). Paroxetine and fluoxetine are not used in combination with TCAs, whose hepatic metabolism they inhibit through an interaction with CYP2D6, for fear of increasing TCA toxicity.

Unwanted effects

Common side effects include nausea, anorexia, insomnia, loss of libido and failure of orgasm. [3] Some of these unwanted effects result from the enhanced stimulation of postsynaptic 5-HT receptors as a result of the drugs increasing the levels of extracellular 5-HT. This can be either stimulation of the wrong type of 5-HT receptor (e.g. 5-HT_2, 5-HT_3 and 5-HT_4 receptors) or stimulation of the same receptor that gives therapeutic benefit (e.g. postsynaptic 5-HT_{1A} receptors) but in the wrong brain region (i.e. enhanced stimulation of 5-HT receptors can result in both therapeutic and adverse responses).

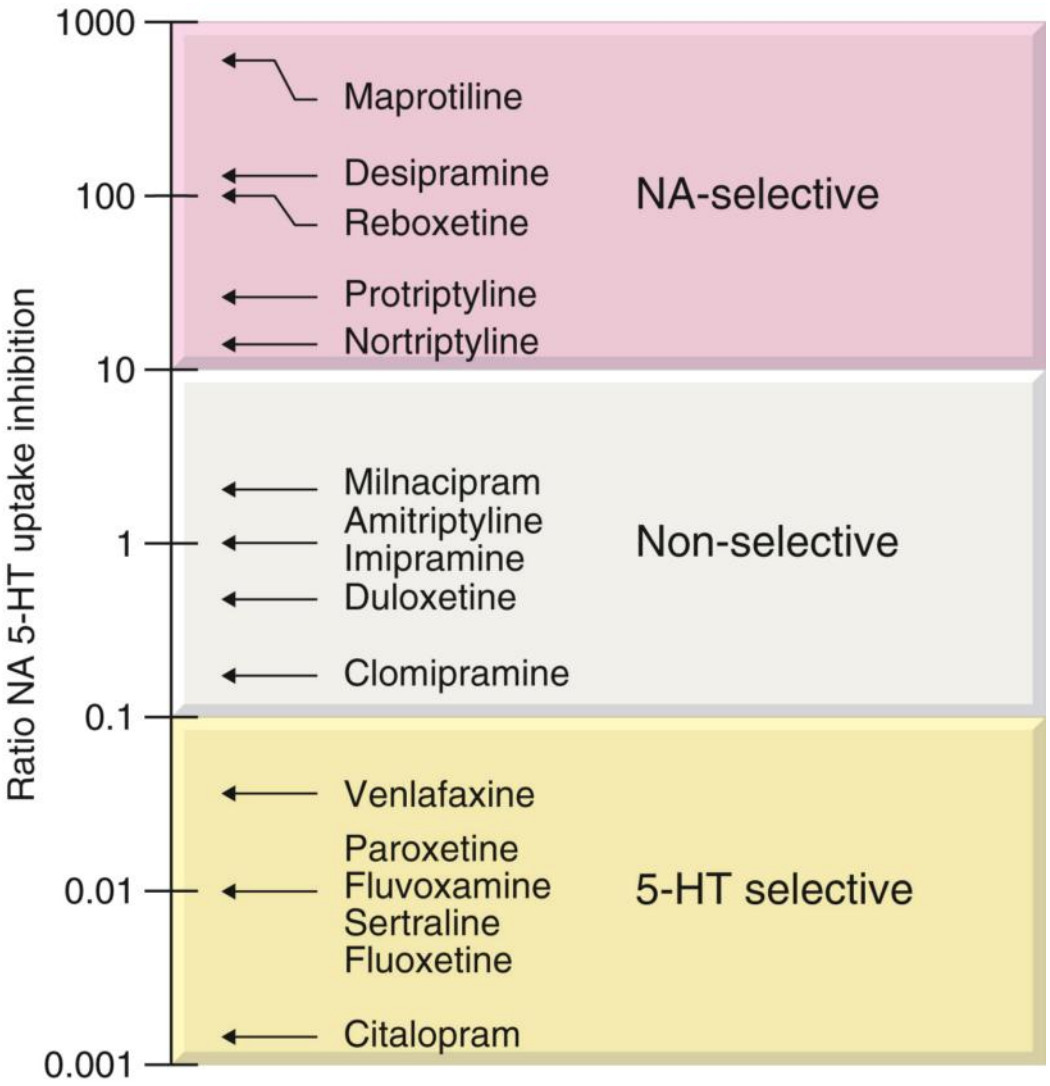

FIG. 48.4 Selectivity of inhibition of noradrenaline **(NA)** and 5-hydroxytryptamine **(5-HT)** uptake by various antidepressants.

A common problem for patients taking reuptake inhibitors is the withdrawal effects they can experience if they stop taking their medication abruptly or try to reduce their dose too quickly. Possibly linked to the adaptive changes induced by chronic treatment, the symptoms include increased anxiety and agitation and a careful programme of dose reduction is needed to manage these.

In combination with MAOIs, SSRIs can cause a 'serotonin syndrome' characterised by tremor, agitation, increased reflexes, hyperthermia and cardiovascular collapse, from which deaths have occurred.

There have been reports of increased aggression, and occasionally violence, in patients treated with fluoxetine, but these have not been confirmed by controlled studies. The use of SSRIs is not recommended for treating depression in children under 18, in whom efficacy is doubtful and adverse effects, including excitement, insomnia and aggression in the first few weeks of treatment, may occur. The possibility of increased suicidal ideation is a concern in this age group. Despite this, SSRIs, particularly fluoxetine, are increasingly being prescribed to patients under 18 years of age.

Despite the apparent advantages of 5-HT uptake inhibitors over TCAs in terms of side effects, the combined results of many trials show little overall difference in terms of efficacy (**Cipriani et al., 2018**).

They are relatively safe in overdose, compared with TCAs (see later section, *Suicide and antidepressants*), but can prolong the cardiac QT interval, giving rise to ventricular arrhythmias (see **Ch. 22**) and risk of sudden death.

5-HT uptake inhibitors are used in a variety of other psychiatric disorders including anxiety disorders, obsessive–compulsive disorder and eating disorders (see **Ch. 45**).

Selective serotonin reuptake inhibitors (SSRIs)

- Examples include fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, escitalopram.
- Antidepressant actions are similar in efficacy and time course to tricyclic antidepressants (TCAs).
- Acute toxicity (especially cardiotoxicity) is less than that of monoamine oxidase inhibitors (MAOIs) or TCAs, so overdose risk is reduced.
- Side effects include nausea, insomnia and sexual dysfunction. SSRIs are less sedating and have fewer antimuscarinic side effects than the older TCAs.
- No food reactions, but dangerous 'serotonin reaction' (hyperthermia, muscle rigidity, cardiovascular collapse) can occur if given with MAOIs.
- There is concern about the use of SSRIs in children and adolescents, due to reports of an increase in suicidal thoughts on starting treatment.
- Also used for some other psychiatric indications (e.g. anxiety and obsessive–compulsive disorder).

Tricyclic Antidepressant Drugs

TCAs (**imipramine**, **desipramine**, **amitriptyline**, **nortriptyline**, **clomipramine**) are still widely used. They are, however, far from ideal in practice, and it was the need for drugs that produce fewer side effects and are less hazardous in overdose that led to the introduction of newer 5-HT reuptake inhibitors and other antidepressants.

TCAs are closely related in structure to the phenothiazines (see **Ch. 47**) and were initially synthesised (in 1949) as potential antipsychotic drugs. Several are tertiary amines and are quite rapidly demethylated in vivo (**Fig. 48.5**) to the corresponding secondary amines (e.g. imipramine to desipramine, amitriptyline to nortriptyline), which are themselves active and may be administered as drugs in their own right. Other tricyclic derivatives with slightly modified bridge structures include **doxepin**. The pharmacological differences between these drugs are not very great and relate mainly to their side effects, which are discussed later.

Some TCAs are also used to treat neuropathic pain (see **Ch. 43**).

Mechanism of action

As discussed previously, the main immediate effect of TCAs is to block the uptake of amines by nerve terminals, by competition for the binding site of the amine transporter (see **Ch. 15**). Most TCAs inhibit noradrenaline and 5-HT uptake (see **Fig. 48.4**) but have much less effect on dopamine uptake. It has been suggested that improvement of emotional symptoms reflects mainly an enhancement of 5-HT-mediated transmission, whereas relief of biological symptoms results from facilitation of noradrenergic transmission. Interpretation is made difficult by the fact that the major metabolites of TCAs have considerable pharmacological activity (in some cases greater than that of the parent drug) and often differ from the parent drug in respect of their noradrenaline/5-HT selectivity (**Table 48.3**).

In addition to their effects on amine uptake, most TCAs affect other receptors, including muscarinic acetylcholine receptors, histamine receptors, α adrenoceptors and 5-HT receptors.

Unwanted effects

In human subjects without depression, TCAs cause sedation, confusion and motor incoordination. These effects occur also in patients with depression in the first few days of treatment, but tend to wear off over 1–2 weeks as tolerance develops.

TCAs produce a number of troublesome side effects, mainly due to interference with autonomic control.

Anti-muscarinic effects include dry mouth, blurred vision, constipation and urinary retention. These effects are strong with amitriptyline and much weaker with desipramine. Postural hypotension, mainly due to α_1 adrenoceptor antagonism, occurs with TCAs. The other common side effect is sedation due to histamine$_1$ receptor antagonism, and the long duration of action means that daytime performance is often affected by drowsiness and difficulty in concentrating.

TCAs, particularly in overdose, may cause ventricular dysrhythmias associated with prolongation of the QT interval (see **Ch. 60**). Usual therapeutic doses of TCAs increase, slightly, but significantly, the risk of sudden cardiac death.

Withdrawal effects similar to those seen with the specific re-uptake inhibitors are also seen with TCAs and gradual dose reduction should be used.

Interactions with other drugs

TCAs are particularly likely to cause adverse effects when given in conjunction with other drugs (see **Ch. 58**). They rely on hepatic metabolism by microsomal cytochrome P450 (CYP) enzymes for elimination, and this may be inhibited by competing drugs (e.g. antipsychotic drugs and some steroids).

TCAs potentiate the effects of alcohol and anaesthetic agents, for reasons that are not well understood, and deaths have occurred as a result of this, when severe respiratory depression has followed a bout of drinking. TCAs also interfere with the action of various antihypertensive drugs (see **Ch. 21**), with potentially dangerous consequences, so their use in hypertensive patients requires close monitoring.

Acute toxicity

TCAs are dangerous in overdose and were at one time commonly used for suicide attempts, which was an important factor prompting the introduction of safer antidepressants. The main effects are on the CNS and the heart. The initial effect of TCA overdosage is to cause excitement and delirium, which may be accompanied by convulsions. This is followed by coma and respiratory depression lasting for some days. Atropine-like effects are pronounced, including dry mouth and skin, mydriasis and inhibition of gut and bladder. Anticholinesterase drugs have been used to counter atropine-like effects but are no longer recommended. Cardiac dysrhythmias are common, and sudden death may occur from ventricular fibrillation.

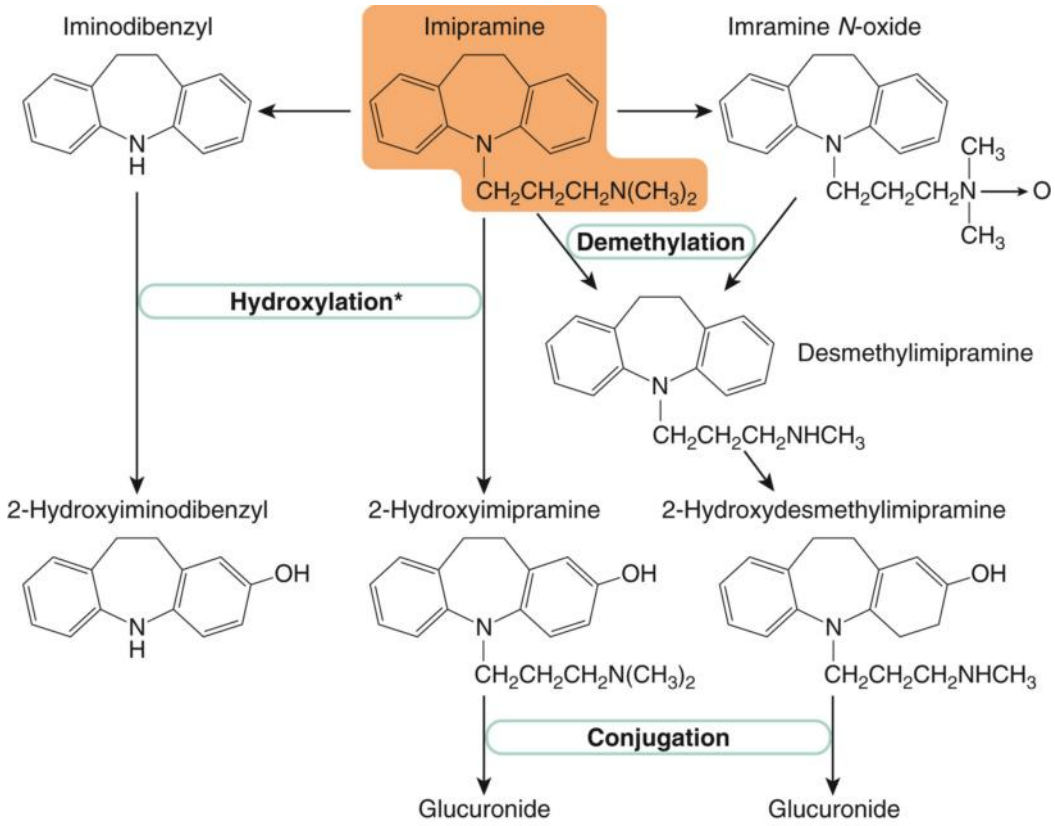

FIG. 48.5 Metabolism of imipramine, which is typical of that of other tricyclic antidepressants. *The hydroxylating enzyme CYP2D6 is subject to genetic polymorphism, which may account for individual variation in response to tricyclic antidepressants (see **Ch. 12**).

Pharmacokinetic aspects

TCAs are all rapidly absorbed when given orally and bind strongly to plasma albumin, most being 90%–95% bound at therapeutic plasma concentrations. They also bind to extravascular tissues, which accounts for their generally very large distribution volumes (usually 10–50 L/kg; see **Ch. 9**) and low rates of elimination. Extravascular

sequestration, together with strong binding to plasma albumin, means that haemodialysis is ineffective as a means of increasing drug elimination.

TCAs are metabolised in the liver by two main routes, *N*-demethylation and ring hydroxylation (see **Fig. 48.5**). Both the desmethyl and the hydroxylated metabolites commonly retain biological activity (**Table 48.4**). During prolonged treatment with TCAs, the plasma concentration of these metabolites is usually comparable to that of the parent drug, although there is wide variation between individuals. Inactivation of the drugs occurs by glucuronide conjugation of the hydroxylated metabolites, the glucuronides being excreted in the urine.

The overall half-times for elimination of TCAs are generally long, ranging from 10 to 20 h for imipramine and desipramine to about 80 h for **protriptyline**. They are even longer in elderly patients. Therefore gradual accumulation is possible, leading to slowly developing side effects.

Tricyclic antidepressants

- Tricyclic antidepressants are chemically related to phenothiazine antipsychotic drugs (see **Ch. 47**), and some have similar non-selective receptor-blocking actions.
- Important examples are **imipramine**, **amitriptyline** and **clomipramine.**
- Most are long acting, and they are often converted to active metabolites.

- Important side effects: sedation (H_1 block); postural hypotension (α-adrenoceptor block); dry mouth, blurred vision, constipation (muscarinic block); occasionally mania and convulsions. Risk of ventricular dysrhythmias.
- Dangerous in acute overdose: confusion and mania, cardiac dysrhythmias.
- Liable to interact with other drugs (e.g. alcohol, anaesthetics, hypotensive drugs and non-steroidal anti-inflammatory drugs; should not be given with monoamine oxidase inhibitors).
- Also used to treat neuropathic pain.

Serotonin and Noradrenaline Uptake Inhibitors

These drugs are relatively non-selective for 5-HT and noradrenaline uptake. They include **venlafaxine**, **desvenlafaxine** and **duloxetine** (see **Table 48.2**).

Table 48.3

Inhibition of neuronal noradrenaline (NA) and 5-hydroxytryptamine (5-HT) uptake by tricyclic antidepressants and their metabolites

Drug/metabolite	NA uptake	5-HT uptake
Imipramine	+++	++
Desmethylimipramine (DMI) (also known as desipramine)	++++	+
Hydroxy-DMI	+++	—
Clomipramine (CMI)	++	+++
Desmethyl-CMI	+++	+
Amitriptyline (AMI)	++	++
Nortriptyline (desmethyl-AMI)	+++	++
Hydroxynortriptyline	++	++

Table 48.4

Substrates and inhibitors for type A and type B monoamine oxidase

	Type A	Type B
Preferred substrates	Noradrenaline 5-Hydroxytryptamine	Phenylethylamine Benzylamine
Non-specific substrates	Dopamine Tyramine	Dopamine Tyramine
Specific inhibitors	Clorgyline Moclobemide	Selegiline
Non-specific inhibitors	Pargyline Tranylcypromine Isocarboxazid	Pargyline Tranylcypromine Isocarboxazid

As the dose of venlafaxine is increased, its efficacy also increases, which has been interpreted as demonstrating that its weak action to inhibit noradrenaline reuptake may add to its 5-HT uptake inhibition that occurs at lower doses, the combination providing additional therapeutic benefit. They are all active orally; slow-release formulations are available that reduce the incidence of nausea. Venlafaxine, desvenlafaxine and duloxetine are effective in some anxiety disorders (see **Ch. 45**). Desvenlafaxine may be useful in treating some perimenopausal symptoms such as hot flushes and insomnia. Duloxetine is also used in the treatment of neuropathic pain and fibromyalgia (see **Ch. 43**) and urinary incontinence.

Venlafaxine and duloxetine are metabolised by CYP2D6. Venlafaxine is converted to desvenlafaxine, which shows greater inhibition of noradrenaline reuptake. The unwanted effects of these drugs – largely due to enhanced activation of adrenoceptors – include headache, insomnia, sexual dysfunction, dry mouth, dizziness, sweating and decreased appetite. The most common symptoms in overdose are CNS depression, serotonin toxicity, seizure and cardiac conduction abnormalities. Duloxetine has been reported to cause hepatotoxicity and is contraindicated for patients with hepatic impairment.

Other Noradrenaline Uptake Inhibitors

Bupropion inhibits both noradrenaline and dopamine (but not 5-HT) uptake but, unlike cocaine and amphetamine (see **Ch. 49**), does not induce euphoria and has so far not been observed to have abuse potential. It is metabolised to active metabolites. It is also used to treat nicotine dependence (see **Ch. 50**). At high doses it may induce seizures. Reboxetine and atomoxetine are highly selective inhibitors of noradrenaline uptake but their efficacy in depression is less than SSRIs and TCAs, possibly related to poor tolerability (**Cipriani et al., 2018**). Atomoxetine is approved for the treatment of attention deficit/hyperactivity disorder (see **Ch. 49**).

Other monoamine uptake inhibitors

- **Venlafaxine** is a 5-HT uptake inhibitor, but less selective for 5-HT versus noradrenaline than SSRIs. It is metabolised to **desvenlafaxine**, which is also an antidepressant.
- **Duloxetine** inhibits noradrenaline and 5-HT uptake.

- **Bupropion** is a noradrenaline and dopamine uptake inhibitor.
- Generally similar to tricyclic antidepressants but lack major receptor-blocking actions, so fewer side effects.
- Less risk of cardiac effects, so safer in overdose than tricyclic antidepressants.
- Can be used to treat other disorders:
  - **venlafaxine, desvenlafaxine** and **duloxetine** – anxiety disorders
  - **duloxetine** – neuropathic pain and fibromyalgia
  - **duloxetine** – urinary incontinence
  - **bupropion** – nicotine dependence.

Receptor Blocking Antidepressants

Mirtazapine blocks not only α_2 adrenoreceptors but also other receptors, including 5-HT_2 and 5-HT_3 receptors, which may contribute to its antidepressant actions and reduce some of the side effects arising from increased 5-HT release. Block of α_2 adrenoceptors will not only increase noradrenaline release but will also enhance 5-HT release (see **Fig. 48.3B**); however, by simultaneously blocking 5-HT_{2A} and 5-HT_3 receptors, it will reduce the unwanted effects mediated through these receptors (e.g. sexual dysfunction and nausea) but leave intact stimulation of postsynaptic 5-HT_{1A} receptors. It also blocks histamine H_1 receptors, which causes sedation sedation particularly at low doses. **Trazodone** is a mixed agonist and antagonist of various 5-HT receptors, antagonist of adrenoceptors, weak histamine H_1 receptor antagonist and weak serotonin reuptake inhibitor. The combined 5-HT_{2A} and 5-HT_{2C}

receptor antagonism with weak 5-HT reuptake inhibition may lead to antidepressant effects with reduced 5-HT_2-related side effects, e.g. sleep disturbance, sexual dysfunction and anxiety.

Mianserin, another α_2 adrenoceptor antagonist that also blocks H_1, 5-HT_{2A} and α_1 adrenoceptors (reducing effects of 5-HT relative to mirtazapine), can cause bone marrow depression, requiring regular blood counts, so its use has declined in recent years.

Monoamine receptor antagonist antidepressant drugs

- **Mirtazapine** blocks α_2 adrenoceptors, 5-HT_2 and 5-HT_3 receptors, enhancing noradrenaline and 5-HT release and reducing 5-HT-related side effects.
- **Mirtazapine** causes less nausea and sexual dysfunction than SSRIs but can lead to weight gain due to 5-HT_{2C} effects.
- **Trazodone** blocks 5-HT_{2A} and 5-HT_{2C} receptors and blocks 5-HT reuptake.
- **Mianserin** is an antagonist at multiple 5-HT receptors (including 5-HT_{2A}) as well as at H_1, α_1 and α_2 receptors. It is also an inverse agonist at H_1 receptors. Use is declining because of risk of bone marrow depression. Regular blood counts are advisable.
- Cardiovascular side effects of these drugs are fewer than those of tricyclic antidepressants.
- **Vortioxetine** has both 5-HT uptake inhibition and multiple 5-HT receptor partial agonist, full agonist or antagonist actions.

Monoamine Oxidase Inhibitors

MAOIs were among the first drugs to be introduced clinically as antidepressants but were largely superseded by other types of antidepressants, whose clinical efficacies were considered better and whose side effects are generally less than those of MAOIs. The main examples are **phenelzine**, **tranylcypromine** and **iproniazid**. These drugs cause irreversible inhibition of the enzyme and do not distinguish between the two main isozymes (see later). The discovery of reversible inhibitors that show isozyme selectivity has rekindled interest in this class of drug. Although several studies have shown a reduction in platelet MAO activity in certain groups of patients with depression, there is no clear evidence that abnormal MAO activity is involved in the pathogenesis of depression.

MAO (see **Ch. 15**) is found in nearly all tissues, and exists in two similar molecular forms coded by separate genes (see **Table 48.4**). MAO-A has a substrate preference for 5-HT and noradrenaline, and is the main target for the antidepressant MAOIs. MAO-B has a substrate preference for phenylethylamine and dopamine. Type B is selectively inhibited by **selegiline**, which is used in the treatment of Parkinson's disease (see **Ch. 40**). Most antidepressant MAOIs act on both forms of MAO, but clinical studies with subtype-specific inhibitors have shown clearly that antidepressant activity, as well as the main side effects of MAOIs, is associated with MAO-A inhibition. MAO is located intracellularly, mostly associated with mitochondria, and has two main functions:

1. Within nerve terminals, MAO regulates the free intraneuronal concentration of noradrenaline or 5-HT. It is not involved in the inactivation of released transmitter.

2. MAO in the gut wall is important in the inactivation of endogenous and ingested amines such as tyramine that would otherwise produce unwanted effects.

Chemical aspects

MAOIs are substrate analogues with a phenylethylamine-like structure, and most contain a reactive group (e.g. hydrazine, propargylamine, cyclopropylamine) that enables the inhibitor to bind covalently to the enzyme, resulting in a non-competitive and long-lasting inhibition. Recovery of MAO activity after inhibition takes several weeks with most drugs, but is quicker after **tranylcypromine**, which forms a less stable bond with the enzyme. **Moclobemide** acts as a reversible competitive inhibitor.

MAOIs are not specific in their actions, and inhibit a variety of other enzymes as well as MAO, including many enzymes involved in the metabolism of other drugs. This is responsible for some of the many clinically important drug interactions associated with MAOIs.

Pharmacological effects

MAOIs cause a rapid and sustained increase in the 5-HT, noradrenaline and dopamine content of the brain, 5-HT being affected most and dopamine least. Similar changes occur in peripheral tissues such as heart, liver and intestine, and increases in the plasma concentrations of these amines are also detectable. Although these increases in tissue amine content are largely due to accumulation within neurons, transmitter release in response to nerve activity is not increased. In contrast to the effect of TCAs, MAOIs do not increase the response of peripheral organs, such as the heart and blood vessels, to sympathetic nerve stimulation. The main

effect of MAOIs is to increase the cytoplasmic concentration of monoamines in nerve terminals, without greatly affecting the vesicular stores that are releasable by nerve stimulation. The increased cytoplasmic pool results in an increased rate of spontaneous leakage of monoamines, and also an increased release by indirectly acting sympathomimetic amines such as amphetamine and tyramine (see **Ch. 15** and **Fig. 15.7**). Tyramine thus causes a much greater rise in blood pressure in MAOI-treated animals than in controls. This mechanism is important in relation to the 'cheese reaction' produced by MAOIs in humans (see later).

In normal human subjects, MAOIs cause an immediate increase in motor activity; euphoria and excitement develop over the course of a few days. This is in contrast to TCAs, which cause only sedation and confusion when given to subjects without depression. The effects of MAOIs on amine metabolism develop rapidly, and the effect of a single dose lasts for several days. There is a clear discrepancy, as with SSRIs and TCAs, between the rapid biochemical response and the delayed antidepressant effect.

Unwanted effects and toxicity

Many of the unwanted effects of MAOIs result directly from MAO inhibition, but some are produced by other mechanisms.

Hypotension is a common side effect; indeed, **pargyline** was at one time used as an antihypertensive drug. One possible explanation for this effect – the opposite of what might have been expected – is that amines such as dopamine or octopamine accumulate within peripheral sympathetic nerve terminals and displace noradrenaline from the storage vesicles, thus reducing noradrenaline release associated with sympathetic activity.

Excessive central stimulation may cause tremors, excitement, insomnia and, in overdose, convulsions.

Increased appetite, leading to weight gain, can be so extreme as to require the drug to be discontinued.

Atropine-like side effects (dry mouth, blurred vision, urinary retention, etc.) are common with MAOIs, although they are less of a problem than with TCAs.

MAOIs of the hydrazine type (e.g. phenelzine and iproniazid) produce, very rarely (less than 1 in 10,000), severe hepatotoxicity, which seems to be due to the hydrazine moiety of the molecule. Their use in patients with liver disease is therefore unwise.

Interaction with other drugs and foods

Interaction with other drugs and foods is the most serious problem with MAOIs and is the main factor that caused their clinical use to decline. The special advantage claimed for the new reversible MAOIs, such as moclobemide, is that these interactions are reduced.

The ‘cheese reaction’ is a direct consequence of MAO inhibition and occurs when normally innocuous amines (mainly tyramine) produced during fermentation are ingested. Tyramine is normally metabolised by MAO in the gut wall and liver, and little dietary tyramine reaches the systemic circulation. MAO inhibition allows tyramine to be absorbed, and also enhances its sympathomimetic effect, as discussed earlier. The result is acute hypertension, giving rise to a severe throbbing headache and occasionally even to intracranial haemorrhage. Although many foods contain some tyramine, it appears that at least 10 mg of tyramine needs to be ingested to produce such a response, and the main danger is from ripe cheeses and from concentrated yeast products such as Marmite.

Administration of indirectly acting sympathomimetic amines (e.g. **ephedrine** – a nasal decongestant – or **amphetamine**) also causes severe hypertension in patients receiving MAOIs; directly acting agents such as noradrenaline (used, for example, in conjunction with local anaesthetics; see **Ch. 44**) are not hazardous. Moclobemide, a specific MAO-A inhibitor, does not cause the 'cheese reaction', probably because tyramine can still be metabolised by MAO-B and through competition with moclobemide at MAO-A.

Hypertensive episodes have been reported in patients given TCAs and MAOIs simultaneously. The probable explanation is that inhibition of noradrenaline reuptake further enhances the cardiovascular response to dietary tyramine, thus accentuating the 'cheese reaction'. This combination of drugs can also produce excitement and hyperactivity.

MAOIs can interact with **pethidine** (see **Ch. 43**) to cause severe hyperpyrexia, with restlessness, coma and hypotension. The mechanism is uncertain, but it is likely that an abnormal pethidine metabolite is produced because of inhibition of demethylation.

Melatonin Agonist

Agomelatine is a potent agonist at MT_1 and MT_2 receptors (see **Ch. 39**) with weak antagonist activity at $5\text{-}HT_{2A,2B,2C}$ receptors (almost 1000-fold lower potency). It has a short biological half-life and does not give rise to the side effects associated with other antidepressant drugs. Used to treat severe depression, it is usually taken once daily before bed and may work by correcting disturbances in circadian rhythms often associated with depression. There are reports of hepatotoxicity in a few patients, and it should not be used in patients with liver disease.

Rapid-Acting Antidepressants

Esketamine is the S(+) enantiomer of ketamine and has been licensed as a nasal spray for once or twice weekly administration for treatment-resistant depression. The S(+) enantiomer of ketamine is about four-fold more potent at the NMDA receptor. It is currently licensed in the United States. In the UK there is a growing number of clinics offering intravenous infusions of low doses of the racemic mixture of ketamine for patients who have failed to respond to conventional antidepressants. A single, sub-anaesthetic dose of ketamine or intranasal esketamine induces an initial dissociative effect accompanied by increased blood pressure and can cause a variety to unpleasant side effects (see **Ch. 41**). These only last for a brief period of time (<1 h) however and the antidepressant effects emerge within a few hours and are sustained for up to 14 days. Ketamine is a non-competitive NMDA channel blocker (see **Ch. 41**); however, it also has effects at a number of other receptors at clinical doses including actions at μ-opioid receptors. To date, clinical trials with other NMDA receptor antagonists, e.g. memantine, have failed to find similar antidepressant effects. There is controversy surrounding whether the putative antidepressant effect is produced by ketamine itself, and which receptor is the primary mediator, or by its metabolite, R,R-hydroxynorketamine. Hydroxynorketamine would have the added advantage that, unlike ketamine, it may not produce psychotomimetic effects as it has low affinity for the NMDA receptor, and thus would be unlikely to be abused (see **Ch. 50**).

Several other classes of hallucinogenic drugs have been investigated as RAADs. The muscarinic antagonist, **scopolamine** (see **Ch. 14**), which is also referred to as a 'deliriant' reflecting is potent induction of a state of delirium, was found to have rapid and

sustained antidepressant effects. Psychedelic serotonin agonists are potent 5-HT_{2A} agonists (as well as acting at other 5-HT receptors) and include drugs such as psilocybin, dimethyltryptamine and lysergic acid diethylamide (LSD). Several clinical trials have now been undertaken and suggest that these drugs may also induce rapid and sustained antidepressant effects including some evidence for effects lasting several months after a single treatment. Although previously used in drug-assisted psychotherapy, until they were banned in the 1970s, research is only just starting to unlock the clinical efficacy of these drugs and how they interact with psychological treatments to generate their effects. A challenge with all these RAADs is their history as drugs which have been used non-medically and their powerful dissociative, deliriant or psychedelic effects requiring intensive patient care. Although still in the early days, the discovery of RAADs has provided a new avenue for research which will hopefully generate new insights into the mechanisms which underlie the antidepressant efficacy of these drugs and may even help us learn more about conventional antidepressants.

Monoamine oxidase inhibitors (MAOIs)

- Main examples are **phenelzine**, **tranylcypromine**, **isocarboxazid** (irreversible, long-acting, non-selective between MAO-A and -B) and **moclobemide** (reversible, short-acting, MAO-A selective).
- Long-acting MAOIs:
  - main side effects: postural hypotension (sympathetic block); atropine-like effects (as with tricyclic

antidepressants (TCAs)); weight gain; CNS stimulation, causing restlessness, insomnia; hepatotoxicity and neurotoxicity (rare);
  - acute overdose causes CNS stimulation, sometimes convulsions;
  - 'cheese reaction', i.e. severe hypertensive response to tyramine-containing foods (e.g. cheese, beer, wine, well-hung game, yeast or soy extracts); such reactions can occur up to 2 weeks after treatment is discontinued.
- Interaction with other amines (e.g. **ephedrine** in over-the-counter decongestants, **clomipramine** and other TCAs) and some other drugs (e.g. **pethidine**) are also potentially lethal.
- **Moclobemide** is used for major depression and social phobia. 'Cheese reaction' and other drug interactions are less severe and shorter lasting than with irreversible MAOIs.
- MAOIs are used much less than other antidepressants because of their adverse effects and serious interactions. They are indicated for major depression in patients who have not responded to other drugs.

Other Antidepressant Approaches

Brexanolone is an allopregnanolone-based treatment recently licensed in the United States for postpartum depression. The drug acts as a neuroactive steroid and is a positive allosteric modulator at the $GABA_A$ receptor (see **Ch. 38**) which is thought to be the primary mechanism mediating its therapeutic effects.

Oestrogen, which is known to elevate mood in perimenopausal women, may also be of value for the treatment of postnatal

depression. Its effectiveness in treating other forms of depression is unclear. In addition to its well-documented hormonal actions in the body (see **Ch. 35**), it also has actions on monoaminergic, GABAergic and glutamatergic systems in the brain (see Chs **38** and **39**).

Clinical Effectiveness of Antidepressant Treatments

The overall clinical efficacy of antidepressants is generally accepted for severe depression, although there is concern that the published clinical trials evidence may be misleading, because many negative trials have gone unreported. However, 30%–40% of patients with depression fail to show improvement, and those who do may only show partial improvement, reinforcing the need for new drugs with novel mechanisms of action. Clear evidence of benefit from current antidepressant drugs in mild to moderate depression is lacking. Interpretation of trials data is complicated by a high placebo response, and spontaneous recovery independent of any treatment. Clinical trial data do not suggest that drugs currently in use differ in terms of efficacy. Nevertheless, clinical experience suggests that individual patients may, for unknown reasons, respond better to one drug than another. Current treatment guidelines recommend evidence-based psychological procedures as first-line treatments in most cases, before antidepressant drugs.

Pharmacogenetic factors

The individual variation in response to antidepressants and the incidence of adverse effects may be partly due to genetic factors (**Crisafulli et al., 2014**). Two genetic factors have received particular attention, namely:

- polymorphism of cytochrome P450 genes, especially *CYP2D6 and CYP2C19, which are responsible for hydroxylation and demethylation of TCAs and SSRIs*;
- polymorphism of serotonin and noradrenaline transporter genes.

Up to 10% of Caucasians possess a dysfunctional *CYP2D6* gene, and consequently may be susceptible to the side effects of antidepressants and various other drugs (see **Ch. 12**) that are metabolised by this route. The opposite effect, caused by duplication of the gene, is common in Eastern European and East African populations, and may account for a lack of clinical efficacy in some individuals. There is some evidence to suggest that responsiveness to SSRIs and serotonin and noradrenaline uptake inhibitors (SNRIs) is related to polymorphism of the serotonin and noradrenaline transporter genes.

Although genotyping may prove to be a useful approach in the future to individualising antidepressant therapy, its practical realisation is still some way off.

Suicide and antidepressants

SSRI and SNRI antidepressants can increase the risk of 'suicidality' and increase aggression in children, adolescents and young adults (see **Sharma et al., 2016**). The term *suicidality* encompasses suicidal thoughts and planning as well as unsuccessful attempts; actual suicide, although one of the major causes of death in young people, is much rarer than suicidality. The risk is less in older age groups. However, the risk has to be balanced against the beneficial

effects of these drugs, not only on depression but also on anxiety, panic and obsessive–compulsive disorders (see **Ch. 45**).

Clinical uses of drugs in depression

- Mild depression is often best treated initially with non-drug measures (such as cognitive behavioural therapy), with antidepressant drugs being used in addition if the response is poor.
- The use of antidepressant drugs is advisable in the treatment of moderate to severe depression.
- The clinical efficacy of antidepressant drugs is limited, and varies between individuals. Clinical trials have produced inconsistent results, because of placebo responses and spontaneous fluctuations in the level of depression.
- Different classes of antidepressant drugs have similar efficacy but different side effects.
- Choice of drug is based on individual aspects including concomitant disease treatment, suicide risk and previous response to treatment. Other things being equal, a SSRI is preferred as these are usually better tolerated and are less dangerous in overdose.
- Conventional antidepressant drugs take several weeks before taking effect, so decisions on dose increment or switching to another class should not be made precipitately. Use of MAOIs is managed by specialists.
- An effective regimen should be continued for at least 2 years.

- Treatment-resistant patients may benefit from treatment with the rapid-acting antidepressant, ketamine.
- Anxiolytic (e.g. benzodiazepine, see **Ch. 45**) or antipsychotic (see **Ch. 47**) drugs are useful adjuncts in some patients.

Future Antidepressant Drugs

The successive failures of adjunct therapies targeting autoreceptors has limited further progress in this area and most new clinical trials in depression focus on the RAADs. This includes ongoing clinical trials with different NMDA receptor antagonists, particularly those targeting the NR2B subunit which have been hypothesised to achieve similar RAAD effects as ketamine but with reduced dissociation and abuse liability. There is also interest in methods which could prolong the effects of ketamine (and possibly other RAAD) through targeting of downstream effects thought to mediate the neurotrophic effects. Clinical trials with the psychedelics are ongoing and preclinical projects are seeking to identify novel targets which could achieve these RAAD effects but with reduced dissociative and hallucinogenic effects and abuse liability.

Brain Stimulation Therapies

A number of brain stimulation techniques are now being used or developed to treat depression. Bright light stimulation has been proposed as a treatment for seasonal affective disorder. The most established brain stimulation techniques are ECT and repetitive transcranial magnetic stimulation (TMS). Brain stimulation

treatments are often used as the therapeutic approach of last resort for patients who have not responded to antidepressant drugs.

ECT involves stimulation through electrodes placed on either side of the head, with the patient lightly anaesthetised, paralysed with a short-acting neuromuscular-blocking drug (e.g. **suxamethonium**; see **Ch. 14**) to avoid physical injury, and artificially ventilated. Controlled trials have shown ECT to be at least as effective as antidepressant drugs, with response rates ranging between 60% and 80%; it appears to be an effective treatment for severe suicidal depression and has the advantage of producing a fast-onset response. The main disadvantage of ECT is that it often causes confusion and memory loss lasting for days or weeks. TMS gives electrical stimulation without anaesthesia or convulsion and does not produce cognitive impairment, but comparative studies suggest that its antidepressant efficacy is less than that of conventional ECT.

The effect of ECT on experimental animals has been carefully analysed to see if it provides clues as to the mode of action of antidepressant drugs, but the clues it gives are enigmatic. 5-HT synthesis and uptake are unaltered, and noradrenaline uptake is somewhat increased (in contrast to the effect of TCAs). Decreased β adrenoceptor responsiveness, both biochemical and behavioural, occurs with both ECT and long-term administration of antidepressant drugs, but changes in 5-HT-mediated responses tend to go in opposite directions.

There have been reports that deep brain stimulation, which has also been used in the treatment of Parkinson's disease (see **Ch. 40**), in which stimulation is delivered in a specific brain region through surgically implanted electrodes, is effective in patients not responding to other treatments (see **Sullivan et al., 2021**). The

effectiveness of another technique, vagal stimulation, in producing long-term benefit in depression is still unclear.

Novel-acting antidepressants

- **Agomelatine** is an agonist at MT_1 and MT_2 melatonin receptors that improves mood, probably by improving sleep patterns.
- **Ketamine**, an NMDA receptor channel blocker, produces rapid and sustained antidepressant effects in patients resistant to other therapies.

Drug Treatment of Bipolar Disorder

The main class of drugs used to manage the symptoms of bipolar disorder are the mood stabilisers. The major drugs are:

- **lithium**;
- certain antiepileptic drugs, e.g. **carbamazepine, valproate, lamotrigine**; and
- some antipsychotic drugs, e.g. **olanzapine, risperidone, quetiapine, aripiprazole, brexpiprazole, cariprazine.**

Other agents that may have some beneficial effects in the treatment of bipolar disorder are benzodiazepines (to calm, induce sleep and reduce anxiety), **memantine**, **amantadine** (to improve depression and cognitive impairments) and **ketamine** (to treat suicidal ideation). The use of antidepressant drugs in bipolar disorder is somewhat controversial. It is recommended that they are given in

combination with an antimanic agent because, in some patients, they may induce or enhance mania.

Used prophylactically in bipolar disorder, these drugs prevent the swings of mood and thus can reduce both the depressive and the manic phases of the illness. They are given over long periods, and their beneficial effects take 3–4 weeks to develop. Given in an acute attack, they are effective only in reducing mania, but not the depressive phase (although lithium is sometimes used as an adjunct to antidepressants in severe cases of unipolar depression). Very little is known about the pathophysiology of bipolar disorder although it has a much higher genetic risk than unipolar depression and some aspects of the disorder reflect symptoms seen in schizophrenia. The mechanisms of action of mood stabilisers are also poorly understood and even though the molecular targets have been investigated, how actions at these receptors or downstream signalling pathways translate to effects on mood remains unknown.

Lithium

The psychotropic effect of lithium was discovered in 1949 by Cade, who had predicted that urate salts should prevent the induction by uraemia of a hyperexcitability state in guinea pigs. He found lithium urate to produce an effect, quickly discovered that it was due to lithium rather than urate and went on to show that lithium produced a rapid improvement in a group of manic patients.

Antiepileptic and atypical antipsychotic drugs (see later) are equally effective in treating acute mania; they act more quickly and are considerably safer, so the clinical use of lithium is mainly confined to prophylactic control of bipolar disorder. The use of lithium is declining. [4] It is relatively difficult to use, as plasma

concentration monitoring is required, and there is the potential for problems in patients with renal impairment and for drug interactions, for example with diuretics (see **Ch. 58**).

Pharmacological effects and mechanism of action

Lithium is clinically effective at a plasma concentration of 0.5–1 mmol/L, and above 1.5 mmol/L it produces a variety of toxic effects, so the therapeutic window is narrow. In normal subjects, 1 mmol/L lithium in plasma has no appreciable psychotropic effects. It does, however, produce many detectable biochemical changes, and it is still unclear how these may be related to its therapeutic effect.

Lithium is a monovalent cation that can mimic the role of Na^+ in excitable tissues, being able to permeate the voltage-gated Na^+ channels that are responsible for action potential generation (see **Ch. 4**). It is, however, not pumped out by the Na^+-K^+-ATPase, and therefore tends to accumulate inside excitable cells, leading to a partial loss of intracellular K^+ and depolarisation of the cell.

The biochemical effects of lithium are complex, and it inhibits many enzymes that participate in signal transduction pathways. Those that are thought to be relevant to its therapeutic actions are as follows:

- Inhibition of inositol monophosphatase, which blocks the phosphatidylinositol (PI) pathway (see **Ch. 3**) at the point where inositol phosphate is hydrolysed to free inositol, resulting in depletion of PI. This prevents agonist-stimulated inositol trisphosphate formation through various PI-linked receptors, and therefore blocks many receptor-mediated effects.

- Inhibition of GSK3 isoforms, possibly by competing with magnesium for its association with these kinases. GSK3 isoforms phosphorylate a number of key enzymes involved in pathways leading to apoptosis and amyloid formation. Lithium can also affect GSK3 isoforms indirectly by interfering with their regulation by Akt, a closely related serine/threonine kinase regulated through PI-mediated signalling and by arrestins (see **Ch. 3**).

Neuroprotective and neurotrophic effects may account for its delayed onset and prophylactic efficacy and lithium's beneficial effects in neurodegenerative diseases such as Alzheimer's disease (see **Ch. 40**).

Lithium inhibits G protein function, thus reducing K^+ channel activation and hormone-induced cAMP production. It also blocks other cellular responses (e.g. the response of renal tubular cells to antidiuretic hormone, and of the thyroid to thyroid-stimulating hormone; see Chs **29** and **34**, respectively). This is not, however, a pronounced effect in the brain.

The cellular selectivity of lithium appears to depend on its selective uptake, reflecting the activity of sodium channels in different cells. This could explain its relatively selective action in the brain and kidney, even though many other tissues use the same second messengers. Notwithstanding such insights, our ignorance of the nature of the disturbance underlying the mood swings in bipolar disorder leaves us groping for links between the biochemical and prophylactic effects of lithium.

Pharmacokinetic aspects and toxicity

Lithium is given by mouth as carbonate salt and is excreted by the kidney. About half of an oral dose is excreted within about 12 h – the remainder, which presumably represents lithium taken up by cells, is excreted over the next 1–2 weeks. This very slow phase means that, with regular dosage, lithium accumulates slowly over 2 weeks or more before a steady state is reached. The narrow therapeutic window means that monitoring of the plasma concentration is essential. Na^+ depletion reduces the rate of excretion by increasing the reabsorption of lithium by the proximal tubule, and thus increases the likelihood of toxicity. Diuretics that act distal to the proximal tubule (see **Ch. 29**) also have this effect, and renal disease also predisposes to lithium toxicity.

The main toxic effects that may occur during treatment are as follows:

- nausea, vomiting and diarrhoea;
- tremor;
- renal effects: polyuria (with resulting thirst) resulting from inhibition of the action of antidiuretic hormone. At the same time, there is some Na^+ retention associated with increased aldosterone secretion. With prolonged treatment, serious renal tubular damage may occur, making it essential to monitor renal function regularly in lithium-treated patients;
- thyroid enlargement, sometimes associated with hypothyroidism;
- weight gain;
- hair loss.

Acute lithium toxicity results in various neurological effects, progressing from confusion and motor impairment to coma, convulsions and death if the plasma concentration reaches 3–5 mmol/L.

Antiepileptic Drugs

Carbamazepine, **valproate** and **lamotrigine** (see **Ch. 46**) have fewer side effects than lithium and have proved efficacious in the treatment of bipolar disorder.

It is assumed that the mechanisms of action of anticonvulsant drugs in reducing bipolar disorder are related to their anticonvulsant activity although they can also interact with intracellular signalling molecules linked to the effects of lithium. While each drug has multiple actions (see **Table 46.1**), the antiepileptic drugs effective in bipolar disorder share the property of sodium-channel blockade, although there are subtle differences in their effectiveness against the different phases of bipolar disorder. Valproate and carbamazepine are effective in treating acute attacks of mania and in the long-term treatment of the disorder, although carbamazepine may not be as effective in treating the depression phase. Valproate is sometimes given along with other drugs such as lithium. Lamotrigine is effective in preventing the recurrence of both mania and depression.

Second-Generation Antipsychotic Drugs

An ever-increasing number of second-generation antipsychotic drugs (e.g. **olanzapine**, **risperidone**, **quetiapine**, **aripiprazole, cariprazine, brexpiprazole, asenapine**) (see **Ch. 47**) are proving effective in the treatment of bipolar disorder. These agents have D_2 dopamine and 5-HT_{2A} receptor antagonist properties as well

as actions on other receptors and amine transporters that may contribute to their effectiveness. All appear to be effective against mania while some may also be effective against bipolar depression. In bipolar depression, they are often used in combination with lithium or valproate. Olanzapine is given in combination with the antidepressant fluoxetine. Haloperidol, a first-generation antipsychotic drug, is also sometimes used to treat bipolar disorder.

Treatment of bipolar disorder

- **Lithium**, an inorganic ion, taken orally as lithium carbonate.
- Mechanism of action is not understood. The main biochemical possibilities are:
  - interference with inositol trisphosphate formation
  - inhibition of kinases
  - effects on neurotrophic mechanisms leading to neuroprotective effects
- Antiepileptic drugs (e.g. carbamazepine, valproate, lamotrigine):
  - better side effect and safety profile.
- Atypical antipsychotic drugs (e.g. olanzapine, risperidone, quetiapine, aripiprazole) and also haloperidol.

Clinical uses of mood-stabilising drugs

- **Lithium** (as the carbonate) is the classical drug. It is used:

  - in prophylaxis and treatment of *mania*, and in the prophylaxis of *bipolar* or *unipolar disorder* (bipolar disorder or recurrent depression).
- Points to note include the following:
  - there is a narrow therapeutic window and long duration of action;
  - acute toxic effects include cerebellar effects, nephrogenic *diabetes insipidus* (see **Ch. 29**) and renal failure;
  - dose must be adjusted according to the plasma concentration;
  - elimination is via the kidney and is reduced by proximal tubular reabsorption. Diuretics increase the activity of the reabsorptive mechanism and hence can precipitate lithium toxicity;
  - thyroid disorders and mild cognitive impairment occur during chronic use.
- **Carbamazepine valproate** and **lamotrigine** (sodium-channel blockers with antiepileptic actions; see **Ch. 46**) are used for:
  - the prophylaxis and treatment of manic episodes in patients with *bipolar disorder*;
  - the treatment of *bipolar disorder* (**valproate**, **lamotrigine**).
- **Olanzapine**, **risperidone**, **quetiapine**, **aripiprazole** (atypical antipsychotic drugs) are primarily used to treat *mania*.

QUESTIONS

QUESTION 48.1

Depression is the most common of the affective disorders and numerous hypotheses have been proposed to explain the cause.

Which of the following physiological changes is NOT associated with depression?

OPTIONS:

A. Increased central nervous system (CNS) concentrations of corticotrophin-releasing hormone (CRH)

B. Reduction in brain-derived neurotrophic factor (BDNF) expression

C. Functional deficit in monoamine transmitters

D. Decreased glutamatergic neurotransmission

E. Neuronal loss in the hippocampus

QUESTION 48.2

Progress in unravelling the neurochemical mechanisms of depression and hence the development of novel therapeutic agents is limited by the lack of good animal models of the clinical condition.

Which of the following models would be least effective for the identification of novel (non-monoaminergic) agents?

OPTIONS:

A. Behavioural despair models

B. Early life adversity models

C. Chronic social and/environmental stressors

D. Observation of changes in reward-related behaviours

E. Negative affective biases

QUESTION 48.3

The formulation of the monoamine hypothesis for the aetiology of depression has led to the development of a number of agents to modulate monoamine transmission.

Which of the following agents would NOT be useful in the treatment of depression?

OPTIONS:

A. Reserpine

B. Desipramine

C. Venlafaxine

D. Mirtazapine

E. Moclobemide

ANSWERS

ANSWER 48.1

RATIONALE:

A. Elevated CRH levels are associated with stress and high levels in animals mimic some of the depressive symptoms in humans.

B. Lowered levels of BDNF or malfunction of its receptor has been implicated in depressive behaviour.

C. Although not conclusively proven, the efficacy of agents that increase monoamine transmission has provided support for this hypothesis.

D.

E. Although still a hypothesis, it is supported by evidence from animal models, postmortem studies and the neurogenic effects of antidepressant agents.

CORRECT ANSWER WITH EXPLANATION:

D. Decreased glutamatergic neurotransmission

Individuals with depression have been shown to have elevated cortical levels of glutamate.

ANSWER 48.2

RATIONALE:

A.

B. Somewhat more success has been achieved using different types of stress to induce a depression-like phenotype including early life adversity and experience of chronic social and/environ stressors.

C. Somewhat more success has been achieved using different types of stress to induce a depression-like phenotype including experience of chronic social and/environmental stressors.

D. Detecting changes in the animal's emotional behaviour mostly focuses on changes in reward-related behaviours akin to the anhedonia seen in many patients.

E. More recently, attempts to improve the translation between human and animal studies have led to novel neuropsychological models based on negative affective biases.

CORRECT ANSWER WITH EXPLANATION:

A. Behavioural despair models (e.g. forced swim test, learned helplessness)

These behaviours are sensitive to the original monoaminergic antidepressants but interpretation of these models in the context of underlying disease processes or non-monoaminergic drugs is limited.

ANSWER 48.3

RATIONALE:

A.

B. Tricyclic antidepressants (TCAs) such as desipramine block reuptake of noradrenaline (NA) and 5-hydroxytryptamine (5-HT) so increasing transmission.

C. Venlafaxine inhibits reuptake with an enhanced selectivity for inhibiting 5-HT reuptake, although this is less than the selective serotonin reuptake inhibitors (SSRIs).

D. Mirtazapine is a monoamine receptor antagonist blocking presynaptic α_2 receptors, which decrease NA release. It also reduces unwanted 5-HT_{2A} and 5-HT_3 effects whilst leaving postsynaptic 5-HT_{1A} signalling intact.

E. Moclobemide is a selective monoamine oxidase (MAO)-A inhibitor, so decreases breakdown.

CORRECT ANSWER WITH EXPLANATION:

A. Reserpine

Reserpine displaces monoamines from neuronal vesicles and causes a gradual depletion in neuronal concentration.

[1] Neurogenesis (see Ch. 40) – the formation of new neurons from stem cell precursors – occurs to a significant degree in the adult hippocampus, and possibly elsewhere in the brain, contradicting the old dogma that it occurs only during brain development.

[2] Although relatively free of acute side effects, hyperforin activates cytochrome P450, resulting in loss of efficacy (see Ch. 10), with serious consequences, of several important drugs, including ciclosporine, oral contraceptives, some anti-HIV and anticancer drugs and oral anticoagulants – underlining the principle that herbal remedies are not inherently safe, and must be used with the same degree of informed caution as any other drug.

[3] Thus conversely, SSRIs can be used to treat premature ejaculation. Dapoxetine has a short half-life and is taken 1–3 h before sex.

[4] The decline in lithium use may have been influenced by the imbalance in the marketing of this simple inorganic ion versus more profitable pharmacological agents.

49: Psychoactive drugs

OVERVIEW

In its broadest sense, the term *psychoactive drug* would cover all drugs that act on the brain to produce changes in perception, mood, consciousness and behaviour, and would thus include anaesthetic, anxiolytic, antipsychotic and antidepressant drugs, which are described elsewhere in this book. Here we describe psychoactive drugs that are not covered in detail elsewhere. Some of these drugs have proven therapeutic usefulness in the treatment of behavioural disorders such as attention deficit/hyperactive disorder and narcolepsy. Others may prove to have clinical potential as antidepressants, anxiolytics and cognition enhancers. Drugs such as nicotine and ethanol have little or no medicinal value but their use is legal in many countries whereas most others are illegal.

Further information on psychoactive drugs is contained in **Miller (2015)**.

Introduction

Attempting to classify psychoactive drugs according to their pharmacological mechanisms of action and their behavioural effects is a challenging task. Several of the drugs exert more than one important pharmacological action, drugs with apparently similar

pharmacological activity can induce different subjective experiences (e.g. amphetamine and 3,4-methylenedioxymethamphetamine [MDMA]) and for a single drug the behavioural response may change with dose (e.g. ethanol induces excitement at low doses but is depressant at higher doses). Here, for convenience, we have grouped psychoactive drugs as

- Psychomotor stimulants
- Psychedelics
- Dissociatives
- Depressants
- Synthetic cannabinoid receptor agonists (SCRAs)

The 21st century has seen an explosion in the availability of novel psychoactive substances (NPS). By and large, these have been developed to circumvent legal restrictions on more established drugs (e.g. amphetamines, cocaine, MDMA and cannabinoids) and were for a time referred to as 'legal highs'. This has led to changes in the law in many countries to make them illegal. The array of psychoactive substances is vast; [1] in this chapter we concentrate on psychoactive drugs for which good evidence of their behavioural effects and mechanisms of action are available.

Psychomotor Stimulants

Table 49.1 lists the major psychomotor stimulants, their mechanisms of action and clinical uses.

Amphetamines [2]

DL-amphetamine (*speed* or *billy whizz*), its active dextroisomer **dextroamphetamine** (*dexies*) and **methamphetamine** (*crystal meth* or *ice*) have very similar chemical structures (**Fig. 49.1**) and pharmacological properties.

Pharmacological effects

The amphetamines act by releasing monoamines, primarily dopamine (DA) and noradrenaline (NA), from nerve terminals in the brain. They do this in a number of ways. They are substrates for the neuronal plasma membrane transporters for dopamine (DAT) and noradrenaline (NET) but not the transporter for 5-hydroxytryptamine (SERT) (see Chs **15**, **16** and **39**), and thus act as competitive inhibitors, reducing the reuptake of DA and NA. In addition, they enter nerve terminals via the uptake processes or by diffusion and interact with the vesicular monoamine pump VMAT-2 to inhibit the uptake into synaptic vesicles of cytoplasmic DA and NA. The amphetamines are taken up into the storage vesicles by VMAT-2 and displace the endogenous monoamines from the vesicles into the cytoplasm. At high concentrations, amphetamines can inhibit monoamine oxidase, which otherwise would break down cytoplasmic monoamines, and monoamine oxidase inhibitors (see **Ch. 48**) potentiate the effects of amphetamine. The cytoplasmic monoamines can then be transported out of the nerve endings via the plasma membrane DAT and NET transporters working in reverse, a process that is thought to be facilitated by amphetamine binding to these transporters. All of these will combine to increase the concentration of extracellular DA and NA in the vicinity of the synapse (see Chs **15** and **39**).

In animals, prolonged administration results in degeneration of monoamine-containing nerve terminals and eventually cell death. This effect is observed with toxic doses and is probably due to the accumulation of reactive metabolites of the parent compounds within the nerve terminals. In human brain-imaging studies a reduction in the levels of DAT and D_2 receptors has been observed in the brains of amphetamine users. It is unclear, however, whether this is due to long-term exposure to the drug-inducing nerve damage or is an underlying vulnerability that was responsible for drug seeking in the first instance.

Table 49.1

ADHD, Attention deficit/hyperactivity disorder; *DA,* dopamine; *5-HT,* 5-hydroxytryptamine; *NA,* noradrenaline.

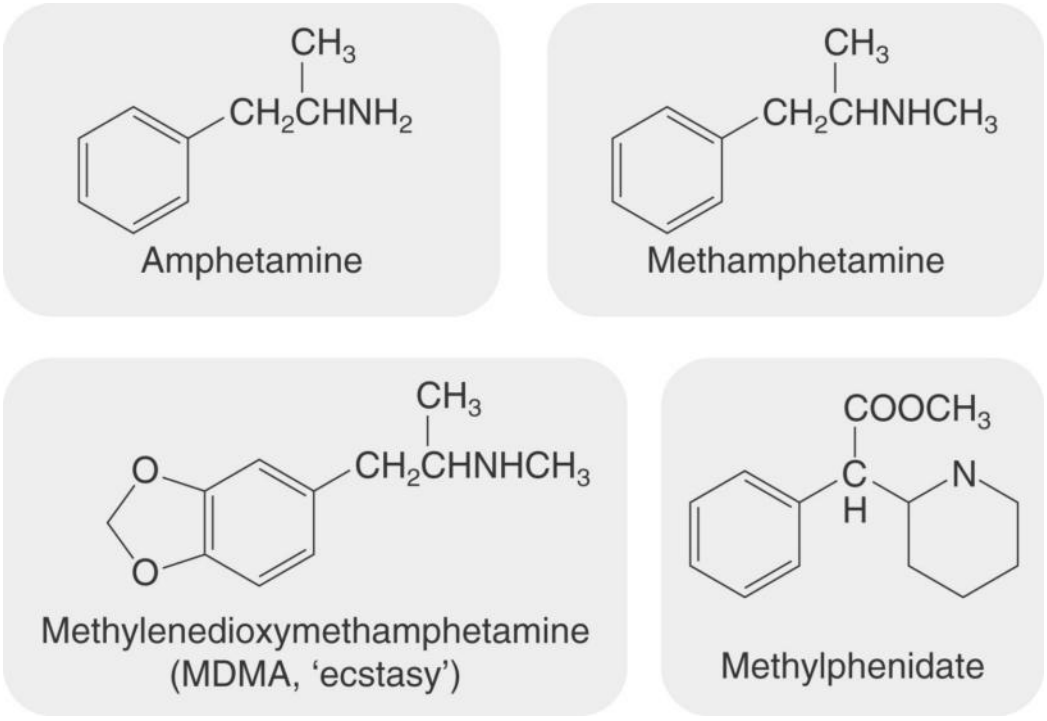

FIG. 49.1 Structures of amphetamine, MDMA and related drugs.

The main central effects of amphetamine-like drugs are:

- locomotor stimulation
- euphoria and excitement
- insomnia
- increased stamina
- anorexia
- long-term psychological effects: psychotic symptoms, anxiety, depression and cognitive impairment

In addition, amphetamines have peripheral sympathomimetic actions (see **Ch. 15**), producing a rise in blood pressure and inhibition of gastrointestinal motility.

In humans, amphetamines cause euphoria; with intravenous injection, this can be so intense as to be described as ‘orgasmic’. Rats quickly learn to press a lever in order to obtain a dose of amphetamine – an indication that the drug is acutely reinforcing. Humans become confident, hyperactive and talkative, and sex drive is said to be enhanced. Fatigue, both physical and mental, is reduced. Amphetamines (and similar drugs such as **dexfenfluramine** and **sibutramine**) cause marked anorexia, but with continued administration this effect wears off and food intake returns to normal. They are no longer used clinically for weight reduction (see **Ch. 32**).

Adverse effects of amphetamines include feelings of anxiety, irritability and restlessness. High doses may induce panic and paranoia.

The locomotor and rewarding effects of amphetamine are due mainly to release of DA rather than NA, since in animal models destruction of the DA-containing nucleus accumbens (see **Ch. 39**) or administration of D_2 receptor antagonists (see **Ch. 47**) inhibits these responses and the effects were absent in mice genetically engineered to lack DAT.

Chronic use, tolerance and dependence

If amphetamines are taken repeatedly over a few days, a state of ‘amphetamine psychosis’ can develop, resembling an acute schizophrenic attack (see **Ch. 47**), with hallucinations, paranoia and aggressive behaviour. At the same time, repetitive stereotyped behaviour may develop. The close similarity of this condition to

schizophrenia, and the effectiveness of antipsychotic drugs in controlling it, is consistent with a DA-mediated effect (see **Ch. 47**).

Tolerance develops rapidly to euphoric and anorexic effects of amphetamines, but more slowly to the other effects. Presumably tolerance is due to depletion of DA in nerve terminals or DA receptor desensitisation.

Addiction to amphetamines, a consequence of the insistent memory of euphoria, is very strong (see **Ch. 50**). When drug taking is stopped there is usually a period of deep sleep, and on awakening the subject feels lethargic, depressed, anxious, irritable (sometimes even suicidal) and hungry. These after-effects may be the result of depletion of the normal stores of DA and NA. It is estimated that about 10%–15% of users progress to full dependence, the usual pattern being that the dose is increased as tolerance develops, and then uncontrolled 'binges' occur in which the user takes the drug repeatedly over a period of a day or more, remaining continuously intoxicated. Large doses may be consumed in such binges, with a high risk of acute toxicity, and the demand for the drug displaces all other considerations.

Experimental animals, given unlimited access to amphetamine, take it in such large amounts that they die from the cardiovascular effects within a few days. Given limited amounts, they too develop a binge pattern of dependence.

Pharmacokinetic aspects

Amphetamines are readily absorbed from the gastrointestinal tract, but to increase the intensity of the hit the drugs can be snorted or injected. In crystal form, the free base of methamphetamine can be

ignited and smoked in a manner similar to crack cocaine. Amphetamines freely penetrate the blood–brain barrier; methamphetamine is reported to cross the blood–brain barrier fastest which may in part explain its more potent and addictive nature. They are more readily brain penetrant than other indirectly acting sympathomimetic amines such as **ephedrine** or **tyramine** (see **Ch. 15**), which probably explains why they produce more marked central effects than those drugs. Amphetamines are mainly excreted unchanged in the urine, and the rate of excretion is increased when the urine is made more acidic (see **Fig. 10.6**).

Amphetamines

- The main effects are:
  - increased motor activity
  - euphoria and excitement
  - insomnia
  - anorexia
  - with prolonged administration, stereotyped and psychotic behaviour
- Effects are due mainly to release of catecholamines, especially DA and NA.
- Stimulant effect lasts for a few hours and is followed by depression and anxiety.
- Tolerance to the stimulant effects develops rapidly, although peripheral sympathomimetic effects may persist.
- Amphetamines are highly addictive.

- Amphetamine psychosis, which closely resembles schizophrenia, can develop after prolonged use.
- Amphetamines may be useful in treating narcolepsy, and also (paradoxically) to control hyperkinetic children. They are no longer prescribed as appetite suppressants.
- Their main importance is as non-medicinally used drugs.

Methylphenidate

Methylphenidate (*Ritalin*) inhibits the NET and DAT transporters on the neuronal plasma membrane. Unlike the amphetamines, methylphenidate is not a substrate for these transporters and thus does not enter the nerve terminals to facilitate NA and DA release (**Heal et al., 2009**). It nevertheless produces a profound and sustained elevation of extracellular NA and DA.

Methylphenidate is orally active, being absorbed from the intestine, but it undergoes presystemic metabolism such that only ~20% enters the systemic circulation. Absorption is slow following oral administration – T_{max} ~2 h – which may limit the intensity of any euphoric response to the drug. It is metabolised by carboxylesterase and has a half-life of ~2–4 h. It is used therapeutically to treat attention deficit/hyperactivity disorder (ADHD) and may also have cognition-enhancing effects.

Modafinil

Modafinil is the primary metabolite of **adrafinil**, a drug that was introduced as a treatment for narcolepsy in the 1980s. Since 1994, modafinil has been available as a drug in its own right. It inhibits

DA reuptake by binding to DAT but with low potency. In the human brain, modafinil blocks DAT and increases extracellular DA levels in the caudate, putamen and nucleus accumbens. It also produces a number of other effects including α_1-adrenoceptor activation; enhanced release of 5-hydroxytryptamine (5-HT), glutamate and histamine; and inhibition of GABA release, as well as enhanced electrotonic coupling between neurons. The contribution of each action to the behavioural effects of modafinil remains to be clarified. Modafinil enhances some aspects of cognitive performance and has gained popularity as a 'lifestyle drug' (see **Ch. 59**) for this reason.

Modafinil is well absorbed from the gut, is metabolised in the liver and has a half-life of 10–14 h. While reported to 'brighten mood' there is little evidence that modafinil produces significant levels of euphoria when administered by mouth, but tablets can be crushed and snorted to obtain a quicker onset of effect. Modafinil is too insoluble for intravenous injection to be practical.

Clinical Use of Stimulants

Attention deficit/hyperactivity disorder (ADHD)

The main use of amphetamines and methylphenidate is in the treatment of ADHD, a common and increasingly diagnosed condition, estimated as occurring in up to 9% of children whose overactivity and limited attention span disrupt their education and social development. The efficacy of drug treatment (e.g. with methylphenidate) has been confirmed in controlled trials, but there is concern as to the possible long-term adverse effects since treatment is sometimes continued into adolescence and beyond.

Drug treatment should be part of a programme that includes psychological and behavioural interventions, and is started after the diagnosis has been confirmed by an expert.

Slow-release formulations of amphetamine and methylphenidate have been developed to deliver more stable concentrations of the drug, lower than that required to produce euphoria. D-amphetamine conjugated to lysine (**lisdexamphetamine**) is an inactive prodrug that, following oral administration, is cleaved enzymatically to release D-amphetamine, resulting in a slower onset of action.

Other drug treatments for ADHD include the NA reuptake inhibitors **atomoxetine** and **viloxazine** (see **Ch. 48**), and α_2-adrenoceptor agonists such as **clonidine** and **guanfacine**. The monoamine uptake inhibitor modafinil is not approved for paediatric use but may be effective in adult ADHD, as is **bupropion**. **Melatonin** (**Ch. 39**) improves sleep patterns in ADHD sufferers. The pharmacology of drugs used to treat ADHD is reviewed by **Heal et al. (2009)**.

Narcolepsy

This is a rare, disabling sleep disturbance in which the patient suddenly and unpredictably falls asleep at frequent intervals during the day, while suffering nocturnal insomnia. Amphetamine is helpful but not completely effective. Modafinil is also effective in reducing attacks. Narcolepsy is often accompanied by *cataplexy* (abrupt onset of paralysis of variable extent often triggered by emotion, sometimes with 'frozen' posture). Treatment is usually with **fluoxetine**, a selective 5-HT reuptake inhibitor, or **venlafaxine**, a 5-HT and norepinephrine reuptake inhibitor (see

Ch. 48). **Sodium oxybate**, the sodium salt of γ-hydroxybutyrate (also known as GHB; see Chs 38 and 59), is a CNS depressant that paradoxically is used to prevent cataplexy.

Clinical uses of CNS stimulants

- CNS stimulants have few legitimate therapeutic indications. Where appropriate they are usually initiated by experts.
- ADHD: **methylphenidate**, **atomoxetine** (see Ch. 48). **Dexamphetamine** is an alternative in children who do not respond.
- Narcolepsy: **modafinil** for the excessive sleepiness; **oxybate** to reduce cataplexy (which can be associated with narcolepsy).
- Apnoea of prematurity: *xanthine alkaloids* (under expert supervision in hospital) are effective; **caffeine** is preferred to **theophylline.**

Cocaine

Cocaine is found in the leaves of the South American shrub coca. These leaves are used for their stimulant properties by natives of South America, particularly those in mountainous areas, who use it to reduce fatigue during work at high altitude.

Considerable mystical significance was attached to the powers of cocaine to boost the flagging human spirit, and Freud tested it extensively on his patients and his family, publishing an influential monograph in 1884 advocating its use as a psychostimulant. [3]

Freud's ophthalmologist colleague, Köller, obtained supplies of the drug and discovered its local anaesthetic action (see **Ch. 44**), but the psychostimulant effects of cocaine have not proved to be clinically useful although they have led to its widespread non-medicinal use in Western countries. The mechanisms and treatment of cocaine addiction are discussed in **Chapter 50**.

Pharmacological effects

Cocaine binds to and inhibits the transporters NET, DAT and SERT (see Chs **15**, **16** and **39**), thereby producing a marked psychomotor stimulant effect, and enhancing the peripheral effects of sympathetic nerve activity.

In humans, cocaine produces euphoria, garrulousness, increased motor activity and a magnification of pleasure. Users feel alert, energetic and physically strong and believe they have enhanced mental capabilities. Its effects resemble those of amphetamines, although it has less tendency to produce stereotyped behaviour, delusions, hallucinations and paranoia. Evidence from transgenic knock-out mice indicates that the euphoric effects of cocaine involve inhibition of both DA and 5-HT reuptake. The peripheral sympathomimetic actions lead to tachycardia, vasoconstriction and an increase in blood pressure. Body temperature may increase, owing to the increased motor activity coupled with reduced heat loss. With excessive dosage, tremors and convulsions, followed by respiratory and vasomotor depression, may occur.

Experimental animals rapidly learn to press a lever to self-administer cocaine and will consume toxic amounts of the drug if access is not limited. In transgenic mice lacking the D_2 receptor, the

enhanced locomotor effects of cocaine are reduced, but surprisingly self-administration of cocaine is increased, in contrast to what is found with other self-administered drugs such as ethanol and morphine.

Chronic use, addiction and tolerance

Cocaine is highly addictive (see **Ch. 50**), but there is some debate about whether or not its continued use induces tolerance and physical dependence. Users may increase their intake of the drug but this may reflect a desire for an increased effect rather than the development of tolerance. In experimental animals, sensitisation (the opposite of tolerance) can be observed but the relevance of this to the situation in humans is unclear. Cocaine does not produce a clear-cut withdrawal syndrome but depression, dysphoria and fatigue may be experienced following the initial stimulant effect. Cocaine induces addiction where users crave the drug's euphoric and stimulatory effects. The cellular mechanisms underlying craving, and pharmacological approaches to reduce craving, are discussed in **Chapter 50**. The pattern of drug use, evolving from occasional use through escalating dosage to compulsive binges, is similar to that seen with amphetamines.

Pharmacokinetic aspects

Cocaine is readily absorbed by many routes. For many years illicit supplies have consisted of the hydrochloride salt, which could be taken by nasal inhalation or intravenously. The latter route produces an intense and immediate euphoria, whereas nasal inhalation produces a less dramatic sensation and also tends to cause atrophy and necrosis of the nasal mucosa and septum.

Cocaine use changed dramatically when the free-base form (‘crack’) became available as a street drug. When an aqueous solution of cocaine hydrochloride is heated with sodium bicarbonate, free-base cocaine, water, CO_2 and NaCl are produced. The free-base cocaine is insoluble in water, precipitates out and can then be rolled into ‘rocks’ of crack. Free-base cocaine vaporises at around 90°C, much lower than the melting point of cocaine hydrochloride (190°C), which burns rather than vaporises. Thus crack can be smoked, with the uncharged free base being rapidly absorbed across the large surface area of the alveolae, giving rise to a greater CNS effect than that obtained by snorting cocaine. Indeed, the effect is nearly as rapid as that of intravenous administration. The social and economic consequences of this small change in formulation have been far-reaching.

The duration of its stimulant effect, about 30 min, is much shorter than that of amphetamine. It is rapidly metabolised in the liver. Heroin users may inject cocaine and heroin together intravenously (known as *speedballing*) to obtain the rapid effect of cocaine before the prolonged effect of heroin kicks in.

A cocaine metabolite is deposited in hair, and analysis of its content along the hair shaft allows the pattern of cocaine consumption to be monitored, a technique that has revealed a much higher incidence of cocaine use than was voluntarily reported. Cocaine exposure in utero can be estimated from analysis of the hair of neonates.

Cocaine is still occasionally used topically as a local anaesthetic, mainly in ophthalmology and minor nose and throat surgery, where

its local vasoconstrictor action is an advantage, but has no other clinical uses.

Adverse effects

Toxic effects occur commonly in cocaine users. The main acute dangers are serious cardiovascular events (cardiac dysrhythmias, aortic dissection, and myocardial or cerebral infarction or haemorrhage). Progressive myocardial damage can lead to heart failure, even in the absence of a history of acute cardiac effects.

Cocaine can severely impair brain development in utero. The brain size is significantly reduced in babies exposed to cocaine in pregnancy, and neurological and limb malformations are increased. The incidence of ischaemic and haemorrhagic brain lesions, and of sudden infant death, is also higher in cocaine-exposed babies. Interpretation of the data is difficult because many cocaine users also take other illicit drugs that may affect fetal development, but the probability is that cocaine is highly detrimental.

Cocaine addiction has potentially severe effects on quality of life (see **Ch. 50**).

Cocaine

- **Cocaine** acts by inhibiting catecholamine uptake (especially DA) by nerve terminals.
- The behavioural effects of cocaine are very similar to those of amphetamines, although psychotomimetic effects are rarer. Duration of action is shorter.

- **Cocaine** used in pregnancy impairs fetal development and may produce fetal malformations.
- **Cocaine** regular use can lead to addiction.

MDMA

MDMA (*ecstasy* or *molly*) and related drugs are widely used as 'party drugs' because of the feelings of empathy and euphoria, and the loss of inhibitions, heightened sensations and energy surge, that they produce. They are sometimes referred to as 'empathogens' or 'enactogens'. They also have mild hallucinogenic effects. Common examples are listed in **Table 49.1**. In conjunction with psychotherapy, MDMA is in phase III clinical trials for the treatment of post-traumatic stress disorder (PTSD).

Pharmacological effects

Although an amphetamine derivative (see **Fig. 49.1**), MDMA affects monoamine function in a different manner from the amphetamines. It inhibits monoamine transporters, principally the 5-HT transporter, and also releases 5-HT, the net effect being a large increase in free 5-HT in certain brain regions, followed by depletion. Similar but smaller changes occur in relation to DA and NA release. Simplistically, the effects on 5-HT function determine the psychotomimetic effects, while DA and NA changes may account for the initial euphoria and later rebound dysphoria. MDMA does not induce physical dependence or addiction but its use carries several serious risks. Unintentional consumption of high doses may occur if pills have a higher than expected MDMA content or when MDMA is

taken in powdered form. Also, illicit MDMA tablets or powders may be contaminated with or entirely substituted with ***para*-methoxyamphetamine** (PMA), a more dangerous psychoactive agent.

Common adverse effects of MDMA ingestion are:

- Feeling nauseous is common but vomiting is much less likely to occur.
- Acute hyperthermia (**Fig. 49.2**), resulting in damage to skeletal muscle and consequent renal failure. It is still unclear how hyperthermia is produced in humans. It may be mediated centrally through release of 5-HT, DA and NA acting on various receptors for these monoamines (**Docherty and Green, 2010**). It could also reflect an action of MDMA on mitochondrial function. It is exacerbated by energetic dancing and high ambient temperature and certain individuals may be particularly susceptible to this danger.
- Excess water intake and water retention. Users may consume large amounts of water as a result of increased physical activity and feeling hot. In addition, MDMA causes inappropriate secretion of antidiuretic hormone (see **Ch. 33**). This can lead to overhydration and hyponatraemia ('water intoxication'). Symptoms include dizziness and disorientation, leading to collapse into coma.

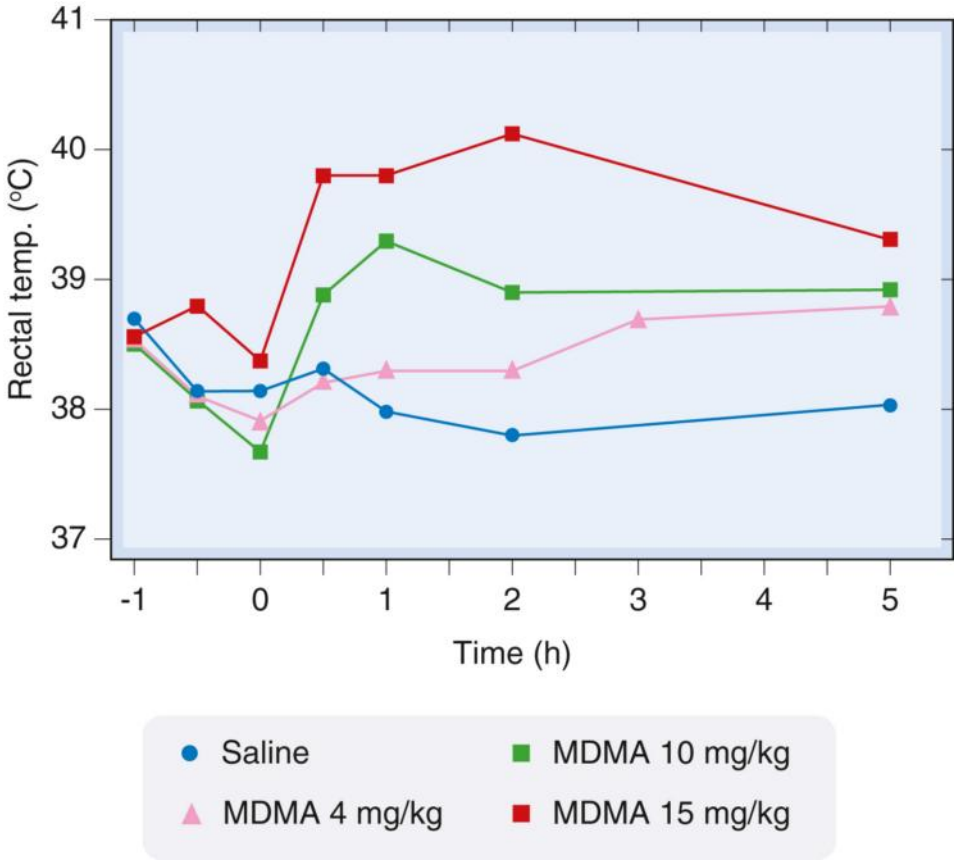

FIG. 49.2 A single injection of 3,4-methylenedioxymethamphetamine (MDMA) causes a dose-related increase in body temperature in rats.Drug administered at time zero. Reproduced with permission from Green et al., 2004. Eur. J. Pharmacol. 500, 3–13.

- Heart failure in individuals with an undiagnosed heart condition.

The after-effects of MDMA persist for a few days and comprise symptoms of depression, anxiety, irritability and increased aggression – the ‘mid-week blues’. There is also evidence of long-

term deleterious effects on memory and cognitive function in heavy MDMA users. In animal studies, MDMA can cause degeneration of 5-HT and DA neurons, but whether this occurs in humans is uncertain (see **Green et al., 2012**).

Potential therapeutic use

PTSD is a common and debilitating condition. Current treatments include selective serotonin reuptake inhibitor (SSRI) drugs (see **Ch. 48**) and psychotherapies such as cognitive behavioural therapy. The effectiveness of these, however, is limited and many sufferers fail to respond or continue to have significant symptoms. Recent clinical trials have demonstrated marked improvements in sufferers receiving MDMA along with psychotherapy (see **Ch. 45** and **Mitchell et al., 2021**). The potential for MDMA in the treatment of alcohol use disorder is currently being evaluated.

MDMA (ecstasy)

- **MDMA** is an amphetamine analogue that has powerful psychostimulant as well as mild psychotomimetic effects.
- **MDMA** inhibits monoamine transporters, principally the 5-HT transporter, and releases 5-HT.
- **MDMA** can cause an acute hyperthermic reaction as well as overhydration and hyponatraemia, sometimes fatal.
- **MDMA** does not cause physical dependence.
- **MDMA** has shown benefit in the treatment of PTSD.

Cathinones

Cathinone and **cathine** are the active ingredients in the khat shrub. Chewing the leaves is popular in parts of Africa, such as Ethiopia and Somalia, and its use is spreading through immigrant populations in Western countries. They are chemically related to amphetamines but with a ketone functional group rather than a methyl group on the side chain.

Synthetic cathinone derivatives have become popular street drugs as they produce feelings of elevated mood and improved mental function. **Mephedrone** elevates extracellular levels of both DA and 5-HT, possibly by inhibiting reuptake and enhancing release.

Methylxanthines

Various beverages, particularly tea, coffee and cocoa, contain methylxanthines, to which they owe their mild central stimulant effects. The main compounds responsible are **caffeine** and **theophylline**. The nuts of the cola plant also contain caffeine, which is present in cola-flavoured soft drinks. However, the most important sources, by far, are coffee and tea, which account for more than 90% of caffeine consumption. Further information on the pharmacology and toxicology of caffeine is presented by **Fredholm et al. (1999)**.

Pharmacological effects

Methylxanthines have the following major pharmacological actions:

- CNS stimulation
- mild diuresis, not clinically significant
- stimulation of cardiac muscle (see **Ch. 20**)

- relaxation of smooth muscle, especially bronchial muscle (see **Ch. 28**)

The latter two effects resemble those of β-adrenoceptor stimulation (see Chs **15**, **20** and **28**). This is thought to be because methylxanthines (especially **theophylline**) inhibit phosphodiesterase, which is responsible for the intracellular metabolism of cAMP (see **Ch. 3**). They thus increase intracellular cAMP and produce effects that mimic those of mediators that stimulate adenylyl cyclase. Methylxanthines also antagonise many of the effects of adenosine, acting on both A_1 and A_2 receptors (see **Ch. 16**). Transgenic mice lacking functional A_2 receptors are abnormally active and aggressive, and fail to show increased motor activity in response to caffeine, suggesting that antagonism at A_2 receptors accounts for part, at least, of its CNS stimulant action. Caffeine also sensitises ryanodine receptors (see **Ch. 4**) but this effect occurs at higher concentrations (>10 mmol/L) than those achieved by recreational intake of caffeine. The concentration of caffeine reached in plasma and brain after two or three cups of strong coffee – about 100 μmol/L – is sufficient to produce appreciable adenosine receptor block and a small degree of phosphodiesterase inhibition. Adenosine receptor block probably causes the diuretic effect by reducing proximal tubular reabsorption of sodium.

Caffeine and theophylline have very similar stimulant effects on the CNS. Human subjects experience a reduction of fatigue, with improved concentration and a clearer flow of thought. This is confirmed by objective studies, which have shown that caffeine reduces reaction time and produces an increase in the speed at

which simple calculations can be performed (although without much improvement in accuracy). Performance at motor tasks, such as typing and simulated driving, is also improved, particularly in fatigued subjects. Mental tasks, such as syllable learning, association tests and so on, are also facilitated by moderate doses (up to about 200 mg of caffeine, or about two cups of coffee) but impaired by larger doses. Insomnia is common. By comparison with amphetamines, methylxanthines produce less locomotor stimulation and do not induce euphoria, stereotyped behaviour patterns or a psychotic state, but their effects on fatigue and mental function are similar.

Tolerance and habituation develop to a small extent, but much less than with amphetamines; withdrawal effects are modest but can be troublesome. [4] Caffeine is not classified as a dependence-producing drug.

Clinical use and unwanted effects

There are few clinical uses for caffeine. It is included with aspirin in some preparations for treating headaches and other aches and pains, and with ergotamine in some antimigraine preparations, the objective being to produce a mildly agreeable sense of alertness. Methylxanthines are effective respiratory stimulants in the treatment of apnoea of prematurity (a developmental disorder caused by immaturity of central respiratory control), for which indication caffeine is preferred to theophylline because of its long half-life and safety. Theophylline (formulated as **aminophylline**) is used mainly as a bronchodilator in treating severe asthmatic attacks (see **Ch. 28**). In vitro tests show that it has mutagenic

activity, and large doses are teratogenic in animals. However, epidemiological studies have shown no evidence of carcinogenic or teratogenic effects of tea or coffee drinking in humans. Some people have heightened sensitivity to caffeine and in these individuals it can trigger cardiac tachycardia and arrhythmias.

Methylxanthines

- **Caffeine** and **theophylline** produce psychomotor stimulant effects.
- Average **caffeine** consumption from beverages is about 200 mg/day.
- Main psychological effects are reduced fatigue and improved mental performance, without euphoria. Even large doses do not cause stereotyped behaviour or psychotomimetic effects.
- Methylxanthines act mainly by antagonism at A_2 purine receptors, and partly by inhibiting phosphodiesterase.
- Peripheral actions are exerted mainly on heart, smooth muscle and kidney.
- **Theophylline** is used clinically as a bronchodilator; **caffeine** is used as a respiratory stimulant for apnoea of prematurity and as an additive in many beverages and over-the-counter analgesics.

Nicotine

Nicotine [5] is the psychoactive ingredient in tobacco.

Tobacco growing, chewing and smoking were indigenous throughout the American subcontinent and Australia at the time that European explorers first visited these places. Smoking spread through Europe during the 16th century, coming to England mainly as a result of its enthusiastic espousal by Walter Raleigh at the court of Elizabeth I. James I strongly disapproved of both Raleigh and tobacco, and in the early 17th century initiated the first antismoking campaign, with the support of the Royal College of Physicians. Parliament responded by imposing a substantial duty on tobacco, thereby giving the state an economic interest in the continuation of smoking at the same time that its official expert advisers were issuing emphatic warnings about its dangers.

Until the latter half of the 19th century, tobacco was smoked in pipes, and primarily by men. Cigarette manufacture began at the end of the 19th century. Filter cigarettes (which give a lower delivery of carcinogenic tars and nicotine than standard cigarettes) and 'low-tar' cigarettes (which are also low in nicotine) became available in the 1950s and were thought to be less harmful. [6] More recently, the use of electronic cigarettes (e-cigarettes) to deliver nicotine, without the carcinogenic tars of cigarette smoke, has become popular. Laws banning smoking in public places and the increased use of e-cigarettes have led to a reduction in cigarette consumption in some countries. The World Health Organization (WHO) estimate, however, that over 80% of the world's 1.3 billion tobacco users live in low- and middle-income countries where there are fewer controls.

Pharmacological Effects of Nicotine

Effects on the CNS

At the neuronal level, nicotine acts on nicotinic acetylcholine receptors (nAChRs) (see **Ch. 39**), which are widely expressed in the brain, particularly in the cortex and hippocampus, and are believed to play a role in cognitive function, as well as in the ventral tegmental area (VTA), from which dopaminergic neurons project to the nucleus accumbens (the reward pathway, **Fig. 39.3**). nAChRs are ligand-gated cation channels located both pre- and postsynaptically, causing, respectively, enhanced transmitter release and neuronal excitation (see **Wonnacott et al., 2005**). Nicotine increases the firing rate and phasic activity of VTA dopaminergic neurons (see **Fig. 49.3**). Of the various subtypes of nAChR (see **Table 39.2**), the α4β2, α6β2 and α7 subtypes have received most attention, but other subtypes may also be involved in the rewarding effects of nicotine. As well as activating the receptors, nicotine also causes desensitisation, so the effects of a dose of nicotine are diminished after sustained exposure to the drug. Chronic nicotine administration leads to a substantial increase in the number of nAChRs (an effect opposite to that produced by sustained administration of most receptor agonists), which may represent an adaptive response to prolonged receptor desensitisation. It is likely that the overall effect of nicotine reflects a balance between activation of nAChRs, causing neuronal excitation, and desensitisation, causing synaptic block.

The higher-level functioning of the brain, as reflected in the subjective sense of alertness or by the electroencephalography (EEG) pattern, can be affected in either direction by nicotine, according to dose and circumstances. Nicotine wakes people up

when they are drowsy and calms them down when they are tense, and EEG recordings broadly bear this out. It also seems that small doses of nicotine tend to cause arousal, whereas large doses do the reverse. Tests of motor and sensory performance (e.g. reaction time measurements or vigilance tests) in humans generally show improvement with nicotine, and nicotine enhances learning in rats. Nicotine and other nicotinic agonists such as **epibatidine** has analgesic activity in animal models, but, taken in the form of tobacco smoke or administered by other delivery systems such as patch or nasal spray, has only a weak analgesic effect in humans.

(B) Action potential firing is phasic after nicotine injection. Adapted from De Biasi, M., Dani, J.A., 2011. Reward, addiction, withdrawal to nicotine. Annu. Rev. Neurosci. 34, 105–130.

Peripheral Effects

The peripheral effects of small doses of nicotine result from stimulation of autonomic ganglia (see **Ch. 14**) and of peripheral sensory receptors, mainly in the heart and lungs. Stimulation of these receptors produces tachycardia, increased cardiac output and arterial pressure, sweating, and a reduction of gastrointestinal motility. When people take nicotine for the first time, they usually experience nausea and sometimes vomit, probably because of stimulation of sensory receptors in the stomach. All these effects decline with repeated dosage, although the central effects remain. Secretion of adrenaline and NA from the adrenal medulla contributes to the cardiovascular effects, and release of antidiuretic hormone from the posterior pituitary causes a decrease in urine flow. [7] The plasma concentration of free fatty acids is increased, probably owing to sympathetic stimulation and adrenaline secretion.

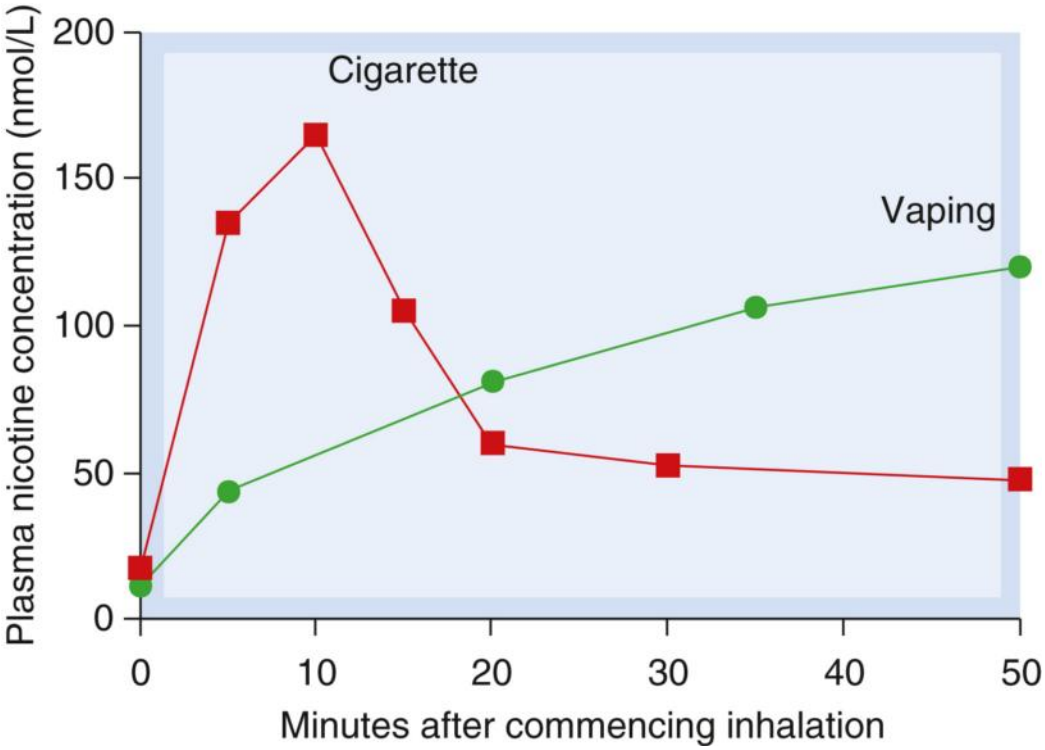

FIG. 49.4 Nicotine concentration in plasma during smoking or vaping.The subjects were habitual users who inhaled from a traditional cigarette or an e-cigarette according to their usual habit. Data from Bowman, W.C., Rand, M., 1980. **Chapter 4**. In: Textbook of Pharmacology. Blackwell, Oxford; and Farsalinos et al., 2015. Sci. Rep. 5, 11269.

Smokers weigh, on average, about 4 kg less than non-smokers, mainly because of reduced food intake; giving up smoking usually causes weight gain associated with increased food intake.

Pharmacokinetic Aspects

Nicotine is rapidly absorbed from the lungs but less readily from the mouth and nasopharynx. [8] Therefore inhalation is required to give

appreciable absorption of nicotine, each puff delivering a distinct bolus of drug to the CNS. The amount of nicotine absorbed varies greatly with the habits of the user and the way in which nicotine is self-administered.

An average cigarette, smoked over 10 min, causes the plasma nicotine concentration to rise to 15–30 ng/mL (100–200 nmol/L), falling to about half within 10 min and then more slowly over the next 1–2 h (**Fig. 49.4**). The rapid decline results mainly from redistribution between the blood and other tissues; the slower decline is due to hepatic metabolism, mainly by oxidation to an inactive ketone metabolite, *cotinine*. This has a long plasma half-life, and measurement of urinary cotinine provides a useful indication of nicotine consumption.

E-cigarettes work by heating a liquid (usually propylene glycol and glycerine) to generate a vapour containing nicotine which is then inhaled (a process commonly referred to as vaping). Vaping avoids inhalation of the toxic chemicals present in tobacco smoke. Early e-cigarette devices were found to deliver only minimal amounts of nicotine to the user. However, the technology has advanced rapidly and new-generation devices have been developed that deliver more nicotine more rapidly, but as yet, not quite as fast as a traditional cigarette (see **Fig. 49.4**).

Other routes of nicotine administration that provide a more sustained delivery are used by smokers trying to quit. A transdermal nicotine patch applied for 24 h causes the plasma concentration of nicotine to rise to 75–150 nmol/L over 6 h and to remain fairly constant for about 20 h. Administration by nasal spray or chewing

gum results in a time course intermediate between that of smoking and the nicotine patch.

Addiction and Tolerance

Nicotine is a highly addictive drug. Regular use also results in the development of tolerance. For reviews on nicotine and addiction see **De Biasi and Dani (2011)** and **Leslie et al. (2013)**.

The effects of nicotine associated with peripheral ganglionic stimulation show rapid tolerance, perhaps as a result of desensitisation of nAChRs. With large doses of nicotine, this desensitisation produces a block of ganglionic transmission (see **Ch. 14**). Tolerance to the central effects of nicotine (e.g. in the arousal response) is much less than in the periphery. The increase in the number of nAChRs in the brain produced by chronic nicotine administration in animals also occurs in heavy smokers. Because the cellular effects of nicotine are diminished, it is possible that the additional binding sites represent desensitised rather than functional receptors.

The addictiveness of nicotine is due to the effects of the drug combined with the ritual of taking it (see **Le Foll and Goldberg, 2005**). Rats choose to drink dilute nicotine solution in preference to water if given a choice, and in a situation in which lever pressing causes an injection of nicotine to be delivered – admittedly at high doses – they quickly learn to self-administer it. Similarly, monkeys who have been trained to smoke, by providing a reward in response to smoking behaviour, will continue to do so spontaneously (i.e. unrewarded) if the smoking medium contains nicotine, but not if nicotine-free tobacco is offered instead. Humans, however, are

unlikely to become addicted to nicotine delivered from patches, suggesting that other factors are also involved, such as the controlled pulsatile delivery associated with smoking and vaping.

Like other addictive drugs, nicotine causes excitation of the mesolimbic reward pathway and increased DA release in the nucleus accumbens. Transgenic mice lacking the β2 subunit of the nAChR lose the rewarding effect of nicotine and its DA-releasing effect, confirming the importance of the β2-containing nAChR subtypes and mesolimbic DA release in the response to nicotine. In contrast to normal mice, the mutant mice could not be induced to self-administer nicotine, even though they did so with cocaine.

In contrast to euphoria, induction of physical dependence involves nicotinic receptors containing α5 and β4 subunits in the medial habenula–interpeduncular nucleus pathway. A physical withdrawal syndrome occurs in humans on cessation of smoking. Its main features are increased irritability, impaired performance of psychomotor tasks, aggressiveness and sleep disturbance. The withdrawal syndrome is much less severe than that produced by opioids, and can be alleviated by replacement nicotine. It lasts for 2–3 weeks, although the craving for cigarettes persists for much longer than this; relapses during attempts to quit occur most commonly at a time when the physical withdrawal syndrome has long since subsided.

Pharmacology of nicotine

- At the cellular level, **nicotine** acts on nicotinic acetylcholine receptors (nAChRs) to enhance neurotransmitter release and

increase neuronal excitation. Its central effects are blocked by receptor antagonists such as **mecamylamine.**

- At the behavioural level, nicotine produces a mixture of inhibitory and excitatory effects.
- **Nicotine** shows reinforcing properties, associated with increased activity in the mesolimbic dopaminergic pathway, and self-administration can be elicited in animal studies.
- Electroencephalography changes show an arousal response, and subjects report increased alertness accompanied by a reduction of anxiety and tension.
- Learning, particularly under stress, is facilitated by **nicotine.**
- The peripheral effects of **nicotine** are due mainly to ganglionic stimulation: tachycardia, increased blood pressure and reduced gastrointestinal motility. Tolerance develops rapidly to these effects.
- **Nicotine** is metabolised to cotinine, mainly in the liver, within 1–2 h.
- **Nicotine** gives rise to tolerance, physical dependence and addiction. Attempts at long-term cessation succeed in only about 20% of cases.
- **Nicotine** replacement therapy (e-cigarettes, chewing gum or skin patch preparations) improves the chances of giving up smoking when combined with active counselling.

Harmful Effects of Tobacco Smoking

The life expectancy of smokers is shorter than that of non-smokers. Smoking causes almost 90% of deaths from lung cancer, about 80% of deaths from bronchitis and emphysema and 17% of deaths from heart disease. The increased use of e-cigarettes should reduce the number of such deaths. About one-third of all cancer deaths can be attributed to smoking. Smoking is, by a large margin, the biggest preventable cause of death, responsible for about 1 in 10 adult deaths worldwide. Despite the introduction of e-cigarettes, deaths from smoking worldwide are continuing to rise. It is estimated that in 2021 smoking was responsible for some 7 million deaths (and 1.2 million additional deaths of non-smokers from involuntary secondary inhalation).

The main health risks are as follows:

- *Cancer, particularly of the lung and upper respiratory tract but also of the oesophagus, pancreas and bladder*. Smoking 20 cigarettes per day is estimated to increase the risk of lung cancer about 10-fold. Tar, rather than nicotine, is responsible for the cancer risk. Genetic variants of nicotinic-receptor subunits have been associated with lung cancer although the mechanisms behind this association are unclear (see **Hung et al., 2008**).
- *Coronary heart disease and other forms of peripheral vascular disease*. The mortality among men aged 55–64 from coronary thrombosis is about 60% greater in men who smoke 20 cigarettes per day than in non-smokers. Although the increase in risk is less than it is for lung cancer, the actual number of excess deaths associated with smoking is larger, because coronary heart disease is so common. Other

kinds of vascular disease (e.g. stroke, intermittent claudication and diabetic gangrene) are also strongly smoking related. E-cigarettes and nicotine preparations, used to help smokers give up cigarettes, are not thought to carry a serious risk. Carbon monoxide (see later) could be a factor. However, there is no clear increase in ischaemic heart disease in pipe and cigar smokers, even though similar blood nicotine and carboxyhaemoglobin concentrations are reached, suggesting that other factors may be responsible for the risk associated with cigarettes.

- *Chronic obstructive pulmonary disease* (COPD; see **Ch. 28**) is a major global health problem. Cigarette smoking is the main cause. Stopping smoking slows the progression of the disease. Bronchitis, inflammation of the mucous membranes of the bronchi, is much more common in smokers than in non-smokers. These effects are probably due to tar and other irritants rather than nicotine.
- *Harmful effects in pregnancy*. Smoking, particularly during the latter half of pregnancy, significantly reduces birth weight (by about 8% in women who smoke 25 or more cigarettes per day during pregnancy) and increases perinatal mortality (by an estimated 28% in babies born to mothers who smoke in the last half of pregnancy). There is evidence that children born to smoking mothers remain behind, in both physical and mental development, for at least 7 years. By 11 years of age, the difference is no longer significant. These effects of smoking, although measurable, are much smaller than the effects of other factors, such as social class

and birth order. Various other complications of pregnancy are also more common in women who smoke, including spontaneous abortion (increased 30%–70% by smoking), premature delivery (increased about 40%) and placenta praevia (where the placenta obstructs normal vaginal delivery, increased 25%–90%). Nicotine is excreted in breast milk in sufficient amounts to cause tachycardia in the infant.

The agents probably responsible for the harmful effects are as follows:

- Tar and irritants, such as nitrogen dioxide and formaldehyde. Cigarette smoke tar contains many known carcinogenic hydrocarbons, as well as tumour promoters, which together account for the high cancer risk. It is likely that the various irritant substances are also responsible for the increase in bronchitis and emphysema.
- Nicotine probably accounts for retarded fetal development because of its vasoconstrictor properties.
- Carbon monoxide. Cigarette smoke contains about 3% carbon monoxide. Carbon monoxide has a high affinity for haemoglobin, and the average carboxyhaemoglobin content in the blood of cigarette smokers is about 2.5% (compared with 0.4% for non-smoking urban dwellers). In very heavy smokers, up to 15% of haemoglobin may be carboxylated, a level that affects fetal development in rats. Fetal haemoglobin has a higher affinity for carbon monoxide than adult haemoglobin, and the proportion of

carboxyhaemoglobin is higher in fetal than in maternal blood.

- Increased oxidative stress may contribute to atherogenesis (see **Ch. 22**) and COPD (see **Ch. 28**).

Other Effects of Tobacco Smoking

Parkinson's disease is approximately twice as common in non-smokers as in smokers. It is possible that this reflects a protective effect of nicotine. Ulcerative colitis appears to be a disease of non-smokers. Former smokers are at high risk for developing ulcerative colitis, while current smokers have the least risk. This tendency indicates that smoking cigarettes may prevent the onset of ulcerative colitis. In contrast, smoking tends to worsen the effects of Crohn's disease (another type of inflammatory bowel disease). Earlier reports that Alzheimer's disease is less common in smokers have not been confirmed; indeed there is evidence that smoking may increase the occurrence of Alzheimer's disease in some genetic groups.

Effects of tobacco smoking

- Smoking accounts for more than 10% of deaths worldwide, mainly due to:
  - cancer, especially lung cancer, of which about 90% of cases are smoking related; carcinogenic tars are responsible;
  - chronic bronchitis; tars are mainly responsible.

- Smoking in pregnancy reduces birth weight and retards childhood development. It also increases abortion rate and perinatal mortality. **Nicotine** and possibly carbon monoxide are responsible.
- Use of e-cigarettes (vaping) avoids the inhalation of tar and carbon monoxide that occurs with smoking.
- The incidence of Parkinson's disease is lower in smokers than in non-smokers.

Cognition-Enhancing Drugs

'Cognition' embraces many aspects of mental function, including memory, reasoning and problem-solving skills, situational judgements, decision-making and executive function. A variety of different test batteries have been designed to measure these functions in humans (e.g. Cambridge Neuropsychological Test Automated Battery [CANTAB]) and test the effects of drugs. Many clinical disorders, such as dementia (see **Ch. 40**), schizophrenia (see **Ch. 47**), depression (see **Ch. 48**) and drug addiction (see **Ch. 50**), impair these functions, and the hope is to develop cognition-enhancing drugs to restore them. Progress has been limited, although much hyped, as much with the questionable aim of 'improving' mental function in healthy humans, as in alleviating deficits in the sick.

Drugs currently available have been shown to:

- alter memory processing (i.e. enhance memory);

- reduce fatigue (stimulants), thus permitting the user to function for longer (i.e. perform complex tasks, study for examinations, overcome jet lag);
- increase motivation, energy, confidence and concentration.They are also referred to as ‘smart drugs’ or ‘nootropics’.

Drugs for which there is some evidence of an ability to enhance cognitive performance are **caffeine, amphetamines, methylphenidate, modafinil, arecoline, donepezil**, **vortioxetine** and **piracetam** but the clinical efficacy of these drugs is limited, and development of more effective cognition enhancers could have significant benefits for many patient groups.

Cognition-enhancing drugs are also used by healthy individuals aiming to enhance their performance, e.g. in revising for and taking examinations (**D’Angelo et al., 2017**) or in demanding professional roles. The use of drugs by healthy individuals to enhance academic performance does raise ethical issues in relation to fairness, academic pressure and fears of coercion by ‘pushy’ parents. There are also safety issues. Although many of the drugs taken are available as medicines (i.e. have gone through standard drug safety testing) there is still a lack of information on their acute and long-term effects in children and adolescents, whose brains are still in development. In healthy individuals, cognitive performance can be enhanced by improved sleep and mood as well as reduced anxiety. It would seem more appropriate to achieve this by lifestyle changes and behavioural therapy rather than resorting to the use of drugs. [9]

Effectiveness

While the effectiveness of cognition enhancers on healthy individuals is often trumpeted by individuals who use them and in the media, their actual effectiveness as assessed in scientific studies is somewhat inconclusive and ambiguous. [10] Also, drugs may affect different forms of memory differently (**D'Angelo et al., 2017**). It is important to distinguish between drugs that only improve a subject's abilities when they are fatigued and those that might improve cognitive ability in non-fatigued individuals.

Many studies have shown that amphetamines improve mental performance in fatigued subjects. Mental performance is improved for simple tedious tasks much more than for difficult tasks. Amphetamines are thought to increase ability to focus and maintain self-control. In addition to reducing fatigue, methylphenidate has a positive effect on long-term memory consolidation. Amphetamines and modafinil have been used to improve the performance of soldiers, military pilots and others who need to remain alert under extremely fatiguing conditions. Modafinil appears to enhance cognition in non-fatigued individuals (**Battleday and Brem, 2015**) while also improving wakefulness, memory and executive functions in sleep-deprived individuals. Evidence for efficacy in patients with chronic cognitive impairment is controversial.

Non-Stimulant Drugs

The novel antidepressant **vortioxetine** (see **Ch. 48**) improves cognitive dysfunction in patients suffering from major depression.

Piracetam, which is a positive allosteric modulator at AMPA receptors (see **Ch. 38**), enhances memory in non-fatigued adults,

and there is limited clinical evidence of reading improvement in dyslexic children. **Phenylpiracetam** is said to be more potent and may also have nicotinic antagonist properties. As with many CNS disorders, the possible importance of glutamate and its receptors was widely speculated on, but new, effective drugs acting on the glutamatergic system are still awaited (see, for example, **Collingridge et al., 2013**; **Harms et al., 2013**).

Psychedelic Drugs

Psychedelic drugs (also sometimes referred to as *hallucinogenic* or *psychotomimetic* drugs) affect thought, perception and mood, without causing marked psychomotor stimulation or depression (see **Nichols, 2004**). Thoughts and perceptions tend to become distorted and dream-like, rather than being merely sharpened or dulled, and the change in mood is likewise more complex than a simple shift in the direction of euphoria or depression. Importantly, psychedelic drugs do not cause dependence. Common psychedelic drugs are listed in **Table 49.2**.

Lysergic Acid Diethylamide, Psilocybin and Mescaline

Lysergic acid diethylamide (LSD) is an exceptionally potent psychotomimetic drug capable of producing strong effects in humans in doses less than 1 μg/kg. It is a chemical derivative of lysergic acid, which occurs in the cereal fungus ergot (see **Ch. 16**).

LSD was first synthesised by Hoffman in 1943. Hoffman deliberately swallowed about 250 μg of LSD (the threshold dose is now known to be around 20 μg) and wrote 30 years later of the

experience: ‘the faces of those around me appeared as grotesque coloured masks … marked motoric unrest, alternating with paralysis … heavy feeling in the head, limbs and entire body, as if they were filled with lead … clear recognition of my condition, in which state I sometimes observed, in the manner of an independent observer, that I shouted half insanely.’ These effects lasted for a few hours, after which Hoffman fell asleep, ‘and awoke next morning feeling perfectly well.’ Apart from these dramatic psychological effects, LSD has few physiological effects in humans at doses that cause hallucinations.

Mescaline, which is derived from the Mexican peyote cactus and has been known as a hallucinogenic agent for many centuries, was made famous by Aldous Huxley in *The Doors of Perception*.

Psilocybin is obtained from fungi (‘magic mushrooms’). It is rapidly dephosphorylated to psilocin, the active moiety. Its effects are similar to those experienced with LSD.

The potential of LSD and psilocybin as treatments for depression and some forms of anxiety is discussed in **Chapters 45** and **48**.

Pharmacological effects

The main effects of these drugs are on mental function, most notably an alteration of perception in such a way that sights and sounds appear distorted and fantastic. Hallucinations – visual, auditory, tactile or olfactory – also occur, and sensory modalities may become confused, so that sounds are perceived as visions. Thought processes tend to become illogical and disconnected, but subjects retain insight into the fact that their disturbance is drug induced, and generally find the experience exhilarating.

Occasionally, especially if the user is already anxious, LSD produces a syndrome that is extremely disturbing (the 'bad trip'), in which the hallucinatory experience takes on a menacing quality and may be accompanied by paranoid delusions. 'Flashbacks' of the hallucinatory experience may occur subsequent to drug use.

LSD acts on various 5-HT receptor subtypes (see Chs **16** and **39**); its psychotomimetic effects are thought to be mediated mainly by its 5-HT_{2A} receptor agonist actions (see **Nichols, 2004**). It inhibits the firing of 5-HT-containing neurons in the raphe nuclei (see **Ch. 39**), apparently by acting as an agonist on the inhibitory somatodendritic 5-HT_{1A} receptors on these cells. The significance of this response to its psychotomimetic effects is unclear. Psilocybin is dephosphorylated to psilocin, which is a weak agonist at several 5-HT receptors including the 5-HT_{2A} receptor. The mechanism of action of mescaline is less well defined. It has lower affinity and efficacy at 5-HT_{2A} receptors than LSD and psylocybin. The binding affinity and agonist efficacies of LSD, psilocybin, mescaline and other psychedelic drugs at monoamine receptors and transporters are described in detail by **Rickli et al. (2016)**.

Table 49.2

Major psychedelic drugs

Drugs	Mode(s) of action	Notes
LSD	Interacts with 5-HT and DA receptors Psychedelic effects are thought to be mainly through 5-HT_{2A} receptor activation	Potential as an antidepressant is currently being evaluated (see **Ch. 48**)
Mescaline	Lower potency partial agonist at 5-HT_{2A} and other 5-HT receptors Chemically related to amphetamine	No current clinical use Found in Peyote cactus plant
Psilocybin	Rapidly metabolised to psilocin, a partial agonist at 5-HT receptors including 5-HT_{1A} and 5-HT_{2A} receptors Chemically related to 5-HT	May have potential for the treatment of depression and some forms of anxiety (see Chs **45** and **48**)

Drugs	Mode(s) of action	Notes
DMT	Interacts with a wide range of amine receptors, including 5-HT_{2A} receptors	Major component of Ayahuasca, a psychoactive 'tea' that originates from the Amazon region
Salvinorin A	κ Opioid receptor agonist (see **Ch. 43**)	No clinical use Found in *Salvia divinorum* (plant)

DA, Dopamine; *DMT*, dimethyltryptamine; *5-HT,* 5-hydroxytryptamine; *LSD,* lysergic acid diethylamide.

Addictive liability

LSD, psilocybin and mescaline are seldom self-administered by experimental animals. Indeed, in contrast to most of the psychoactive drugs that are widely used by humans, they have aversive rather than reinforcing properties in behavioural tests. Tolerance to their effects develops quite quickly, but there is no physical withdrawal syndrome in animals or humans.

Psychedelic drugs induce head twitching in rodents through activation of 5-HT_{2A} receptors. However, the main effects of these psychedelic drugs in humans are subjective, so it is not surprising that animal tests that model psychedelic activity in humans have not been devised. [11]

Other Psychedelic Drugs

Salvinorin A is a hallucinogenic agent contained in the American sage plant *Salvia divinorum*, a member of the mint family. It was originally used by the Mazatecs in Mexico; in recent years its use has spread and it has become known as *herbal ecstasy*. It is a κ opioid receptor agonist (see **Ch. 43**). [12] It also produces dissociative effects (see later) and, at high doses, delirium.

Other hallucinogens include **α-MT** (methyltryptamine) and **DMT** (dimethyltryptamine), which are naturally occurring, and **DPT** (dipropyltryptamine) and **DOM** (2,5-dimethoxy-4-methylamphetamine).

Muscarinic receptor antagonists (see Chs **14** and **39**), **hyoscine**, **hyoscyamine** and **atropine**, are contained in various plants, including henbane and mandrake. Consumption can cause hallucinations, drowsiness, disorientation, amnesia and delirium

Ibogaine is contained in the root bark of iboga shrubs in Africa, South America and Australia. At high doses, it is hallucinogenic. Users have reported experiencing a reduced desire to take other drugs such as cocaine and heroin, leading to ibogaine being used as treatment for drug craving (see **Ch. 50**).

Psychedelic drugs

- The main types are lysergic acid diethylamide (LSD), psilocybin and mescaline.
- LSD and psilocybin are 5-HT_{2A} receptor agonists.
- They cause sensory distortion and hallucinatory experiences.

- **LSD** is exceptionally potent, producing a long-lasting sense of dissociation and disordered thought. Hallucinatory episodes can recur after a long interval.
- In animal behavioural tests, they exhibit aversive rather than rewarding properties.
- **Salvinorin A** is a κ opioid receptor agonist that causes hallucinatory and dissociative effects.

Dissociative Drugs

Ketamine (*Special K*), a dissociative anaesthetic (see **Ch. 41**) with antidepressant properties (see **Ch. 48**), is also used for its psychoactive properties (see **Morgan and Curran, 2012**). Its fore-runner, **phencyclidine** (PCP, *angel dust*), was a popular hallucinogen in the 1970s but its use has declined. These drugs produce a feeling of euphoria. At higher doses they cause hallucinations and feelings of detachment, disorientation and numbness. PCP was reported to cause psychotic episodes and is used in experimental animals to produce a model of schizophrenia (see **Ch. 47** and **Morris et al., 2005**).

Pharmacological effects

Their main pharmacological effect is non-competitive block of the *N*-methyl-D-aspartate (NMDA) receptor channel (see **Ch. 38**). **Methoxetamine**, a chemical derivative of ketamine, is an NMDA antagonist as well as an inhibitor of 5-HT reuptake, which may contribute to its CNS effects.

Adverse effects

Tolerance develops with repeated use of ketamine, resulting in higher doses being taken to achieve the same effect. Repeated use is associated with serious and persistent toxic effects, including abdominal pain, ulcerative cystitis (with associated severe bladder pain), liver damage and cognitive impairment (**Morgan and Curran, 2012**). Combination of ketamine with depressant drugs such as **alcohol**, **barbiturates** and **heroin** can result in dangerous overdose.

Nitrous oxide is a weak general anaesthetic with analgesic properties that acts as an antagonist at NMDA receptors (see **Ch. 41**). It is a colourless, slightly sweet-smelling gas that is also used in catering to whip cream. Recreational users normally purchase nitrous oxide in the form of small whipped-cream chargers from which they fill a balloon and then inhale the gas. [13] Users experience a brief rush of dizziness, euphoria – it is often referred to as 'laughing gas' – relaxation and dissociation that lasts only for a few minutes and so they may take a number of 'hits' over the space of a few hours. Regular and prolonged use can result in vitamin B_{12} deficiency which causes peripheral neuropathy (see **Ch. 41**).

Table 49.3

Depressant drugs

Drugs	Described further in Chapter	Notes
Benzodiazepines (diazepam, temazepam, alprazolam, etizolam)	45	Etizolam and pyrazolam are derived from benzodiazepines and act similarly
Zopiclone and other Z drugs	45	Short acting but similar effects to benzodiazepines
Gabapentin and pregabalin	46	Often taken in high doses to induce a feeling of drunkenness and stupor May enhance likelihood of overdose in opioid users
γ-Hydroxybutyric acid (GHB)	39, 59	γ-Butyrolactone (GBL) and 1,4-butanediol (BD) are broken down to GHB in the body

Drugs	Described further in Chapter	Notes
Ethanol	This chapter	
Propofol	42	Sub-anaesthetic doses induce a general feeling of well-being, euphoria and sexual disinhibition

Depressants

Many CNS depressant drugs (**Table 49.3**) that are used for their psychoactive effects also have important therapeutic uses that are described in detail elsewhere in this book. Here we will concentrate on ethanol, which has little or no therapeutic value but is widely used in many countries for its psychoactive properties.

Ethanol

It may at first seem strange to categorise ethanol as a depressant drug [14] given that its consumption in alcoholic beverages can make people excited, garrulous and violent. However, as with general anaesthetics (see **Ch. 41**), at low concentrations ethanol depresses inhibitions, resulting in apparent behavioural stimulation, whereas at higher concentrations all brain functions are depressed.

Judged on a molar basis, the consumption of ethanol far exceeds that of any other drug. The ethanol content of various drinks ranges from about 2.5% (weak beer) to about 55% (strong spirits), and the

size of the normal measure is such that a single drink usually contains about 8–12 g (0.17–0.26 mol) of ethanol. Its low pharmacological potency is reflected in the range of plasma concentrations needed to produce pharmacological effects: minimal effects occur at about 10 mmol/L (46 mg/100 mL), and 10 times this concentration may be lethal. The average per capita consumption of ethanol in the United Kingdom doubled between 1970 and 2007, but has fallen slightly since then. There has been an increase in non-drinkers, mainly amongst young people. Amongst those who do drink, the main changes have been a growing consumption of wine in preference to beer among adults, greater consumption in the home and an increasing tendency for binge drinking, especially among young people.

For practical purposes, ethanol intake is often expressed in terms of units. One unit is equal to 8 g (10 mL) of ethanol, and is the amount contained in half a pint of normal-strength beer, one measure of spirits or one small glass of wine. The current UK government's guidelines state that for both men and women it is safest not to drink regularly more than 14 units per week, and that if as much as 14 units per week are drunk, it is best to spread this evenly over 3 days or more. It is estimated that in the United Kingdom, about 31% of men and 16% of women exceed these levels. Governments in most developed countries are attempting to curb alcohol consumption.

An excellent detailed review of all aspects of alcohol and alcoholism is provided by **Spanagel (2009)**.

Pharmacological Effects of Ethanol

Effects on CNS neurons

The main effects of ethanol are on the CNS, where its depressant actions resemble those of volatile anaesthetics (see **Ch. 41**). At a neuronal level, the effect of ethanol is depressant, although it increases neuronal activity – presumably by disinhibition – in some parts of the CNS, notably in the mesolimbic dopaminergic pathway that is involved in reward. The main acute cellular effects of ethanol that occur at concentrations (5–100 mmol/L) relevant to alcohol consumption by humans are:

- enhancement of both GABA- and glycine-mediated inhibition
- inhibition of Ca^{2+} entry through voltage-gated calcium channels
- activation of certain types of K^+ channel
- inhibition of ionotropic glutamate receptor function
- inhibition of adenosine transportFor review, see **Harris et al. (2008)**.

Ethanol enhances the action of GABA on $GABA_A$ receptors in a similar way to benzodiazepines (see **Ch. 45**). Its effect is, however, smaller and less consistent than that of benzodiazepines, and no clear effect on inhibitory synaptic transmission in the CNS has been demonstrated for ethanol. This may be because the effect of ethanol is seen only on some subtypes of $GABA_A$ receptor (see **Ch. 38**), e.g. the extrasynaptic α6β3δ $GABA_A$ receptor subtype has been reported to be sensitive to ethanol. Ethanol may also act presynaptically to enhance GABA release.

Ethanol enhances glycine receptor function, due both to a direct interaction with the α1 subunit of the glycine receptor and to

indirect effects mediated through protein kinase C (PKC) activation. Ethanol can also enhance glycine release from nerve terminals.

Ethanol reduces transmitter release in response to nerve terminal depolarisation by inhibiting the opening of voltage-gated calcium channels in neurons. It also reduces neuronal excitability by activating G protein–activated inwardly rectifying K^+ (GIRK) channels as well as potentiating calcium-activated potassium (BK) channel activity.

The excitatory effects of glutamate are inhibited by ethanol at concentrations that produce CNS depressant effects in vivo. NMDA receptor activation is inhibited at lower ethanol concentrations than are required to affect AMPA receptors (see **Ch. 38**). Other effects produced by ethanol include an enhancement of the excitatory effects produced by activation of nAChRs and 5-HT_3 receptors. The relative importance of these various effects in the overall effects of ethanol on CNS function is not clear.

The depressant effects of ethanol on neuronal function resemble those of adenosine acting on A_1 receptors (see **Ch. 16**). Ethanol in cell culture systems increases extracellular adenosine by inhibiting adenosine uptake, and there is some evidence that inhibition of the adenosine transporter may account for some of its CNS effects.

Endogenous opioids also play a role in the CNS effects of ethanol, because both human and animal studies show that the opioid receptor antagonist **naltrexone** reduces the reward associated with ethanol.

Behavioural effects

The effects of acute ethanol intoxication in humans are well known and include slurred speech, motor incoordination, increased self-confidence and euphoria. The effect on mood varies among individuals, most becoming louder and more outgoing, but some becoming morose and withdrawn. At higher levels of intoxication, the mood tends to become highly labile, with euphoria and melancholy, aggression and submission, often occurring successively. The association between alcohol consumption and violence is well documented.

Intellectual and motor performance and sensory discrimination are impaired by ethanol, but subjects are generally unable to judge this for themselves. [15] Much effort has gone into measuring the effect of ethanol on driving performance in real life, as opposed to artificial tests under experimental conditions. In a US study of city drivers, it was found that the probability of being involved in an accident was unaffected at blood ethanol concentrations up to 50 mg/100 mL (10.9 mmol/L); by 80 mg/100 mL (17.4 mmol/L) the probability was increased about four-fold, and by 150 mg/100 mL (32.6 mmol/L), about 25-fold. In Scotland, driving with a blood ethanol concentration greater than 50 mg/100 mL is illegal whereas in the rest of the United Kingdom the legal limit is 80 mg/100 mL.

The relationship between plasma ethanol concentration and effect is highly variable. A given concentration produces a larger effect when the concentration is rising than when it is steady or falling. A substantial degree of cellular tolerance develops in habitual drinkers, with the result that a higher plasma ethanol concentration is needed to produce a given effect. In one study, ‘gross intoxication’ (assessed by a battery of tests that measured

speech, gait and so on) occurred in 30% of subjects between 50 and 100 mg/100 mL and in 90% of subjects with more than 150 mg/100 mL. Coma generally occurs at about 400 mg/100 mL, and death from respiratory failure is likely at levels exceeding 500 mg/100 mL.

Ethanol significantly enhances – sometimes to a dangerous extent – the CNS depressant effects of many other drugs, including benzodiazepines, antidepressants, antipsychotic drugs and opioids.

Neurotoxicity

In addition to the acute effects of ethanol on the nervous system, chronic administration also causes irreversible neurological damage (see **Harper and Matsumoto, 2005**). This may be due to ethanol itself, or to metabolites such as acetaldehyde or fatty acid esters, or to dietary deficiencies (e.g. of thiamine) that are common in alcoholics. Binge drinking is thought to produce greater damage, probably due to the high brain concentrations of ethanol achieved and to repeated phases of withdrawal between binges. Heavy drinkers often exhibit convulsions and may develop irreversible dementia and motor impairment associated with thinning of the cerebral cortex (apparent as ventricular enlargement) detectable by brain-imaging techniques. Degeneration of the cerebellar vermis, the mammillary bodies and other specific brain regions can also occur, as well as peripheral neuropathy.

Effects on other systems

The main acute cardiovascular effect of ethanol is to produce cutaneous vasodilatation, central in origin, which causes a warm feeling but actually increases heat loss. [16] It has been proposed that

mild consumption of ethanol reduces the incidence of coronary heart disease, by increasing circulating levels of high-density lipoprotein (HDL), thus reducing the incidence of atherosclerosis (see **Ch. 22**). The much hyped notion that a glass of red wine each day (red wine contains the antioxidant, resveratrol) reduces coronary artery disease has come in for criticism in recent years. Moderate ethanol consumption may protect against ischaemic heart disease, especially in older people, perhaps partly by inhibiting platelet aggregation. This effect occurs at ethanol concentrations in the range achieved by moderate drinking (10–20 mmol/L) and probably results from inhibition of arachidonic acid formation from phospholipid. However, chronic or intermittent drinking of excessive amounts of ethanol causes raised blood pressure, which is one of the most important risk factors for having a heart attack or a stroke.

Diuresis is a familiar effect of ethanol. It is caused by inhibition of antidiuretic hormone secretion, and tolerance develops rapidly, so that the diuresis is not sustained. There is a similar inhibition of oxytocin secretion, which can delay parturition.

Ethanol increases salivary and gastric secretion, perhaps a reason in some cultures for the popularity of a glass of sherry before dinner. However, heavy consumption of spirits causes damage directly to the gastric mucosa, causing chronic gastritis. Both this and the increased acid secretion are factors in the high incidence of gastric bleeding in alcoholics. CNS depression predisposes to aspiration pneumonia and lung abscess formation. Acute pancreatitis may become chronic with pseudocyst formation (collections of fluid in the peritoneal sac), fat malabsorption and

ultimately loss of B-cell function, and insulin-dependent diabetes mellitus.

Ethanol produces a variety of endocrine effects. In particular, it increases the output of adrenal steroid hormones by stimulating the anterior pituitary gland to secrete adrenocorticotrophic hormone. However, the increase in plasma hydrocortisone usually seen in alcoholics (producing a 'pseudo-Cushing's syndrome' [see **Ch. 33**]) is due partly to inhibition by ethanol of hydrocortisone metabolism in the liver.

Acute toxic effects on muscle are exacerbated by seizures and prolonged immobility; severe myositis ('rhabdomyolysis') with myoglobinuria can cause acute renal failure. Chronic toxicity affects particularly cardiac muscle, giving rise to alcoholic cardiomyopathy and chronic heart failure.

Chronic ethanol consumption may also result in immunosuppression, leading to increased incidence of infections such as pneumonia (immunisation with pneumococcal vaccine is important in chronic alcoholics) and increased cancer risk, particularly of the mouth, larynx and oesophagus.

Male alcoholics are often impotent and show signs of feminisation. This is associated with impaired testicular steroid synthesis, but induction of hepatic microsomal enzymes by ethanol, and hence an increased rate of testosterone inactivation, also contributes.

Effects of ethanol on the liver

Together with brain damage, liver damage is the most common serious long-term consequence of excessive ethanol consumption

(see **Lieber, 1995**). Ethanol increases fat accumulation in the liver even after a single dose. Increased fat accumulation (fatty liver) progresses to hepatitis (i.e. inflammation of the liver) and eventually to irreversible hepatic necrosis and fibrosis. Cirrhosis is an end stage, with extensive fibrosis and foci of regenerating hepatocytes that are not correctly 'plumbed in' to the blood and biliary systems. Diversion of portal blood flow around the cirrhotic liver often causes portal hypertension and the development of oesophageal varices, which can bleed suddenly and catastrophically.

With chronic ethanol consumption, many other factors contribute to the liver damage. One is malnutrition, for alcoholic individuals may satisfy much of their calorie requirement from ethanol itself. Three hundred grams of ethanol (equivalent to one bottle of whisky) provides about 2000 kcal but, unlike a normal diet, it provides no vitamins, amino acids or fatty acids. Thiamine deficiency is an important factor in causing chronic neurological damage. Folate deficiency (see **Ch. 24**) is also common in alcoholics, often associated with macrocytosis of red blood cells.

The overall incidence of chronic liver disease is a function of cumulative ethanol consumption over many years. An increase in the plasma concentration of the liver enzyme γ-glutamyl transpeptidase (a marker of cytochrome P450 induction; see **Ch. 10**) often raises the suspicion of ethanol-related liver damage, although not specific to ethanol.

The effect of ethanol on fetal development

Drinking alcohol, especially in the first 3 months of pregnancy, increases the risk of miscarriage, premature birth and low birth

weight. The adverse effect of heavier ethanol consumption during pregnancy on fetal development was demonstrated in the early 1970s, when the term *fetal alcohol syndrome* (FAS) was coined.

The features of full FAS include:

- abnormal facial development, with wide-set eyes, short palpebral fissures and small cheekbones;
- reduced cranial circumference;
- growth restriction;
- intellectual disability and behavioural abnormalities, often taking the form of hyperactivity and difficulty with social integration;
- other anatomical abnormalities, which may be major or minor (e.g. congenital cardiac abnormalities, malformation of the eyes and ears).

A lesser degree of impairment, termed *alcohol-related neurodevelopmental disorder* (ARND), results in behavioural problems, and cognitive and motor deficits, often associated with reduced brain size. Full FAS occurs in about 3 per 1000 live births and affects about 30% of children born to alcoholic mothers. It is rare with mothers who drink less than about 5 units/day, and most common in binge drinkers who sporadically consume much larger amounts, resulting in high peak levels of ethanol. ARND is about three times as common. Although there is no clearly defined safe threshold, there is no evidence that amounts less than about 2 units/day are harmful. There is no critical period during pregnancy when ethanol consumption is likely to lead to FAS, although one study suggests that FAS incidence correlates most strongly with

ethanol consumption very early in pregnancy, even before pregnancy is recognised, implying that not only pregnant women but also women who are likely to become pregnant should be advised not to drink heavily. Experiments on rats and mice suggest that the effect on facial development may be produced very early in pregnancy (up to 4 weeks in humans), while the effect on brain development is produced rather later (up to 10 weeks).

Effects of ethanol

- **Ethanol** acts as a general CNS depressant, similar to volatile anaesthetic agents, producing the familiar effects of acute intoxication.
- Several cellular mechanisms are postulated: enhancement of GABA and glycine action, inhibition of calcium channel opening, activation of potassium channels and inhibition at NMDA receptors.
- Effective plasma concentrations:
  - threshold effects: about 20 mg/100 mL (5 mmol/L)
  - severe intoxication: about 150 mg/100 mL
  - death from respiratory failure: about 500 mg/100 mL
- Main peripheral effects are self-limiting diuresis (reduced antidiuretic hormone secretion), and cutaneous vasodilatation.
- Neurological degeneration occurs with heavy and binge drinking, causing dementia and peripheral neuropathies.

- Long-term ethanol consumption causes liver disease, progressing to cirrhosis and liver failure.
- Excessive consumption in pregnancy causes impaired fetal development, associated with small size, abnormal facial development and other physical abnormalities, and intellectual disability.
- Addiction, physical dependence and tolerance all occur with **ethanol.**

Pharmacokinetic Aspects

Metabolism of ethanol

Ethanol is rapidly absorbed, an appreciable amount being absorbed from the stomach. A substantial fraction is cleared by first-pass hepatic metabolism. Hepatic metabolism of ethanol shows saturation kinetics (see Chs **10** and **11**) at quite low ethanol concentrations, so the fraction of ethanol removed decreases as the concentration reaching the liver increases. Thus if ethanol absorption is rapid and portal vein concentration is high, most of the ethanol escapes into the systemic circulation, whereas with slow absorption more is removed by first-pass metabolism. This is one reason why drinking ethanol on an empty stomach produces a much greater pharmacological effect. Ethanol is quickly distributed throughout the body water, the rate of its redistribution depending mainly on the blood flow to individual tissues, as with volatile anaesthetics (see **Ch. 41**).

Ethanol is about 90% metabolised, 5%–10% being excreted unchanged in expired air and in urine. This fraction is not

pharmacokinetically significant but provides the basis for estimating blood ethanol concentration from measurements on breath or urine. The ratio of ethanol concentrations in blood and alveolar air, measured at the end of deep expiration, is relatively constant, 80 mg/100 mL of ethanol in blood producing 35 µg/100 mL in expired air; this being the basis of the breathalyser test. The concentration in urine is more variable and provides a less accurate measure of blood concentration.

Ethanol metabolism occurs almost entirely in the liver, and mainly by a pathway involving successive oxidations, first to acetaldehyde and then to acetic acid (**Fig. 49.5**). Since ethanol is often consumed in large quantities (compared with most drugs), 1–2 mol daily being by no means unusual, it constitutes a substantial load on the hepatic oxidative systems. The oxidation of 2 mol of ethanol consumes about 1.5 kg of the co-factor nicotinamide adenine dinucleotide (NAD^+). Availability of NAD^+ limits the rate of ethanol oxidation to about 8 g/h in a normal adult, independently of ethanol concentration (**Fig. 49.6**), causing the process to show saturating kinetics (see **Ch. 10**). It also leads to competition between the ethanol and other metabolic substrates for the available NAD^+ supplies, which may be a factor in ethanol-induced liver damage (see **Ch. 58**). The intermediate metabolite, acetaldehyde, is a reactive and toxic compound, and this may also contribute to the hepatotoxicity. A small degree of esterification of ethanol with various fatty acids also occurs in the tissues, and these esters may also contribute to long-term toxicity.

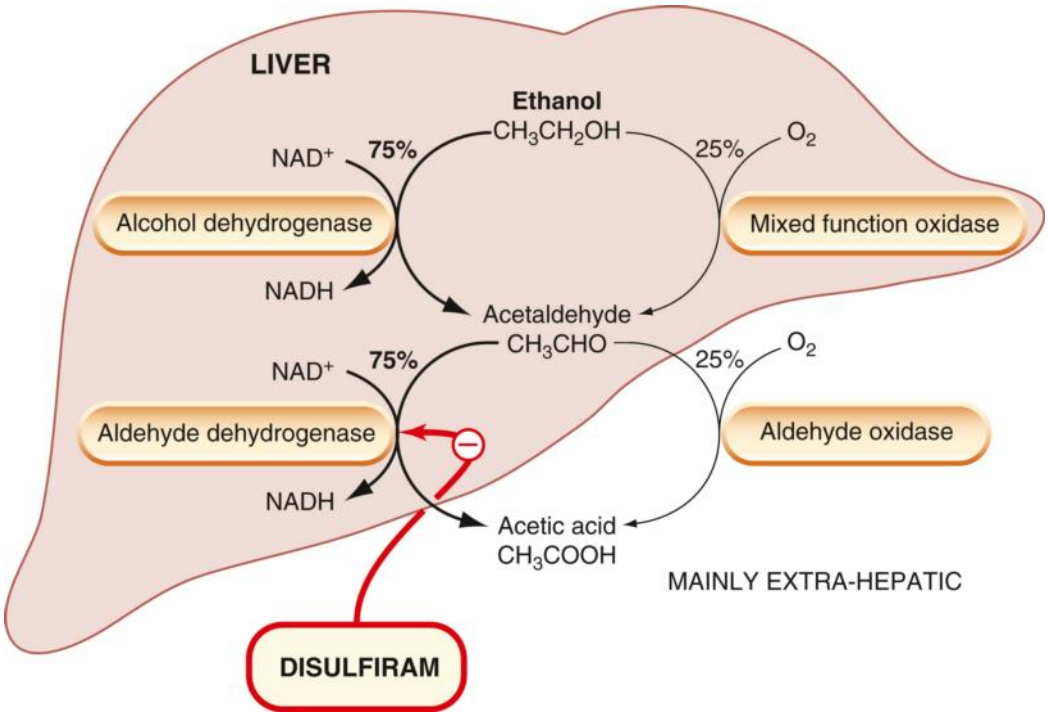

FIG. 49.5 Metabolism of ethanol. *NAD*, Nicotinamide adenine dinucleotide.

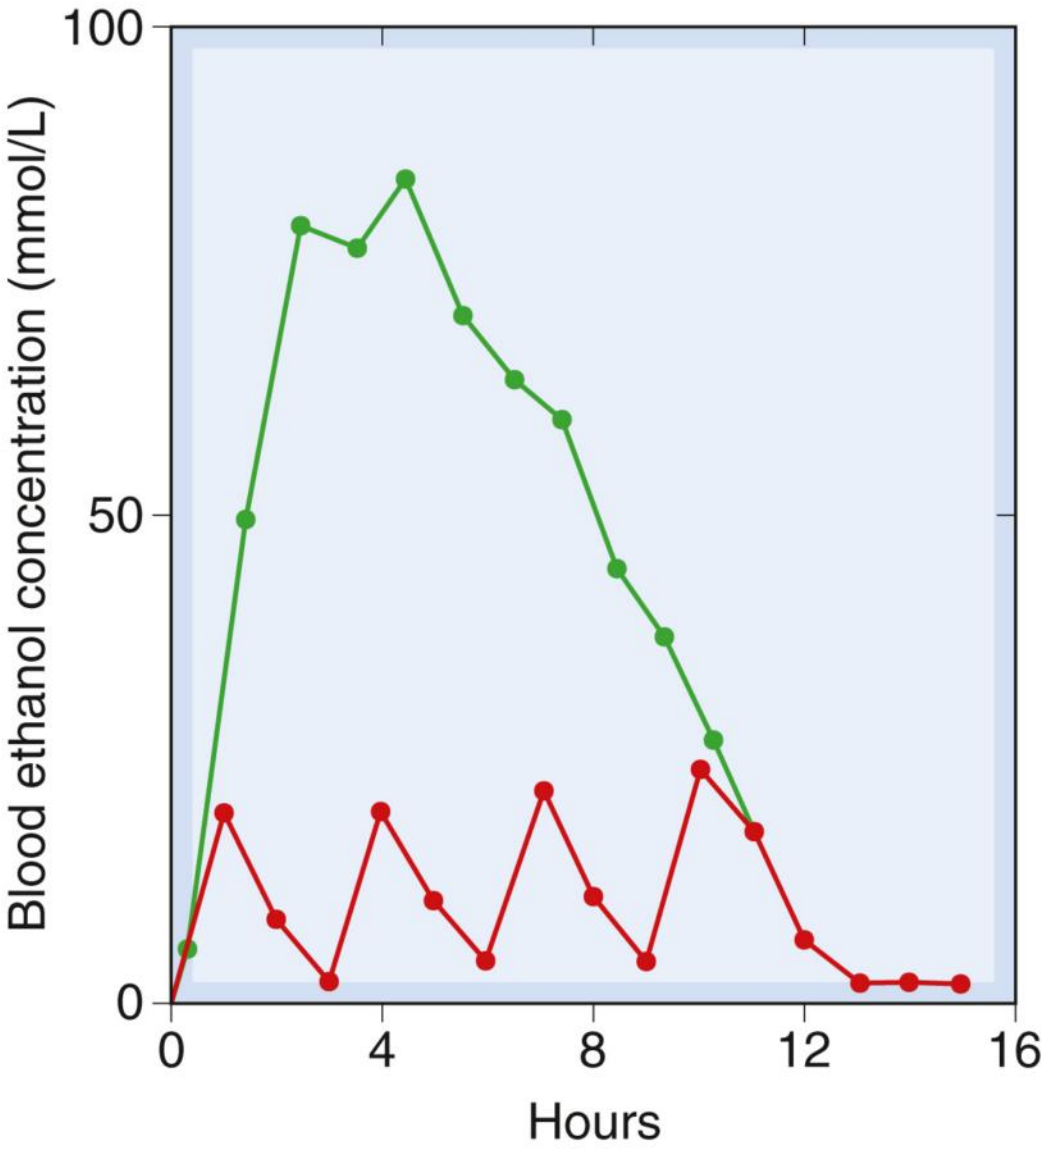

FIG. 49.6 Zero-order kinetics of ethanol elimination in rats.Rats were given ethanol orally (104 mmol/kg) either as a single dose or as four divided doses. The single dose results in a much higher and more sustained blood ethanol concentration than the same quantity given as divided doses. Note that, after the single dose, ethanol concentration declines linearly, the rate of decline being similar after a small or large

dose, because of the saturation phenomenon. From Kalant, H., et al., 1975. Biochem. Pharmacol. 24, 431.

Alcohol dehydrogenase is a soluble cytoplasmic enzyme, confined mainly to liver cells, which oxidises ethanol at the same time as reducing NAD^+ to NADH (see **Fig. 49.5**). Ethanol metabolism causes the ratio of NAD^+ to NADH to fall, and this has other metabolic consequences (e.g. increased lactate and slowing down of the Krebs cycle). The limitation on ethanol metabolism imposed by the limited rate of NAD^+ regeneration has led to attempts to find a 'sobering up' agent that works by regenerating NAD^+ from NADH. One such agent is fructose, which is reduced by an NADH-requiring enzyme. In large doses, it causes a measurable increase in the rate of ethanol metabolism, but not enough to have a useful effect on the rate of return to sobriety.

Normally, only a small amount of ethanol is metabolised by the microsomal mixed function oxidase system (see **Ch. 10**), but induction of this system occurs in alcoholics. Ethanol can affect the metabolism of other drugs that are metabolised by the mixed function oxidase system (e.g. **phenobarbital**, **warfarin** and **steroids**), with an initial inhibitory effect produced by competition, followed by enhancement due to enzyme induction.

Nearly all the acetaldehyde produced is converted to acetate in the liver by *aldehyde dehydrogenase* (see **Fig. 49.5**). Normally, only a little acetaldehyde escapes from the liver, giving a blood acetaldehyde concentration of 20–50 μmol/L after an intoxicating dose of ethanol in humans. The circulating acetaldehyde usually has little or no effect, but the concentration may become much larger

under certain circumstances and produce toxic effects. This occurs if aldehyde dehydrogenase is inhibited by drugs such as **disulfiram**. In the presence of disulfiram, which produces no marked effect when given alone, ethanol consumption is followed by a severe reaction comprising flushing, tachycardia, hyperventilation and considerable panic and distress, which is due to excessive acetaldehyde accumulation in the bloodstream. This reaction is extremely unpleasant but not usually harmful, at least in otherwise relatively healthy drinkers, and disulfiram can be used as aversion therapy to discourage people from taking ethanol. Some other drugs (e.g. **metronidazole**; see **Ch. 52**) produce similar reactions to ethanol. Interestingly, a Chinese herbal medicine used traditionally to cure alcoholics contains **daidzin**, a specific inhibitor of aldehyde dehydrogenase. [17]

Genetic factors

In 50% of Asian people, an inactive genetic variant of one of the aldehyde dehydrogenase isoforms (ALDH-2) is expressed; these individuals experience a disulfiram-like reaction after alcohol, and the incidence of alcoholism in this group is extremely low (see **Tyndale, 2003**).

Metabolism and toxicity of methanol and ethylene glycol

Methanol is metabolised in the same way as ethanol but produces formaldehyde instead of acetaldehyde from the first oxidation step. Formaldehyde is more reactive than acetaldehyde and reacts rapidly with proteins, causing the inactivation of enzymes involved in the tricarboxylic acid cycle. It is converted to another toxic metabolite, formic acid. This, unlike acetic acid, cannot be utilised in the

tricarboxylic acid cycle and is liable to cause tissue damage. Conversion of alcohols to aldehydes occurs not only in the liver but also in the retina, catalysed by the dehydrogenase responsible for retinol–retinal conversion. Formation of formaldehyde in the retina accounts for one of the main toxic effects of methanol, namely blindness, which can occur after ingestion of as little as 10 g. Formic acid production and derangement of the tricarboxylic acid cycle also produce severe acidosis.

Methanol is used as an industrial solvent and also to adulterate industrial ethanol in order to make it unfit to drink. Methanol poisoning is quite common, and used to be treated by administration of large doses of ethanol, which acts to retard methanol metabolism by competition for alcohol dehydrogenase. **Fomepizole** inhibits alcohol dehydrogenase and is now preferred, if available. Such treatment may be in conjunction with haemodialysis to remove unchanged methanol, which has a small volume of distribution.

Poisoning with ethylene glycol, used in automobile antifreeze and brake fluid, is a medical emergency. It is rapidly absorbed from the gut and metabolised to glycolate and then more slowly to oxalate. Glycolate interferes with metabolic processes and produces metabolic acidosis. It affects the brain, heart and kidneys. Treatment is with fomepizole or, with caution, ethanol, [18] and haemodialysis.

Tolerance and Physical Dependence

Tolerance to the effects of ethanol can be demonstrated in both humans and experimental animals, to the extent of a two- to three-

fold reduction in potency occurring over 1–3 weeks of continuing ethanol administration. A small component of this is due to the more rapid elimination of ethanol. The major component is cellular tolerance, which accounts for a roughly two-fold decrease in potency and which can be observed in vitro (e.g. by measuring the inhibitory effect of ethanol on transmitter release from synaptosomes) as well as in vivo. The mechanism of this tolerance is not known for certain. Ethanol tolerance is associated with tolerance to many anaesthetic agents, and alcoholics are often difficult to anaesthetise.

Chronic ethanol administration produces various changes in CNS neurons, which tend to oppose the acute cellular effects that it produces. There is a small reduction in the density of $GABA_A$ receptors, and a proliferation of voltage-gated calcium channels and NMDA receptors.

A well-defined physical abstinence syndrome develops in response to ethanol withdrawal. As with most other dependence-producing drugs, this is probably important as a short-term factor in sustaining the drug habit, but other (mainly psychological) factors are more important in the longer term (see **Ch. 50**). The physical abstinence syndrome usually subsides in a few days, but the craving for ethanol and the tendency to relapse last for very much longer. Treatment of alcohol dependence is described in **Chapter 50**.

The physical abstinence syndrome in humans, in severe form, develops after about 8 h. In the first stage, the main symptoms are tremor, nausea, sweating, fever and sometimes hallucinations. These last for about 24 h. This phase may be followed by seizures (‘rum fits’). Over the next few days, the condition of ‘delirium

tremens' develops, in which the patient becomes confused, agitated and often aggressive, and may suffer much more severe hallucinations. Treatment of this medical emergency is by sedation with large doses of a benzodiazepine such as **chlordiazepoxide** (see **Ch. 45**) together with large doses of thiamine.

Metabolism of ethanol

- **Ethanol** is metabolised mainly by the liver, first by alcohol dehydrogenase to acetaldehyde, then by aldehyde dehydrogenase to acetate. About 25% of the acetaldehyde is metabolised extrahepatically.
- Small amounts of **ethanol** are excreted in urine and expired air.
- Hepatic metabolism shows saturation kinetics, mainly because of limited availability of nicotinamide adenine dinucleotide (NAD^+). The maximal rate of **ethanol** metabolism is about 10 mL/h. Thus plasma concentration falls linearly rather than exponentially.
- Acetaldehyde may produce toxic effects. Inhibition of aldehyde dehydrogenase by **disulfiram** accentuates nausea, etc., caused by acetaldehyde, and can be used in aversion therapy.
- **Methanol** is similarly metabolised to formic acid, which is toxic, especially to the retina.
- Asian people show a high rate of genetic polymorphism of alcohol and aldehyde dehydrogenase, associated with alcoholism and alcohol intolerance, respectively.

Synthetic Cannabinoid Receptor Agonists

The endogenous cannabinoid system and cannabinoids contained in the *Cannabis sativa* plant (phytocannabinoids) are described in detail in **Chapter 18**. Here we will focus on SCRAs, which are sometimes referred to colloquially as *Spice*, *K2* or *Black Mamba*. The chemical structures of SCRAs are diverse, with over 10 chemical families having been described (see **Davidson et al., 2017**; **Advisory Council on the Misuse of Drugs, 2020**). Some originated from legitimate attempts by pharmaceutical companies to develop new therapeutic compounds but more recently others have been developed purely for non-medicinal purposes. SCRA solutions are often sprayed on herbal material or paper and subsequently smoked, but SCRAs are also available in crystal and powder form. Smoking, vaping, insufflation and ingestion are the main ways in which SCRAs are used. They are full agonists at the CB_1 cannabinoid receptor, the target through which **Δ^9-tetrahydrocannabinol** (THC), the major psychoactive ingredient in cannabis, has its effects. THC is a partial agonist at CB_1 receptors. SCRAs are said to exert a 'more forceful' activation of the CB_1 receptor, in that users often become 'zombie-like' or cataleptic. This may explain their popularity amongst the homeless and prisoners in jail, allowing them a period of escape from their daily lives.

Unlike cannabis itself, SCRAs are quite harmful and can induce hallucinations, psychotic episodes, panic attacks, seizures, respiratory depression and death. The precise reasons for these toxic effects are not known. They may have 'off-target' effects

unrelated to their actions on CB_1 receptors. Furthermore, when smoked, the parent compounds are subject to pyrolysis giving rise to unexpected derivatives, which may be responsible for some of the damaging effects. Quality control is not a priority for the producers of these agents and so there may be toxic contaminants in occasional batches of chemicals. Cessation of use can result in withdrawal symptoms in heavy users.

QUESTIONS

QUESTION 49.1

Cocaine has been used for many years for its stimulant properties by natives of South America to reduce high altitude fatigue. However, the psychostimulant properties of the drug have led to it becoming a widespread drug of abuse.

Which of the following statements about the pharmacological properties of cocaine is correct?

OPTIONS:

A. Cocaine exerts a psychomotor stimulant effect by increasing the release of monoamines from nerve terminals.

B. Hypothermia can occur at high doses.

C. Continued use of cocaine induces tolerance.

D. The free base form of cocaine is more rapidly absorbed than the hydrochloride salt.

E. The main adverse effect is respiratory depression.

QUESTION 49.2

Amphetamines induce a stimulant effect by increasing the levels of noradrenaline (NA) in the brain.

Which of the following is not a proposed mechanism of action for the amphetamines?

OPTIONS:

A. They competitively inhibit serotonin transporters (SERTs) by competing with the endogenous transmitter for uptake into nerve terminals.

B. They bind vesicular monoamine transporter (VMAT)-2 to inhibit transmitter uptake into synaptic vesicles.

C. They inhibit monoamine oxidase.

D. They increase NA release by facilitating norepinephrine transporter (NET) transport of NA out of the nerve endings via the plasma membrane.

E. They cause degeneration of monoamine-containing nerve terminals.

QUESTION 49.3

Ethanol has similar effects to general anaesthetics, causing a depression of neuronal excitability.

Which of the following is NOT a pharmacological effect of ethanol?

OPTIONS:

A. Enhancement of $GABA_A$-mediated neuronal inhibition

B. Enhancement of glycine release from nerve terminals

C. Enhancement of adenosine uptake by the adenosine transporter

D. Activation of K^+ channels

E. Inhibition of voltage-gated calcium channels

QUESTION 49.4

Nicotine is the most prevalent of the psychoactive drugs in society and has placed a significant burden on healthcare due to its carcinogenic effects.

Which of the following statements about the neuronal mechanisms of nicotine is incorrect?

OPTIONS:

A. The β2 subunit of the nicotinic acetylcholine receptor (nAChR) mediates dopamine release in the response to nicotine.

B. The physical dependence of nicotine involves nicotinic receptors containing α5 and β4 subunits in the medial habenula–interpeduncular nucleus pathway.

C. Nicotine produces a mixture of inhibitory and excitatory effects.

D. The peripheral effects of nicotine are due mainly to ganglionic stimulation.

E. Chronic nicotine administration leads to a decrease in the number of nAChRs.

ANSWERS

ANSWER 49.1

RATIONALE:

A. Cocaine blocks the reuptake of several different monoamines enhancing postsynaptic transmission.

B. Cocaine increases body temperature (hyperthermia) due to increased motor activity coupled with decreased heat loss.

C. Cocaine causes a strong psychological dependence but there is no strong evidence for tolerance, rather increased dosage due to a desire for increased effect.

D.

E. The main adverse effects are cardiovascular events. Cocaine increases the risk of myocardial infarction and cardiac dysrhythmias.

CORRECT ANSWER WITH EXPLANATION:

D. The free base form of cocaine is more rapidly absorbed than the hydrochloride salt.

Free-base cocaine vaporises at around 90°C, much lower than the melting point of cocaine hydrochloride (190°C), which burns rather than vaporises. Thus crack can be smoked, with the uncharged free base being rapidly absorbed across the large surface area of the alveolae, giving rise to a greater central nervous system (CNS) effect than that obtained by snorting cocaine.

ANSWER 49.2

RATIONALE:

A.

B. They enter nerve terminals via the uptake processes or by diffusion and interact with the vesicular monoamine pump VMAT-2 to inhibit the uptake into synaptic vesicles of cytoplasmic dopamine and NA.

C. At high concentrations, amphetamines can inhibit monoamine oxidase, which otherwise would break down cytoplasmic

monoamines, and monoamine oxidase inhibitors potentiate the effects of amphetamine.

D. They facilitate the transport of cytoplasmic monoamines out of the nerve endings via the plasma membrane DATs and NETs working in reverse.

E. In animals, prolonged administration results in degeneration of monoamine-containing nerve terminals and eventually cell death.

CORRECT ANSWER WITH EXPLANATION:

A. They competitively inhibit SERTs by competing with the endogenous transmitter for uptake into nerve terminals.

They are substrates for the neuronal plasma membrane monoamine uptake transporters DAT and NET but not SERT.

ANSWER 49.3

RATIONALE:

A. Ethanol enhances both GABA and glycine-mediated neuronal inhibition.

B. Ethanol potentiates glycine effects by interactions with the receptor and enhancing glycine release.

C.

D. Ethanol decreases neuronal excitability by activation of G protein–coupled inwardly rectifying potassium (GIRK) channels.

E. Ethanol reduces transmitter release by inhibiting voltage-operated calcium channels (VOCCs).

CORRECT ANSWER WITH EXPLANATION:

C. Enhancement of adenosine uptake by the adenosine transporter

Ethanol may exert some of its depressant effects by increasing the activation of A_1 receptors through the inhibition of adenosine uptake.

ANSWER 49.4

RATIONALE:

A. Transgenic mice lacking the β2 subunit lose the rewarding effect of nicotine and its dopamine-releasing effect.

B. A physical withdrawal syndrome occurs in humans on cessation of smoking. Its main features are increased irritability, impaired performance of psychomotor tasks, aggressiveness and sleep disturbance.

C. Electroencephalography changes show an arousal response, and subjects report increased alertness accompanied by a reduction of anxiety and tension.

D. The peripheral effects of nicotine (tachycardia, increased blood pressure and reduced gastrointestinal motility) are due mainly to ganglionic stimulation but tolerance develops rapidly to these effects.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Chronic nicotine administration leads to a decrease in the number of nAChRs.

Chronic nicotine administration leads to a substantial increase in the number of nAChRs (an effect opposite to that produced by sustained administration of most receptor agonists), which may

represent an adaptive response to prolonged receptor desensitisation.

[1] The Drugs Wheel (http://www.thedrugswheel.com/) provides an up-to-date, easily understood classification of the more prevalent psychoactive drugs.

[2] As discussed in the Preface to this book, in Chapters 49 and 50, where mainly illicit drug use is being described, we use common drug names and spellings (e.g. amphetamine and heroin) rather than their recommended international non-proprietary names (amfetamine and 3,6-diacetyl morphine).

[3] In the 1860s a Corsican pharmacist, Mariani, devised cocaine-containing beverages, Vin Mariani and Thé Mariani, which were sold very successfully as tonics. Imitators soon moved in, and Thé Mariani became the forerunner of Coca-Cola. In 1903, cocaine was removed from Coca-Cola because of its growing association with addiction and criminality.

[4] Caffeine withdrawal symptoms are a well-recognised cause of adverse events (headache, irritability) in residential phase I clinical trial units where caffeine-containing beverages are routinely prohibited.

[5] From the plant *Nicotiana*, named after Jean Nicot, French ambassador to Portugal, who presented seeds to the French king in 1560, having been persuaded by natives of South America of the medical value of smoking tobacco leaves. Smoking was believed to protect against illness, particularly the plague.

[6] Smokers, however, adapted by smoking more low-tar cigarettes and inhaling more deeply to maintain their nicotine consumption.

[7] This may explain why, in years gone by, men smoked cigars while chatting over drinks after dinner.

[8] Nicotine absorbed from cigar smoke is via the buccal mucosa but cigars deliver a much higher dose per puff than cigarettes, so a substantial amount gets in despite a low fraction absorbed.

[9] A popular phenomenon is ‘microdosing’ with very small quantities of psychedelic drugs such as LSD, psilocybin or mescaline every few days with the aim of improving concentration, creativity and problem solving. At such low doses users do not experience psychedelic effects. Properly controlled scientific studies have revealed that while psychological outcomes do improve over time, the placebo group also improved and there were no significant differences between microdosing with a psychedelic drug and placebo.

[10] A survey of information available on the www came up with 142 substances (plants, herbs and drugs) for which claims of cognition enhancing ability have been made (Napoletano et al., 2020). However, for most of the agents little or no good scientific evidence was available to support claims of efficacy.

[11] One of the more bizarre attempts involves spiders, whose normal elegantly symmetrical webs become jumbled and erratic if the animals are treated with LSD. Search the web (worldwide rather than arachnid) for ‘spiders LSD’ to see images.

[12] In phase I clinical trials of synthetic κ-opioid receptor agonists as potential analgesic agents, the drugs were reported to induce a feeling of dysphoria. Perhaps the 'normal' volunteers in those trials were disturbed by the hallucinations they probably experienced. Interesting then that a naturally occurring κ agonist has now become popular amongst some people who use drugs.

[13] Taking the gas directly into the mouth from the pressurised container can result in severe freezing of the lips and mouth as the temperature may be as low as -40°C. Breathing only nitrous oxide (e.g. by filling a large bag and placing it over the head) is extremely dangerous as there will be no oxygen in the inhaled gas (see Ch. 41).

[14] In some countries ethanol is classed as a food, not a drug! This reflects the lobbying power of the alcohol industry. Ethanol meets the criteria for 'What is a drug?' given in Chapter 1.

[15] Bus drivers were asked to drive through a gap that they selected as the minimum for their bus to pass through; ethanol caused them not only to hit the barriers more often at any given gap setting, but also to set the gap to a narrower dimension, often narrower than the bus.

[16] The image of a large St Bernard dog carrying a small keg of brandy around its neck to revive avalanche victims is an apocryphal one created by the English painter Edwin Landseer, who in 1820 produced a painting called 'Alpine Mastiffs Reanimating a Distressed Traveller'. With their keen sense of smell, such dogs were useful in searching for people buried in the snow, but taking a tot of brandy would only have enhanced the victim's heat loss.

[17] In hamsters (which spontaneously consume alcohol in amounts that would defeat even the hardest two-legged drinker, while remaining, as far as one can tell in a hamster, completely sober), daidzin markedly inhibits alcohol consumption.

[18] When presented with a late evening emergency poisoning of a dog with ethylene glycol, a veterinarian colleague of one of the authors ran to the local supermarket and purchased a bottle of vodka – the dog survived!

50: Drug use and addiction

OVERVIEW

In other chapters, we have considered how drugs that are taken because some people find their effects pleasurable (hedonic) exert their profound effects in the brain. In this chapter, we now focus on factors that relate specifically to their use – routes of administration, harms involved in drug taking, compulsive drug use (addiction). Finally, pharmacological treatments for compulsive drug use are described. The reasons why the use of a particular drug may be viewed as a problem by some societies, but not others, are complex and largely outside the scope of this book. The use of drugs to enhance sexual arousal is discussed separately in **Chapter 59**.

Drug Use

A number of terms are used, sometimes interchangeably and sometimes incorrectly, to describe drug use and the consequences of taking drugs which have not been prescribed for that person or for that purpose. Terms that are best avoided are listed in **Table 50.1**. Other, more useful, terms are defined in the text.

A vast and ever-increasing array of drugs is used to alter mood and perception. [1] These include drugs that are also used as medicines – anxiolytics (see **Ch. 45**), opioids (see **Ch. 43**), general

anaesthetics (see **Ch. 41**), cannabinoids (see **Ch. 18**) and some stimulants (see **Ch. 49**) – as well as non-medicinal psychoactive drugs (see **Ch. 49**) and volatile organic solvents (present in glues and aerosols). The popularity of each varies between different societies across the world, and within societies popularity differs among different groups of individuals. [2] Frequently, users will take more than one drug concomitantly (e.g. heroin users will inject cocaine and heroin together, an activity known as *speedballing*) or sequentially. Sequential use is often intended to reduce adverse effects that occur when coming down off the first drug (e.g. use of benzodiazepines when coming down from stimulants). Polydrug use is an under-researched area in regard to why it is done, how different drugs may interact and the potential harm that may arise from such practices. For example, ethanol alters cocaine metabolism, resulting in the production of *cocaethylene*, which is more potent than cocaine and has potentially greater cardiovascular toxicity.

The drugs taken are an extremely heterogeneous pharmacological group; we can find little in common in the behavioural effects produced by say, **heroin**, **cocaine** and **LSD** (lysergic acid diethylamide). What links them is that some people find their effects pleasurable (hedonic) and tend to want to repeat the experience. The drug experience may take the form of intense euphoria, mood elevation, hallucinations, stimulation, calming or sedation, depending upon the specific drug taken. Many drug users have existing mental health problems and for them drug taking is a means of self-medicating to alleviate symptoms they are experiencing.

The popularity and availability of drugs change with time. For example, over the last 20 years the opioid epidemic in the United States has been fuelled first by the ease of obtaining prescription opioids such as **oxycodone**, and more recently by the widespread availability of illicitly produced **fentanyl** and related drugs (**fentanyls**), such that in 2019 in the United States, of over 70,000 drug overdose deaths, some 52% involved **fentanyls**, 20% involved prescription opioids (e.g. **oxycodone**) and only 20% involved **heroin** (official name **diamorphine**). The situation is different in other countries such as the United Kingdom, where heroin remains the predominant opioid that is available.

Drug use involves effects on the brain that can be both acute and chronic (**Fig. 50.1**). The immediate, acute effect on mood is the reason the drug is taken. For some drugs (e.g. **amphetamines** and **3,4-methylenedioxymethamphetamine** (**MDMA)**, see **Ch. 49**), this may be followed by a rebound negative or depressed phase. Persistent use of a drug may lead to compulsive drug use and to the development of tolerance.

Drug Administration

For drugs that induce strong feelings of euphoria, there are two components to the experience: an initial rapid effect (the *rush* or *buzz*) and a more prolonged pleasurable effect (the *high*) that may for some drugs (e.g. gabapentinoids or opioids) be accompanied by a period of sedation (*gouching*). The intensity of the initial effect is determined by how fast the drug enters the brain and activates its effector mechanism. For many casual drug users, ease of administration defines how the drug is taken (e.g. smoking,

swallowing or snorting a drug is relatively easy). However, for other drug users chasing a more intense experience, the route of administration and the choice of individual drug become important. Intravenous injection or smoking results in faster absorption of a drug than when it is taken orally. Heroin, cocaine, amphetamines, tobacco and cannabis are all taken by one or other of these routes. Heroin is more popular as a street drug than morphine despite its lack of activity at μ-opioid receptor (see **Ch. 43**). This is because heroin is rapidly deacetylated to an active metabolite, 6-acetylmorphine, which rapidly enters the brain and stimulates the receptors (**Gottås et al., 2013**). The subsequent conversion of 6-acetylmorphine to morphine occurs relatively slowly.

Table 50.1

Glossary of frequently used and 'abused' terms

Addict	Person for whom the desire to experience a drug's effects overrides any consideration for the serious physical, social or psychological problems that the drug may cause to the individual or others. Often used in non-scientific circles to convey criminal intent and so has fallen out of favour with those involved in treating people with drug use disorders
Junkie	Pejorative term for someone who has a drug use disorder usually involving opioids
Drug abuse and drug misuse	Non-medicinal drug use (it is debatable whether taking drugs to alter mood/induce hallucinations should be described as 'misuse' or 'abuse')
Recreational drug use	Originally used to describe all drug use, it is now sometimes used to describe drug use in the bar/club/dance scene.
Narcotics	Originally used as a term to describe opioids as they induce sleep (narcosis). Subsequently this term has been used by non-scientists to describe a wide range of

	drugs (including cocaine, which is a stimulant!).

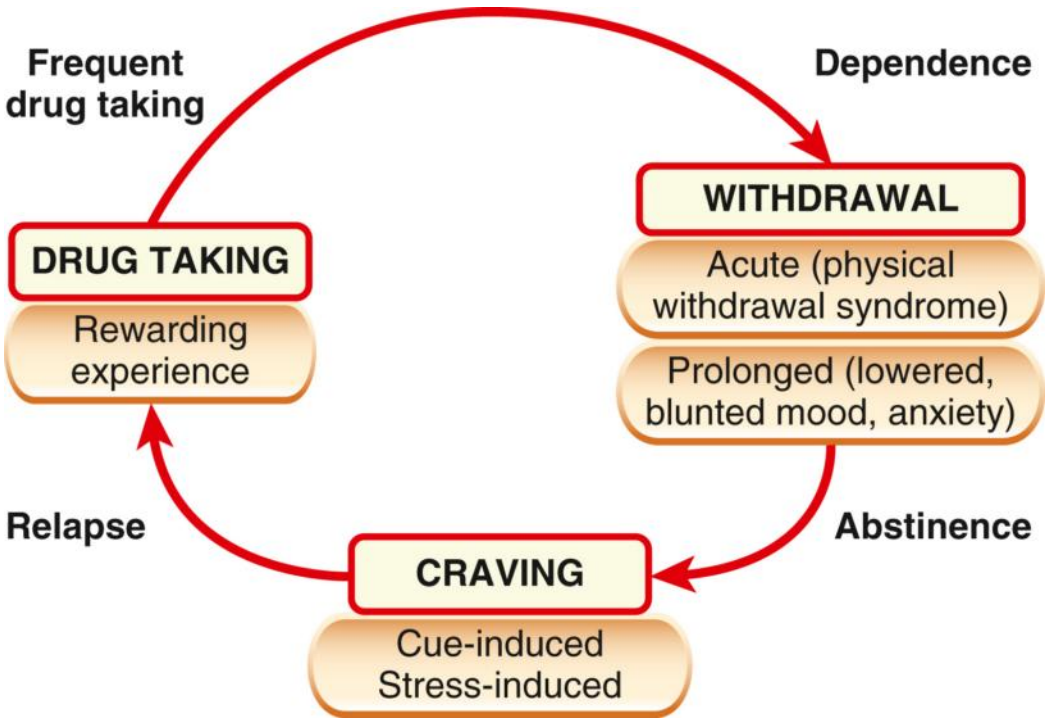

FIG. 50.1 A simplified scheme of the recurring cycle of compulsive drug use.

Drug Harm

All drugs are harmful but to varying degrees. Adverse effects can be the result of drug overdose (e.g. respiratory depression produced by opioids), of effects on tissues other than the brain (e.g. necrosis of the nasal septum resulting from chronic cocaine use), of the route of administration (e.g. HIV, hepatitis C and other infections in drug users who share needles), of effects unrelated to the specific actions of the drug (e.g. carcinogenicity of tobacco smoke, severe bladder pain in regular **ketamine** users) or of use for nefarious purposes

(e.g. **flunitrazepam** or **γ-hydroxybutyrate** (**GHB**) as date-rape drugs). Many major harms relate to the addictive nature of some drugs (e.g. psychostimulants, opioids, ethanol and tobacco) or to their ability to reveal a susceptibility to psychotic illness in some individuals (e.g. amphetamines and cannabis).

There have been attempts by expert panels in the UK, European Union and Australia to produce a rational scale of drug harm, based on assessment of harms to users and harms to others, that results from their physical, psychological and social effects (see **Bonomo et al., 2019**). Ethanol was ranked the most harmful substance overall in each study. While there were differences between the panels on the relative harms of other drugs, there was general agreement that tobacco (nicotine), methamphetamine, heroin, fentanyls, crack cocaine and cocaine are the most harmful after ethanol, with **LSD** and **MDMA** much less so. [3]

Drug Addiction

Drug addiction, also referred to as *substance use disorder,* [4] describes the human condition in which:

- drug taking becomes compulsive, taking precedence over other needs;
- there is a loss of control of the amount of drug taken;
- physical and psychological changes occur when access to drug is denied.

Addiction thus involves both psychological and physiological components and can be considered as a three-stage process around which drug using individuals recycle (see **Fig. 50.1**). As addiction

progresses, taking the drug may only reverse the lowered mood that develops between doses rather than produce the high that was initially experienced at earlier stages of using the drug. The neurobiology of drug addiction is described in detail by **Koob and Volkow (2016)**.

Drug addiction becomes a problem when the need becomes so insistent that it dominates the lifestyle of the individual and damages their quality of life, and the drug use itself causes actual harm to the individual or the community. Examples of the latter are the mental incapacity and liver damage caused by ethanol, the many diseases associated with smoking tobacco, the high risk of infection when injecting intravenously (especially HIV and hepatitis C), the serious risk of overdose with most opioids and the criminal behaviour resorted to when drug users need to finance their drug taking.

Not all psychoactive drugs induce severe addiction. Highly addictive drugs are nicotine, ethanol, opioids, crack and powdered cocaine, methamphetamine, amphetamine and benzodiazepines. On the other hand, cannabis, MDMA and psychedelic drugs are less addictive.

Not everyone who takes a drug progresses to become addicted to it. Family studies show clearly that susceptibility to addiction is an inherited characteristic. Around 50% of the risk of becoming addicted is genetic. Variants of many different genes may each make a small contribution to the overall susceptibility of an individual to addiction – a familiar scenario that provides few pointers for therapeutic intervention. Polymorphisms in ethanol-metabolising

genes (see **Ch. 49**) are the best example of genes that directly affect the tendency to use a drug.

Other factors that contribute to drug addiction are developmental (adolescents are more at risk than adults) and environmental, e.g. stress, social pressures and drug availability. Many individuals who become addicted will also suffer from mental illness – *severe anxiety, depression, attention-deficit hyperactivity disorder (ADHD), bipolar disorder personality disorders or schizophrenia* – or have been physically or mentally abused. These underlying issues may contribute to their wish to take drugs as well as to their inability to stop taking drugs.

Drug-Induced Reward

The common feature of the various types of psychoactive drugs that are addictive is that all produce a *rewarding* experience (e.g. an elevation of mood or a feeling of euphoria or calmness).

In animal studies, where the state of mood cannot be inferred directly, reward is manifest as *positive reinforcement*, i.e. an increase in the probability of occurrence of any behaviour that is associated with the drug experience. In *conditioned place preference* studies, animals receive a drug or placebo and are then placed in different environments. Subsequently, when tested in a drug-free state, they will spend more time in the environment associated with a previous rewarding drug experience. Another way of determining if a drug is rewarding is to test whether or not animals will self-administer the drug by pressing a lever to obtain it. Stimulants and opioids are self-administered by experimental animals whereas psychedelic drugs are less likely to be self-administered, which may

indicate that, unlike humans, they find the experience non-rewarding.

Humans have a choice as to whether or not they wish to experiment with and continue taking drugs – there may therefore be an element of risk-taking when experimenting with drugs. In behavioural tests, some rats have been observed to be much more impulsive than others (**Jupp et al., 2013**). The impulsive rats showed a higher rate of cocaine, nicotine, alcohol and methylphenidate self-administration and had a lower level of expression of D_2 and D_3 dopamine receptors in the nucleus accumbens (see later for the importance of this brain region in drug use). Impulsive rats were not, however, more prone to self-administering opioids.

Reward Pathways

Virtually all of the major addictive drugs so far tested, including opioids, nicotine, amphetamines, ethanol and cocaine, activate the *reward pathway* – the mesolimbic dopaminergic pathway (see **Ch. 39**), that runs, via the medial forebrain bundle, from the ventral tegmental area (VTA) of the midbrain to the nucleus accumbens and limbic region. Even though for some of these drugs their primary sites of action may be elsewhere in the brain, they all increase the extracellular level of dopamine in the nucleus accumbens, as shown by microdialysis in animals and in vivo brain-imaging techniques in humans. Opioids enhance the firing of VTA dopaminergic neurons by reducing the level of GABAergic inhibition (disinhibition) within the VTA, whereas amphetamine and cocaine act on dopaminergic nerve terminals in the nucleus accumbens to

release dopamine or prevent its reuptake (see **Ch. 15**). Given that dopamine release in the nucleus accumbens is also enhanced by naturally rewarding stimuli, such as food, water, sex and nurturing, it would appear that drugs are simply activating, or overactivating, the body's own pleasure system. In experienced drug users the anticipation of the effect may become sufficient to elicit the release of dopamine. Paradoxically, brain-imaging studies have revealed that in chronic users the increase in dopamine may be less than expected when compared with what is seen in naïve individuals, even though the subjective high is still intense. This may reflect some degree of sensitisation, but the mechanism is not well understood.

Chemical or surgical interruption of the VTA–accumbens dopaminergic pathway impairs drug-seeking behaviours in many experimental situations. Deletion of D_2 receptors in a transgenic mouse strain was shown to eliminate the rewarding properties of morphine administration without reducing other opioid effects, and it did not prevent the occurrence of physical withdrawal symptoms in morphine-dependent animals (**Maldonado et al., 1997**), suggesting that the dopaminergic pathway is responsible for the positive reward but not for the negative withdrawal effects. However, D_2-receptor antagonists (antipsychotic drugs; see **Ch. 47**) have not been successful in treating addiction, and more recent evidence suggests that D_1 receptors activated by steep increases in dopamine release and possibly also D_3 receptors play important roles. The translation of preclinical studies into the development of D_3-receptor antagonists or partial agonists as treatments for drug addiction has been extremely slow (see **Galaj et al., 2020**).

Physical Dependence

This is characterised by a *withdrawal* or *abstinence syndrome* whereby on cessation of drug administration or on administering an antagonist, adverse physiological effects are experienced. On prolonged cessation of drug administration the withdrawal effects can persist for a period of days or weeks, the precise withdrawal responses being characteristic of the type of drug taken. The intensity of the withdrawal syndrome also varies between drugs of the same type according to their pharmacokinetic characteristics. The desire to avoid or suppress the withdrawal syndrome increases the drive to retake the drug. In individuals undergoing drug detoxification treatment (detox) pharmacological intervention can be used to reduce the intensity of drug withdrawal (**Table 50.2**).

The mechanisms responsible for the withdrawal syndrome have been most fully characterised for opioid dependence but similar mechanisms may apply to cocaine and ethanol withdrawal. At the cellular level, opioids inhibit cAMP formation, and withdrawal results in a rebound increase as a result of 'superactivation' of adenylyl cyclase, as well as up-regulation of the amount of this enzyme. This results in activation of protein kinase A (PKA), in an increase in adenosine as a consequence of the conversion of cAMP to adenosine and in activation of a transcription factor – cAMP response element binding protein (CREB). The rise in PKA activity increases the excitability of nerve terminals by phosphorylating neurotransmitter transporters to increase their ionic conductance (see **Bagley et al., 2005**), as well as increasing neurotransmitter release by a direct action on the secretory process (**Williams et al., 2001**). Withdrawal results in enhanced GABA release in various

parts of the brain, probably through the mechanisms described earlier (see **Bagley et al., 2011**). The release of other neurotransmitters is also likely to be enhanced. On the other hand, the enhanced extracellular levels of adenosine, acting on presynaptic A_1 receptors (see **Ch. 16**), inhibit glutamate release at excitatory synapses, and thus counteract the neuronal hyperexcitability that occurs during drug withdrawal, suggesting the possibility – not yet clinically proven – that adenosine agonists might prove useful in reducing the withdrawal syndrome. CREB, which is up-regulated in the nucleus accumbens by prolonged administration of opioids or cocaine, plays a key role in regulating various components of cAMP signalling pathways, and transgenic animals lacking CREB show reduced withdrawal symptoms (see **Chao and Nestler, 2004**).

Table 50.2

Antidepressant, mood stabilising, anxiolytic and antipsychotic medications are useful when treating patients who, in addition to their drug use, also suffer from other mental disorders. The cannabinoid CB_1-receptor antagonist rimonabant, in addition to its antiobesity effects, also reduces nicotine, ethanol, stimulant and opioid consumption. However, it also induces depression and its use has been discontinued.

GHB, γ-Hydroxybutyric acid; *LSD,* lysergic acid diethylamide; *MDMA,* 3,4-methylenedioxymethamphetamine; *NMDA, N*-methyl-D-aspartate.

[a] The effectiveness of these agents at reducing the continued use of other drugs over and above the ones listed remains to be determined.

Several types of therapeutic drug, including antidepressant and antipsychotic agents, also produce withdrawal symptoms on cessation of administration, but it is important to distinguish this type of commonly observed 'rebound' phenomenon from the physical dependence associated with drug use. A degree of physical dependence is common when patients receive opioid analgesics in hospital for several days, but this rarely leads to addiction.

Psychological Changes

During periods of drug abstinence, individuals experience irritability, stress, anxiety, low mood and blunted responses to experiences that would normally be pleasurable. These aversive behavioural changes can be long lasting and contribute to the drive

to retake the drug to escape from what is a negative emotional state (*negative affect*). Furthermore, the memory of previous drug-induced experiences can be very intense and long lasting, giving rise to *craving*; it may drive an individual to take the drug again – referred to as *relapse* – even after a prolonged period of abstinence (see **Weiss, 2005**). The relative effort required to transition through detoxification into abstinence and recovery is illustrated in **Fig. 50.2**.

Craving may be triggered by stress or by cues, such as experiencing the environment that a person associates with previously taking the drug or the sight of drug administration paraphernalia, e.g. a crack pipe or syringe. This suggests that associative learning may be important (**Robbins et al., 2008**). It has been suggested that drugs alter memory formation to enhance the recollection of previous drug experience. In this regard, it is of interest that several drugs such as cocaine, morphine, nicotine and ethanol can produce changes in synaptic plasticity, a cellular correlate of memory formation (see **Ch. 38**), in both the VTA and the nucleus accumbens (**Hyman et al., 2006**; **Nestler and Lüscher, 2019**).

The psychological factors in drug addiction are discussed in detail by **Koob and Volkow (2016)** and summarised in **Fig. 50.3**.

Drug addiction

- Addiction occurs when, as a result of repeated administration of the drug, the desire to experience the effects of a drug again becomes compulsive.

- Addiction occurs with a wide range of psychotropic drugs, acting by many different mechanisms.
- The common feature of the major addictive drugs is that they have a positive reinforcing action ('reward') associated with activation of the mesolimbic dopaminergic pathway.
- Physical dependence is characterised by a withdrawal syndrome on cessation of drug use, and varies in type and intensity for different classes of drug.
- Drug withdrawal also results in prolonged mood changes – irritability, stress, anxiety, depression and blunted responses to normally rewarding experiences – and craving.
- Craving can be triggered by stress or cues relating to previous drug experience and may occur in individuals who have been drug-free for some considerable time.
- On repeated drug administration, tolerance may occur to the effects of the drug.
- Although genetic factors contribute to drug-seeking behaviour, no specific genes have yet been identified.

Tolerance

Tolerance (see **Ch. 2**) describes the decrease in pharmacological effect on repeated administration of a drug – it develops over time, as does physical dependence. It does not occur with all drugs. Contrary to earlier thinking, physical dependence and tolerance are now thought to involve different cellular mechanisms (see **Bailey and Connor, 2005**).

For drugs such as opioids that are agonists at specific receptors (see **Ch. 43**), cellular tolerance results in part from desensitisation of the receptors. On prolonged activation by an agonist, the μ receptor is phosphorylated by various intracellular kinases (**Williams et al., 2013**) – which either directly desensitises the receptor or causes the binding to the receptor of other proteins, such as arrestins, that uncouple the receptor from its G protein (see **Ch. 3**). In the intact animal, inhibition or knock-out of these kinases reduces the level of tolerance.

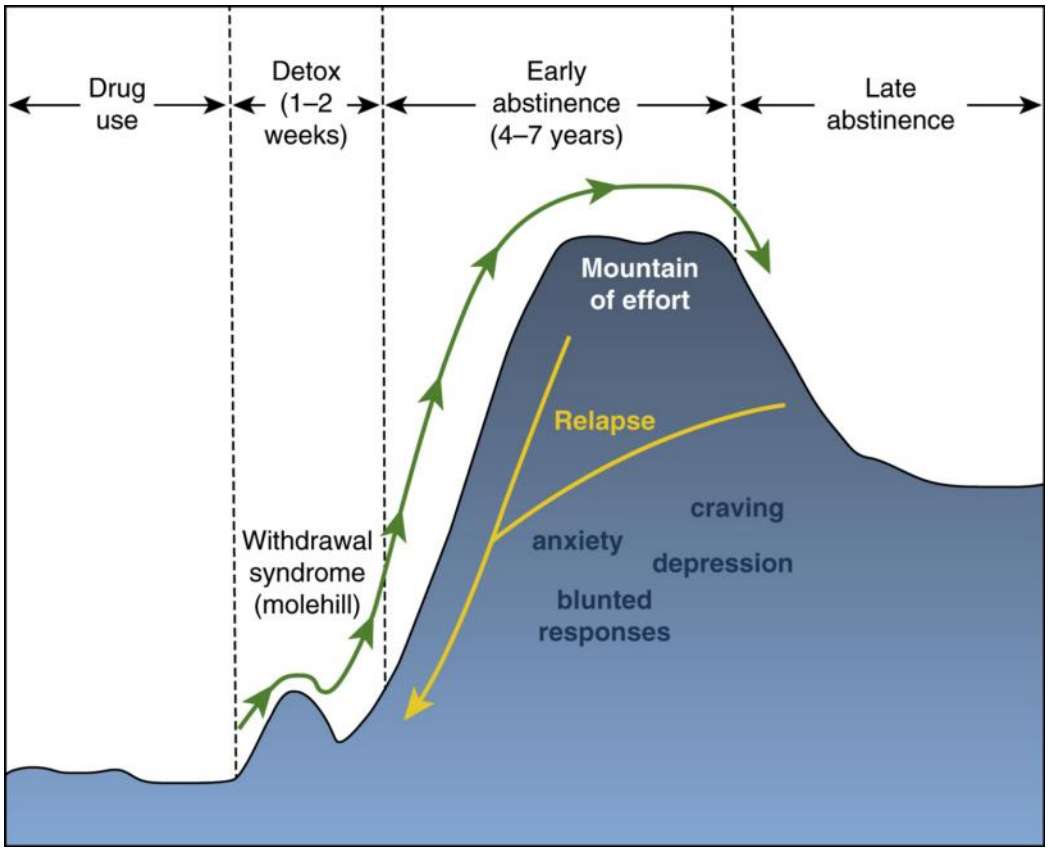

FIG. 50.2 The molehill of detox versus the mountain of abstinence.The graph illustrates the effort required to go through detoxification and maintain abstinence. Adapted from Diaper, A.M., Law, F.M., Melichar, J.K., 2014. Pharmacological strategies for detoxification. Brit. J. Clin. Pharmacol. 77, 302-314.

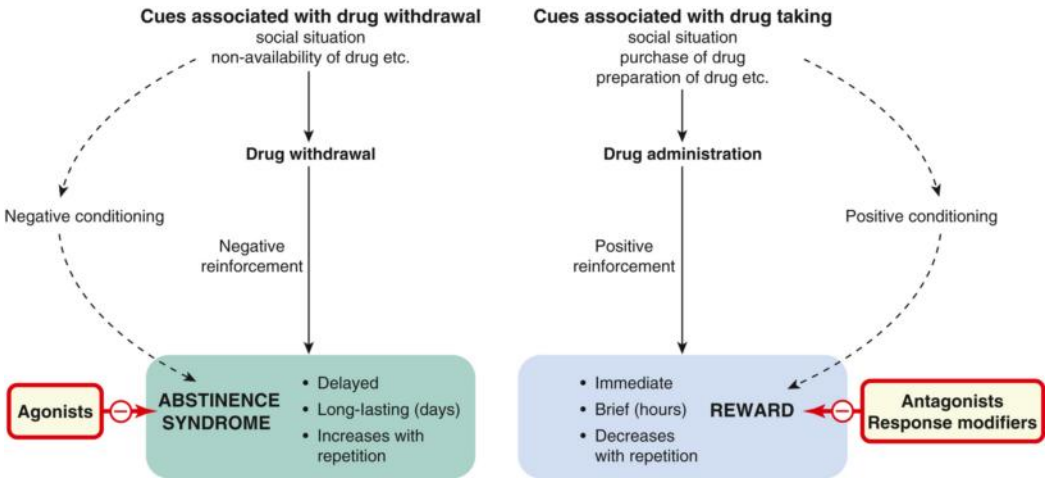

FIG. 50.3 A simplified scheme of some of the psychological factors involved in drug use.

Pharmacological Approaches to Treating Drug Addiction

There are a number of different approaches taken to treat drug addiction. Specific examples of the drugs used in each are given in **Table 50.2**.

- Agonist therapy, in which a medicinal grade drug is provided long term to '*maintain*' the individual, preventing them from going into withdrawal and reducing the craving to take drugs. For heroin users this form of treatment has been shown to also reduce criminal activities to fund illicit drug purchase, to reduce associated health hazards such as HIV and hepatitis C infection and to decrease overdose deaths.
- Facilitating drug withdrawal (detox) by either substituting a drug in the same class from which subsequent withdrawal is less intense or by administration of other drugs during the

withdrawal process that reduce the intensity of the withdrawal symptoms.

- Blocking the effects of a drug by prior administration of an antagonist so that if the individual has detoxed but relapses and retakes the drug again they will not experience the pleasurable effects of the drug. For this to be successful, the antagonist has to be long lasting or administered in the form of a prolonged release preparation that releases the antagonist over a prolonged period.
- Blocking the effects of a drug by immunisation to produce circulating antibodies that sequester the drug and prevent it crossing the blood–brain barrier. Vaccines against nicotine, heroin, fentanyls or cocaine have shown efficacy in animal tests but to date have proved less effective in human trials. Lack of efficacy in humans may be due to low antibody titres or to subjects just taking greater amounts of drug to overcome the sequestering effects of the antibodies generated (**Truong and Kosten, 2022**)
- Making the drug experience unpleasant. The best example of this approach is for ethanol which is rapidly metabolised to acetic acid by a two-step process (see **Ch. 49**, **Fig. 49.5**). Disulfiram, an aldehyde dehydrogenase inhibitor, inhibits the second step, resulting in the build-up of acetaldehyde which elicits an unpleasant response when ethanol is consumed.
- Reducing craving for a drug. A range of drugs have been suggested to reduce craving for various drugs. Their effectiveness is an ongoing area of debate and research.

Drug addiction involves many psychosocial and some genetic factors, as well as neuropharmacological mechanisms, and so while pharmacological approaches to drug treatment are important, they are only one component of the therapeutic approaches that are required. Psychological therapies, treatment for underlying mental and physical health issues and improvement in social circumstances (e.g. providing accommodation for those who are homeless) are essential to the recovery process.

Harm Reduction

For intravenous drug users, the provision of sterile injection equipment (needles, syringes, spoons and water) reduces equipment sharing and the spread of blood-borne diseases such as HIV and hepatitis C. Opioid overdose results in severe respiratory depression that can lead to death. Opioid-induced respiratory depression is rapidly reversed by administration of the opioid antagonist, **naloxone**. Supervised injection rooms and the distribution of naloxone (either as an intramuscular injection kit or in the form of a nasal spray) within the drug-using community are ways to reduce opioid overdose deaths.

Clinical use of drugs in substance use disorders

Tobacco

- Short-term **nicotine** is an adjunct to behavioural therapy in smokers committed to giving up; **varenicline** is also used as

an adjunct but has been linked to suicidal ideation.

- **Bupropion** is also effective but lowers seizure threshold, so is contraindicated in people with risk factors for seizures (and also if there is a history of eating disorder).

Alcohol

- Long-acting benzodiazepines (e.g. **chlordiazepoxide**) can be used to reduce withdrawal symptoms and the risk of seizures; they should be tapered over 1–2 weeks and then discontinued.
- **Disulfiram** is used as an adjunct to behavioural therapy in suitably motivated patients with alcohol use disorder after detoxification; it is contraindicated for patients in whom hypotension would be dangerous (e.g. those with coronary or cerebral vascular disease).
- **Acamprosate** can help to maintain abstinence; it is started as soon as abstinence has been achieved and maintained if relapse occurs, and it is continued for 1 year.

Opioids

- **Naloxone**, a competitive opioid antagonist, has become available for use in community settings to reverse respiratory depression from opioid overdose. It can be administered as a nasal spray or by intramuscular injection.
- Opioid agonists or partial agonists (e.g. respectively, **methadone** or **buprenorphine**) administered orally or sublingually may be substituted for injectable narcotics,

many of whose harmful effects are attributable to the route of administration.

- **Naltrexone**, a long-acting opioid antagonist, is used as an adjunct to help prevent relapse in opioid users who have been detoxified (opioid free for at least 1 week).
- **Lofexidine**, an α_2 agonist (cf. **clonidine**; see **Ch. 15**), is used short term (usually up to 10 days) to ameliorate symptoms of opioid withdrawal, and is then tapered over a further 2–4 days.

QUESTIONS

QUESTION 50.1

There have been attempts by expert panels to produce a rational scale of drug harm, based on assessment of harms to users and harms to others, that result from their physical, psychological and social effects.

From these studies, which is considered to be the most harmful drug of addiction?

OPTIONS:

A. Heroin

B. Tobacco

C. Ethanol

D. Cannabis

E. Lysergic acid diethylamide (LSD)

QUESTION 50.2

A common feature of psychoactive and addictive drugs is their ability to activate the endogenous reward pathway.

Which of the following statements about the reward pathway is incorrect?

OPTIONS:

A. It runs from the ventral tegmental area (VTA) to the nucleus accumbens.

B. Opioids increase dopaminergic transmission by preventing its reuptake.

C. Inhibition of GABA-ergic neurons in the VTA enhances the reward effect.

D. The rewarding properties of morphine appear to be mediated via D_2 receptors.

E. D_3 partial agonists may have potential as treatments for drug use disorder.

QUESTION 50.3

Many drugs of abuse result in physical dependence, as proven by the experience of adverse physiological effects following abstinence or withdrawal.

Which of the following statements about the physical dependence mechanisms associated with opiate withdrawal is incorrect?

OPTIONS:

A. Withdrawal results in an increase in neuronal excitability.

B. Adenosine antagonists may show potential as agents to treat drug use disorder.

C. Withdrawal of opioids results in a rebound increase in cAMP.

D. cAMP response element binding protein (CREB) is a key mediator of physical dependence.

E. Withdrawal results in enhanced transmitter release.

QUESTION 50.4

Several pharmacological agents have been developed to treat drug dependence and aid patients in the withdrawal process.

Which of the following agents is not used as a longer-term therapy to aid withdrawal symptoms?

OPTIONS:

A. Disulfiram to aid alcohol abstinence

B. Methadone to support opioid withdrawal

C. Naloxone to aid opioid withdrawal

D. Low-dose nicotine to aid smoking cessation

E. Chlordiazepoxide to aid alcohol withdrawal

ANSWERS

ANSWER 50.1

RATIONALE:

A. There is a serious risk of overdose and needle infections associated with injected opioids but the number of individuals affected is lower than with ethanol use disorder.

B. There is a high risk of lung cancer and other respiratory diseases associated with tobacco but this does not affect all individuals.

C.

D. Cannabis has a reduced propensity to cause addiction but can trigger psychosis in susceptible individuals.

E. Studies have rated LSD of lower harm rating despite in the UK it is classified as illegal.

CORRECT ANSWER WITH EXPLANATION:

C. Ethanol

Ethanol was ranked the most harmful substance overall in each study mainly due to the mental incapacity and liver damage caused by ethanol.

ANSWER 50.2

RATIONALE:

A. The reward pathway is a mesolimbic dopaminergic pathway that runs from the VTA to the nucleus accumbens.

B.

C. GABA-ergic signalling inhibits the pathway by decreasing the firing of the VTA dopaminergic neurons.

D. Deletion of D_2 receptors was shown to eliminate the rewarding properties of morphine.

E. Although not fully elucidated, D_3 receptors are thought to play a role in the rewarding effects of drug addiction and as such antagonists or partial agonists may be beneficial in drug use disorder.

CORRECT ANSWER WITH EXPLANATION:

B. Opioids increase dopaminergic transmission by preventing its reuptake.

Opioids enhance the firing of the VTA dopaminergic neurons by reducing GABA-ergic inhibition.

ANSWER 50.3

RATIONALE:

A. Opioids inhibit cAMP formation, and withdrawal results in a rebound increase as a result of ‘superactivation’ of adenylyl cyclase. This results in activation of protein kinase A (PKA), which increases the excitability of nerve terminals.

B.

C. Opioid withdrawal causes a ‘superactivation’ of adenylyl cyclase and an increase in enzyme expression.

D. Transgenic mice lacking CREB show reduced physical dependence.

E. PKA-induced neuronal excitability results in enhanced transmitter release including GABA.

CORRECT ANSWER WITH EXPLANATION:

B. Adenosine antagonists may show potential as agents to treat drug use disorder.

Adenosine binding to presynaptic A_1 receptors decreases glutamate release and hence reduces neuronal excitability. Therefore adenosine agonists may be beneficial.

ANSWER 50.4

RATIONALE:

A. Disulfiram is an aldehyde dehydrogenase inhibitor, the use of which results in unpleasant symptoms following alcohol consumption, caused by the build-up of acetaldehyde.

B. Medicinal-grade methadone is an opioid agonist, administered orally as a safer substitute to illicit opioid drug taking.

C.

D. Nicotine preparations can help wean patients off the effects of smoking, maintaining a level of nicotinic stimulation without the associated carcinogens.

E. Chlordiazepoxide is a long-acting benzodiazepine beneficial in reducing alcohol withdrawal symptoms.

CORRECT ANSWER WITH EXPLANATION:

C. Naloxone to aid opioid withdrawal

Intramuscular injections of naloxone are used to rapidly reverse the respiratory depression seen following opioid withdrawal and naltrexone implants, which are longer lasting, can be used to prevent relapse but naloxone is not used routinely to aid withdrawal.

[1] The Drugs Wheel (**http://www.thedrugswheel.com/**) provides an up-to-date, easily understood classification of the ever-expanding array of drugs. Most are illegal, although there are strong lobbies to legalise those that are considered less harmful, a process that is well underway for cannabis in several countries.

[2] A survey in one UK city showed that among Friday-night clubbers, the choice of drug was associated with the type of music the clubs played (**Measham and Moore, 2009**).

[3] This order of harm is not reflected in the classification of drugs under UK law where LSD and MDMA are Class A whereas ethanol and tobacco are legal.

[4] Pharmacologists are more likely to favour the term *drug use disorder* over *substance use disorder* as to them alcohol and solvents are drugs (see Ch. 1 for a pharmacological definition of what is a drug) but other interested parties have decided upon the term *substance use disorder*.

53. Antiviral drugs

54. Antifungal drugs

55. Antiprotozoal drugs

56. Antihelminthic drugs

57. Anticancer drugs

51: Basic principles of antimicrobial chemotherapy

OVERVIEW

The term *chemotherapy* was originally used to describe the use of drugs that were 'selectively toxic' to microbial pathogens (e.g. bacteria, viruses, protozoa, fungi and helminths) while having minimal effects on the host. It also refers to the use of drugs to treat tumours and, in the public mind at least, is usually associated with those cytotoxic anticancer drugs that cause distressing and unwanted effects such as loss of hair, nausea and vomiting. In this chapter, we focus on antimicrobial chemotherapy; anticancer drugs are covered in **Chapter 57**. The feasibility of the selective toxicity strategy depends on the ability to exploit such biochemical differences as may exist between the infecting organism and the host. While the bulk of this section of the book describes the drugs used to combat such infections, in this introductory chapter we consider the nature of these biochemical differences, outline the molecular targets of drug action and discuss the grave problem of antibiotic resistance and its possible solutions.

Background

All living organisms are vulnerable to infection. Humans, being no exception, are susceptible to diseases caused by microorganisms including viruses, bacteria, protozoa and fungi (collectively referred to as *microbial pathogens*) as well as by some larger parasites such as helminths. The concept of 'chemotherapeutic agents' dates back to the work of Ehrlich and others and to the development of selectively toxic arsenical drugs such as **salvarsan** for the treatment of syphilis. [1] Indeed, it was Ehrlich himself who coined the term *chemotherapy* to describe the use of synthetic chemicals to destroy such pathogens, and over time, the definition of the term has been broadened to include *antibiotics* – strictly speaking, substances produced by microorganisms (although latterly by pharmaceutical chemists as well) – that kill or inhibit the growth of other microorganisms. The successful development of these drugs during the 'golden age' of antibiotic research (1940s–1970s) constitutes one of the most important therapeutic advances in the history of medicine.

Unhappily, our success in developing drugs to neutralise these invaders has been paralleled by their own success in counteracting their effects, resulting in the emergence of *drug resistance*. And at present, the invaders – particularly some bacteria – seem close to gaining the upper hand. This is a very important clinical problem, and so we will devote some space to the mechanisms of resistance and the means by which it is spread.

The Molecular Basis of Chemotherapy

Chemotherapeutic agents, then, are chemicals intended to be toxic to a pathogenic organism but innocuous to the host. It is important

to remember that many microorganisms share our body spaces (e.g. the gut [2]) without causing disease (these are called *commensals*), although they may become pathogenic under adverse circumstances (i.e. if the host is immunocompromised or if barrier breakdown results in them setting up shop in an inappropriate location elsewhere in our bodies).

Cells without nuclei (e.g. bacteria) are termed *prokaryotes*, while cells that contain nuclei (e.g. protozoa, fungi, helminths and most of the cells in our own bodies) are *eukaryotes*. In a separate category are the viruses, which need to utilise the metabolic machinery of the host cell to replicate, and thus present a particular kind of problem for chemotherapeutic attack. Lurking in the taxonomic shadows, there remain those mysterious infectious proteins, the *prions* (see **Ch. 40**), which cause disease but resist all attempts at classification and treatment.

Virtually all creatures, host and parasite alike, utilise the same genetic code and while there are differences in genetic make-up, many biochemical processes are common to most, if not all, organisms. It follows that finding drugs that affect only pathogens but not other host cells necessitates finding either qualitative or quantitative biochemical or genetic differences between them which can be exploited therapeutically.

Bacteria

Bacteria are a common cause both of mild and severe infectious disease. **Fig. 51.1** shows, in simplified diagrammatic form, the main components of a notional bacterial cell and their functions. Surrounding the bacterium is the *cell wall*, which characteristically

contains *peptidoglycan* (*Mycoplasma pneumoniae*, a very small bacterium that causes an atypical lung infection – 'pneumonia' – resistant to several antibiotics, is an exception). Peptidoglycan is unique to prokaryotic cells and has no counterpart in eukaryotes. Within the cell wall is the *plasma membrane*, which, like that of eukaryotic cells, consists of a phospholipid bilayer and associated proteins. It functions as a selectively permeable membrane with specific transport mechanisms for various ions and nutrients. However, the plasma membrane in bacteria, unlike that of mammals, does not contain *sterols* (e.g. cholesterol), and this may alter the penetration of some drugs.

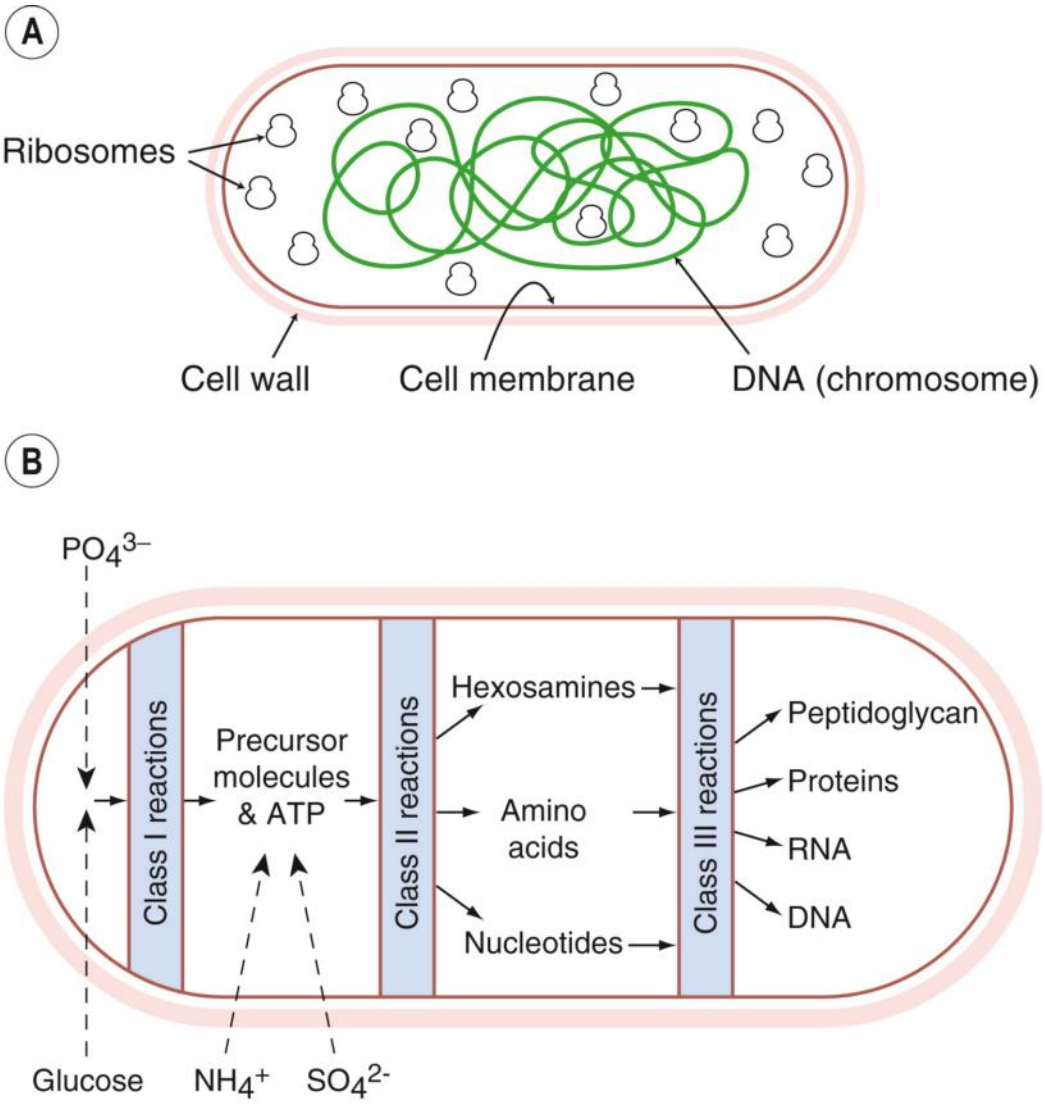

FIG. 51.1 Diagram of the structure and metabolism of a 'typical' bacterial cell. (A) Schematic representation of a bacterial cell. (B) Flow diagram showing the synthesis of the main types of macromolecule of a bacterial cell. *Class I reactions* result in the synthesis of the precursor molecules necessary for *class II reactions*, which result in the synthesis of the constituent molecules; these are then assembled into macromolecules by *class III reactions*. Modified

from Mandelstam, J., McQuillen, K., Dawes, I. (Eds), 1982. Biochemistry of Bacterial Growth. Blackwell Scientific, Oxford.

The cell wall supports the underlying plasma membrane, which is subject to an internal osmotic pressure of about 5 atmospheres in *gram-negative* organisms, and about 20 atmospheres in *gram-positive* organisms (see **Ch. 52** for an explanation of Gram staining). The plasma membrane and cell wall together comprise the *bacterial envelope*.

As in eukaryotic cells, the plasma membrane surrounds the *cytoplasm* and cellular organelles. Bacterial cells have no nucleus or mitochondria. Instead, the genetic material takes the form of a single *chromosome* which lies within the cytoplasm with no surrounding nuclear membrane and cellular energy is generated by enzyme systems located in the plasma membrane rather than dedicated organelles such as mitochondria.

Biochemical reactions that are potential targets for antibacterial drugs are shown in **Fig. 51.1**. These can be broadly classified into three overlapping groups: a drug may affect more than one class of reactions or more than one subgroup of reactions within a class.

- *Class I*: catabolic reactions involved in the utilisation of glucose, or some alternative carbon source, for the generation of energy (ATP) and synthesis of simple carbon compounds used as precursors in the next class of reactions.
- *Class II*: synthetic pathways which utilise these precursors in an energy-dependent synthesis of all the amino acids, nucleotides, phospholipids, amino sugars, carbohydrates

and growth factors required by the cell for survival and growth.

- *Class III*: anabolic reactions which assemble these small molecules into macromolecules – proteins, RNA, DNA, polysaccharides and peptidoglycan.

Other potential drug targets include *formed structures*, for example, the cell membrane, the *microtubules* in fungi or the neuromuscular junction in helminths. Also, in an era in which biopharmaceuticals are impacting upon the treatment of disease (see **Ch. 5**), we must mention the pathogen genome as a potential target.

In our discussion, emphasis will be placed on bacteria because we have a reasonable understanding of bacterial chemotherapy, but reference will also be made to protozoa, helminths, fungi and viruses.

The molecular basis of antibacterial chemotherapy

- Chemotherapeutic drugs should be toxic to invading organisms and innocuous to the host. Such selective toxicity depends on the identification of biochemical differences between the pathogen and the host that can be appropriately exploited.
- Three general classes of biochemical reaction are potential targets for chemotherapy of bacteria:

- *class I*: biochemical reactions that utilise glucose and other carbon sources to produce ATP and simple carbon compounds
- *class II*: metabolic pathways utilising energy and class I compounds to make small molecules (e.g. amino acids and nucleotides)
- *class III*: anabolic pathways that convert small molecules into macromolecules such as proteins, nucleic acids and peptidoglycan

Biochemical Reactions as Potential Targets

Class I Reactions

Class I reactions are generally not promising targets for two reasons. First, bacterial and human cells use similar mechanisms to obtain energy from glucose (the *Embden–Meyerhof pathway* and the *tricarboxylic acid cycle*). Second, even if glucose oxidation is blocked, many other compounds (amino acids, lactate, etc.) can be utilised by bacteria as an alternative energy source.

Class II Reactions

Class II reactions are better targets because some pathways exist in pathogens, but not in human cells. There are several examples, with one of the most significant being the folate biosynthesis pathway.

Folate biosynthesis and utilisation

Folate is required for DNA synthesis in both bacteria and in humans (see Chs **24** and **52**) but in humans, which have no biosynthetic pathway, it must be obtained from the diet and concentrated in cells

by specific uptake mechanisms. Fortunately for pharmacologists, most species of bacteria, as well as the asexual forms of malarial protozoa, lack these transport mechanisms and therefore must synthesise folate de novo. **Sulfonamides** contain a moiety that is a structural analogue of *p*-aminobenzoic acid (PABA). PABA is essential in bacterial synthesis of folate (see **Ch. 52**) and sulfonamides compete with it, inhibiting bacterial growth without impairing mammalian cell function.

The intracellular utilisation of folate, in the form of *tetrahydrofolate*, as a co-factor in thymidylate synthesis is a good example of a pathway where human and bacterial enzymes exhibit a differential sensitivity to chemicals (**Table 51.1**; see **Volpato and Pelletier, 2009**). Although the pathway is virtually identical in microorganisms and humans, one of the key enzymes, *dihydrofolate reductase*, which reduces dihydrofolate to tetrahydrofolate (see **Ch. 52**), is many times more sensitive to the drug **trimethoprim** in bacteria than in humans. In some malarial protozoa, this enzyme is somewhat less sensitive than the bacterial enzyme to **trimethoprim** but more sensitive to **pyrimethamine** and **proguanil**, which are used as antimalarial agents (see **Ch. 55**). The relative IC_{50} values (the concentration causing 50% inhibition) for bacterial, malarial, protozoal and mammalian enzymes are given in **Table 51.1**. The human enzyme, by comparison, is very sensitive to the effect of the folate analogue **methotrexate**, which is used to treat severe psoriasis (see **Ch. 26**), cancer (see **Ch. 57**) and inflammatory arthritis (see **Ch. 25**), although in the latter case, inhibition of folate metabolism is not its main mode of action.

Treatment with a combination of two drugs that affect the same pathway at different points, for example sulfonamides and the folate antagonists, may be more successful than the use of either alone. Thus pyrimethamine and a sulfonamide (**sulfadoxine**) are used to treat *falciparum* malaria (see **Ch. 55**). **Co-trimoxazole** is an antibacterial formulation that contains both a sulfonamide and **trimethoprim.** Once widely used, this combination has become less popular for treating bacterial infections because **trimethoprim** alone is similarly effective and does not cause sulfonamide-specific adverse effects; its use is now mainly restricted to treatment of *Pneumocystis jirovecii*, an opportunistic infection of immunosuppressed patients such as those with acquired immunodeficiency disease (AIDS) and for which high doses are required (see **Chs 52 and 53**).

Table 51.1

IC_{50}, Concentration causing 50% inhibition.

[a] Tested on *Plasmodium berghei*, a rodent malaria.

Class III Reactions

As pathogens cannot take up their own unique macromolecules, class III reactions are particularly good targets for selective toxicity, and there are sometimes distinct differences between mammalian and parasitic cells in this respect. Once again, there are several examples.

The synthesis of peptidoglycan

The cell wall of bacteria contains *peptidoglycan*, a substance that does not occur in eukaryotes and which contains D-amino acids and unusual sugars. It is the equivalent of a non-stretchable string bag enclosing the whole bacterium. In gram-negative bacteria, this bag consists of a single thickness, but in gram-positive bacteria there may be as many as 40 layers of peptidoglycan. Each layer consists of multiple backbones of amino sugars – alternating *N*-acetylglucosamine and *N*-acetylmuramic acid residues (**Fig. 51.2**) – the latter having short peptide side-chains that are cross-linked to form a polymeric lattice. These may constitute up to 10%–15% of the dry weight of the cell and the lattice is strong enough to resist the high internal osmotic pressure. The cross-links differ in different species. In *staphylococci*, for example, they consist of five glycine residues.

To build up this very large insoluble peptidoglycan layer on the outside of the cell membrane, the bacterial cell has the problem of how to transport the hydrophilic cytoplasmic 'building blocks' through the hydrophobic cell membrane structure. This is accomplished by linking them to a very large lipid carrier, containing 55 carbon atoms, which 'tows' them across the membrane. The process of peptidoglycan synthesis is outlined in **Fig. 51.3**. First, *N*-acetylmuramic acid, attached to uridine diphosphate (UDP) and a pentapeptide, is transferred to the C55 lipid carrier in the membrane, with the release of uridine monophosphate. This is followed by a reaction with UDP–*N*-acetylglucosamine, resulting in the formation of a disaccharide–pentapeptide complex attached to the carrier. This complex is the basic building block of the peptidoglycan. In *Staphylococcus aureus*,

the five glycine residues are attached to the peptide chain at this stage. The building block is now transported out of the cell and added to the growing end of the peptidoglycan, the ‘acceptor’, with the release of the C55 lipid, which still has two phosphates attached. The lipid carrier then loses one phosphate group and thus becomes available for another cycle. Cross-linking between the peptide side-chains of the sugar residues in the peptidoglycan layer then occurs, the hydrolytic removal of the terminal alanine supplying the requisite energy.

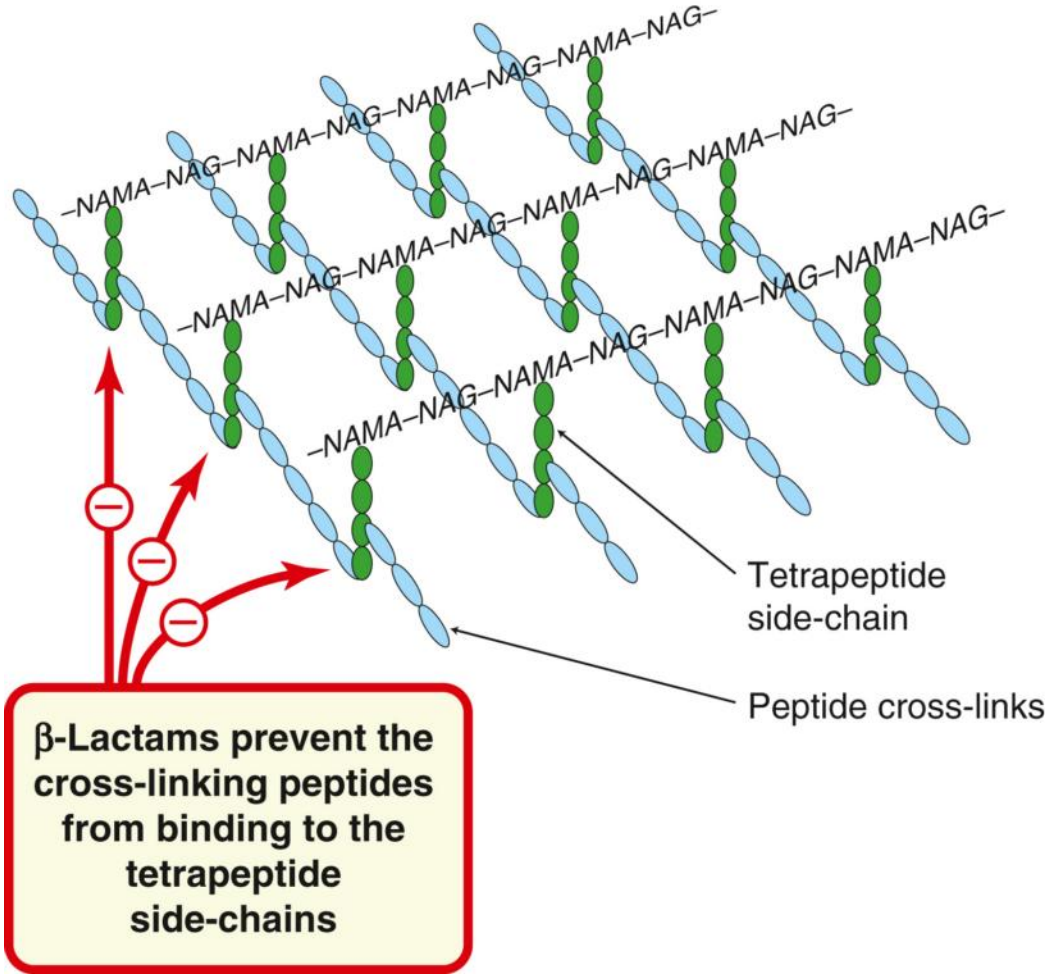

FIG. 51.2 Schematic diagram of a single layer of peptidoglycan from a bacterial cell (e.g. *Staphylococcus aureus*), showing the site of action of the β-lactam antibiotics. In *S. aureus* the peptide cross-links consist of five glycine residues. Gram-positive bacteria have several layers of peptidoglycan. More detail in **Fig. 51.3**. *NAG*, *N*-Acetylglucosamine; *NAMA*, *N*-acetylmuramic acid.

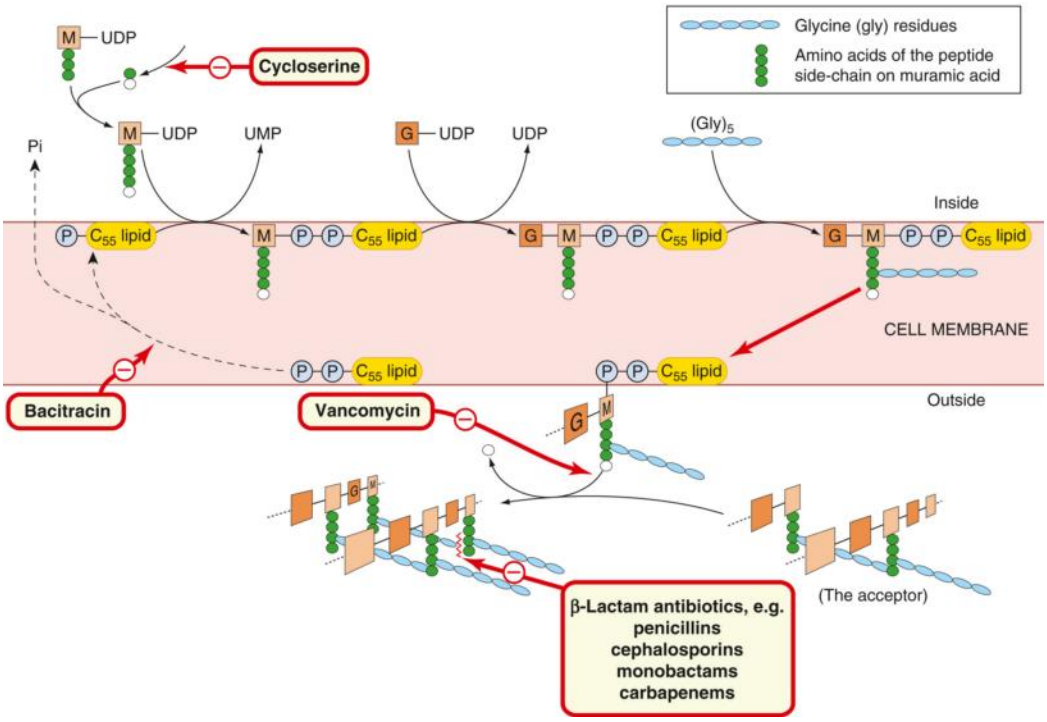

FIG. 51.3 Schematic diagram of the biosynthesis of peptidoglycan in a bacterial cell (e.g. *Staphylococcus aureus*), with the sites of action of various antibiotics. The hydrophilic disaccharide–pentapeptide is transferred across the lipid cell membrane attached to a large lipid (C_{55} lipid) by a pyrophosphate bridge (–P–P–). On the outside, it is enzymically attached to the 'acceptor' (the growing peptidoglycan layer). The final reaction is a transpeptidation, in which the loose end of the (Gly) 5 chain is attached to a peptide side-chain of an M in the acceptor and during which the terminal amino acid (alanine) is lost. The lipid is regenerated by loss of a phosphate group (Pi) before functioning again as a carrier. *G, N*-Acetylglucosamine; *M, N*-

acetylmuramic acid; *UDP,* uridine diphosphate; *UMP,* uridine monophosphate.

This synthesis of peptidoglycan is a vulnerable step and can be blocked at several points by antibiotics (see **Fig. 51.3** and **Ch. 52**). Cycloserine, which is a structural analogue of D-alanine, prevents the addition of the two terminal alanine residues to the initial tripeptide side-chain on *N*-acetylmuramic acid by competitive inhibition. **Vancomycin** inhibits the release of the building block unit from the carrier, thus preventing its addition to the growing end of the peptidoglycan. **Bacitracin** interferes with the regeneration of the lipid carrier by blocking its dephosphorylation. Penicillins, cephalosporins and other β-lactams inhibit the final transpeptidation by forming covalent bonds with *penicillin-binding proteins* that have transpeptidase and carboxypeptidase activities, thus preventing formation of the cross-links.

Protein synthesis

Another very important class III target is protein synthesis. This takes place at the ribosomes, but eukaryotic and prokaryotic ribosomes are different, and this provides the basis for the selective action of some antibiotics. The bacterial ribosome consists of a 50S subunit and a 30S subunit (**Fig. 51.4**), whereas in the mammalian ribosome the subunits are 60S and 40S. The other elements involved in peptide synthesis are messenger RNA (mRNA), which forms the template for protein synthesis, and transfer RNA (tRNA), which specifically transfers the individual amino acids to the ribosome. The ribosome has three binding sites for tRNA, termed the *A, P* and *E sites*. Notably, the final peptidyl transferase reaction

by which the growing peptide chain is extended is catalysed not by a protein, but a *ribozyme*. This means that, unlike the vast majority of other drugs, the antibiotics in question act upon a polynucleotide, rather than a protein target.

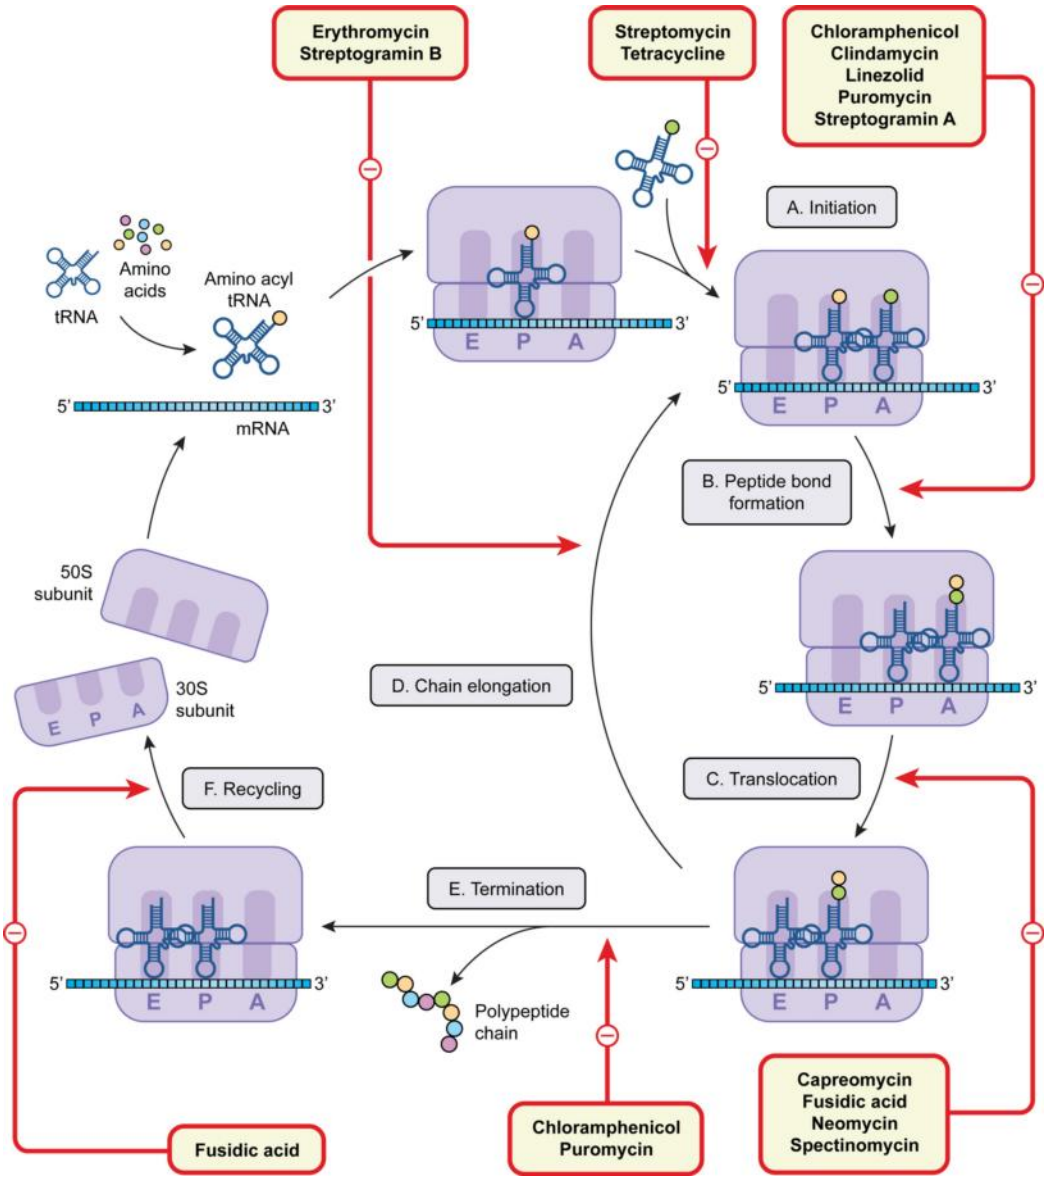

FIG. 51.4 Schematic diagram of bacterial protein synthesis, indicating the points at which some common antibiotics inhibit the process.mRNA is attached to the assembled ribosomes; amino acids, bound to their corresponding aminoacyl tRNA carriers, are attached to the *P* site of the 30S subunit and at (A) the dipeptide is linked together by the

aminoacyl tRNA synthase ribozyme at the *A* site on the ribosome (B). The mRNA molecule then translocates, moving the dipeptide to the *P* site. The 'empty' tRNA is then released. This process of chain elongation (D) continues until a stop codon is reached. At this point (E) the nascent polypeptide is released, the ribosomal apparatus dissociates, and the components are recycled (F) to begin again. Note that some antibiotics can act at several points in the process. For the sake of simplicity, cofactors in this process have been omitted. Adapted and modified from Wilson, D.N., 2014. Ribosome-targeting antibiotics and mechanisms of bacterial resistance. Nat. Rev. Microbiol. 12, 35–48.

In a technical tour de force in 2000, the complete fine structure of the bacterial 30S subunit was elucidated (**Carter et al., 2000**, and others), earning a Nobel Prize for Venki Ramakrishnan, Thomas Steitz and Ada Yonath in 2009. This, together with other work (reviewed in **Wilson, 2014**), provided fresh information about the detailed site of action of antibiotics and providing new leads for antibiotic research and discovery.

A highly simplified version of the ribosomal protein synthesis system in bacteria and the sites of action of some antibiotics are shown in **Fig. 51.4**. To initiate translation, mRNA, transcribed from the DNA template, is attached to the 30S subunit of the ribosome. The 50S subunit then binds to the 30S subunit to form a 70S subunit, [3] which moves along the mRNA such that successive

codons of the messenger pass along the ribosome from the A position to the P position.

Nucleic acid synthesis

Gene expression and cell division also require nucleic acid synthesis, and this class III reaction is an important site of action of many chemotherapeutic drugs as well as some biopharmaceuticals. It is possible to interfere with nucleic acid synthesis in several different ways:

- by inhibiting the synthesis of nucleotides;
- by altering the base-pairing properties of the DNA template;
- by inhibiting either DNA or RNA polymerase;
- by inhibiting DNA gyrase, which uncoils supercoiled DNA to allow transcription;
- by interfering with the transcription of microbial genes;
- by a direct effect on DNA itself. Some anticancer (but no antimicrobial) drugs work in this way.

Inhibition of the synthesis of nucleotides

This can be accomplished by an effect on the metabolic pathways that generate nucleotide precursors. Examples of agents that have such an effect have been described under class II reactions.

Alteration of the base-pairing properties of the template

Agents that intercalate in the DNA have this effect. Examples include acridines (**proflavine** and **acriflavine**), which are used topically as antiseptics. The acridines double the distance between

adjacent base pairs and cause a *frameshift mutation*, whereas some purine and pyrimidine analogues cause base *mispairing*.

Inhibition of either DNA or RNA polymerase

Specific inhibitors of bacterial RNA polymerase that act by binding to this enzyme in prokaryotic, but not in eukaryotic, cells include **rifamycin** and **rifampicin**, which are particularly useful for treating tuberculosis (see **Ch. 52**). **Aciclovir** (an analogue of guanine) is phosphorylated in cells infected with herpes virus, the initial phosphorylation being by a virus-specific kinase to give the active metabolite **aciclovir trisphosphate**, which inhibits the DNA polymerase of the herpes virus (see **Ch. 53**).

RNA retroviruses have a *reverse transcriptase* (viral RNA-dependent DNA polymerase) that copies the viral RNA into DNA that then integrates into the host cell genome as a *provirus*. Antiviral drugs such as **zidovudine** and **didanosine** are phosphorylated by cellular enzymes to the trisphosphate forms, which compete with the host cell precursors essential for the formation by the viral reverse transcriptase of proviral DNA.

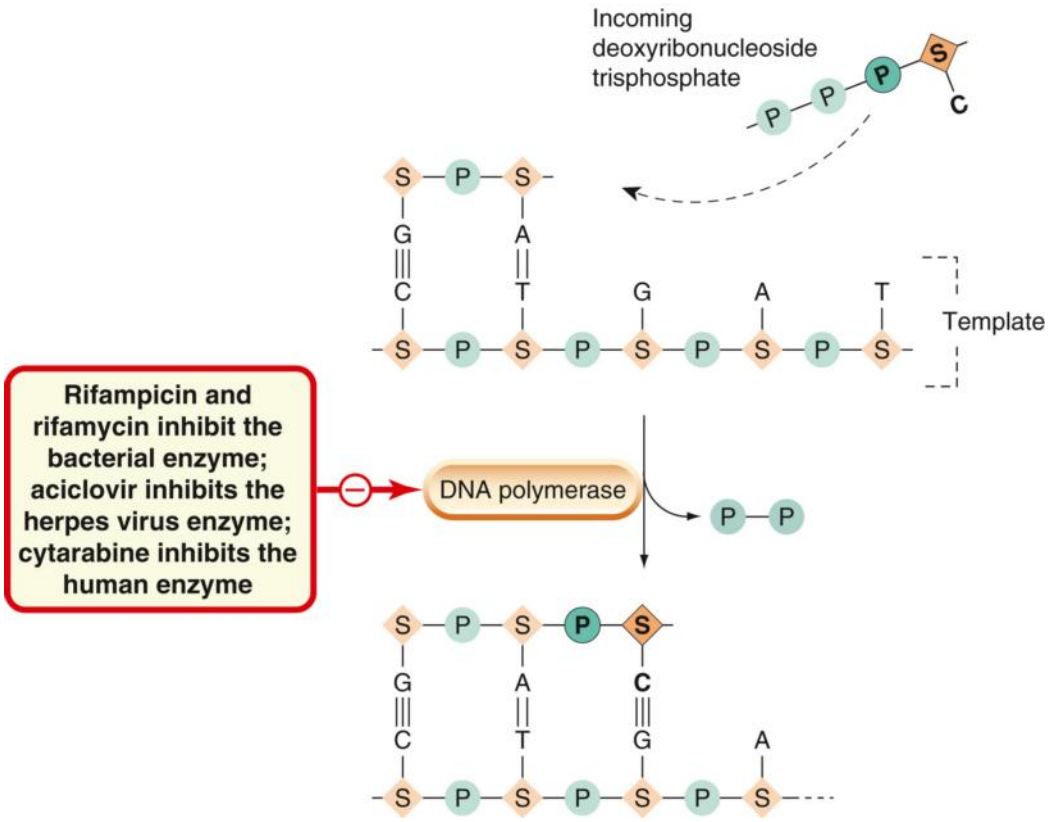

FIG. 51.5 Schematic diagram of DNA replication, showing some antibiotics that inhibit it by acting on DNA polymerase. Nucleotides are added, one at a time, by base pairing to an exposed template strand, and are then covalently joined together in a reaction catalysed by DNA polymerase. The units that pair with the complementary residues in the template consist of a base linked to a sugar and three phosphate groups. Condensation occurs with the elimination of two phosphates. The elements added to the template are shown in *darker colours* and *bold type*. *A*, Adenine; *C,* cytosine; *G*, guanine; *P,* phosphate; *S,* sugar; *T,* thymine.

Interfering with the transcription of microbial genes

RNA-based biopharmaceuticals (see **Ch. 5**) such as antisense agents have been used to prevent viral replication. For example, the anti-cytomegalovirus drug **fomivirsen** blocks transcription of a key gene for the viral protein IE2. This halts the progress of cytomegalovirus retinitis, although it was subsequently withdrawn for commercial reasons.

Inhibition of DNA gyrase

Fig. 51.6 is a simplified scheme showing the functional action of DNA gyrase. The *fluoroquinolones* (**cinoxacin**, **ciprofloxacin**, **nalidixic acid** and **norfloxacin**) act by inhibiting DNA gyrase and are selective for the bacterial enzyme. These chemotherapeutic agents are particularly useful for treating infections with gram-negative organisms (see **Ch. 52**).

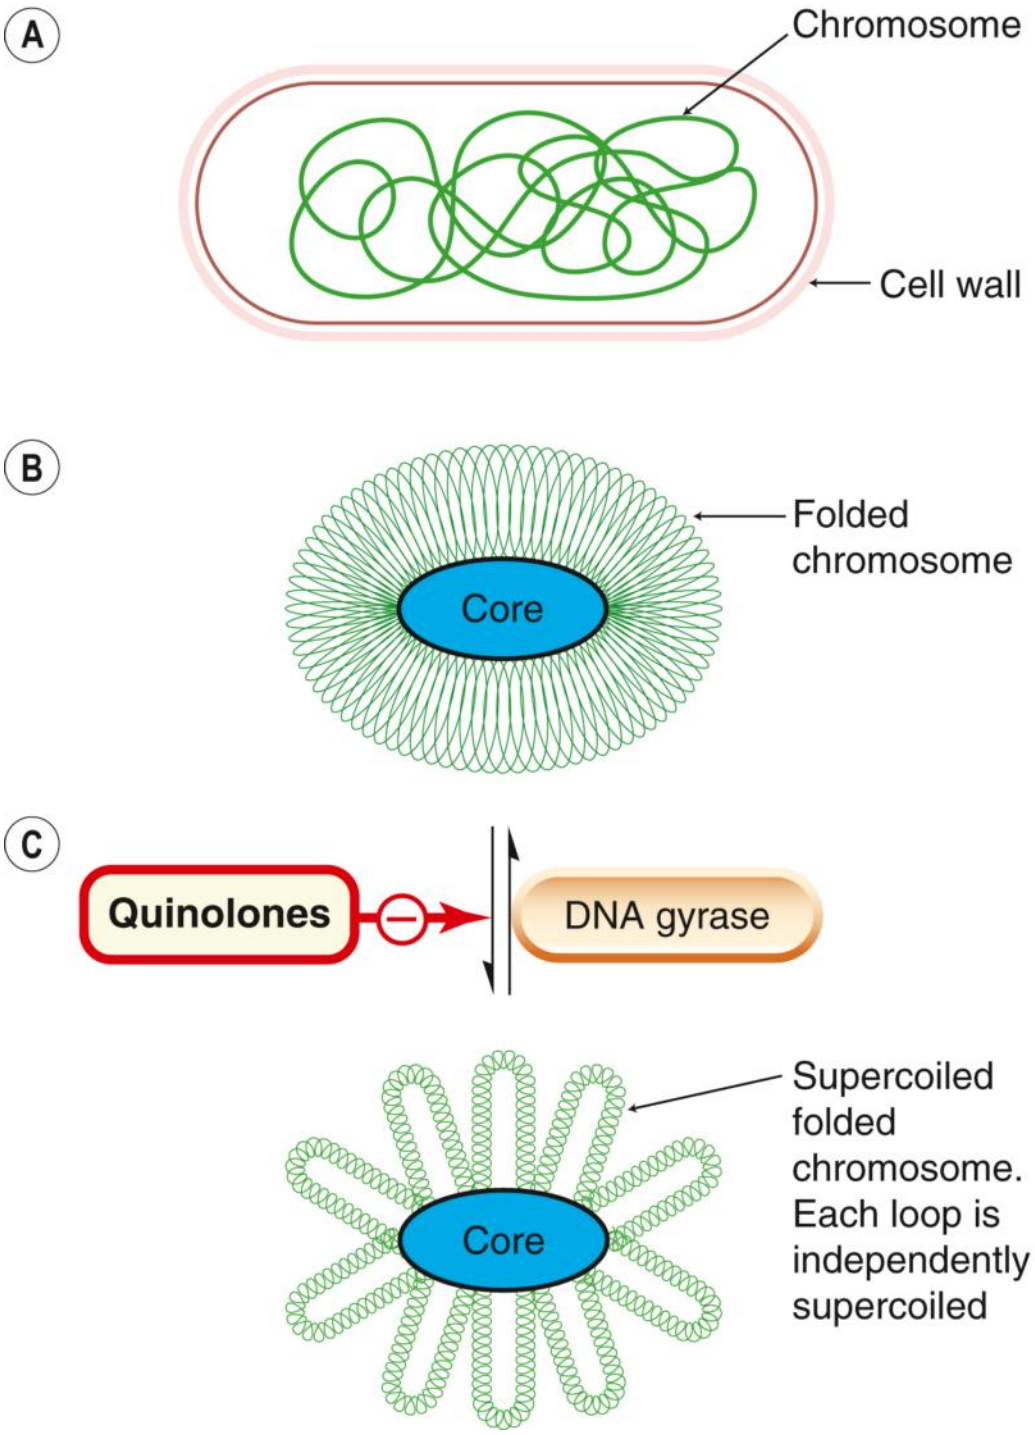

FIG. 51.6 Schematic diagram of the action of DNA gyrase: the site of action for quinolone antibacterials. (A) Conventional diagram used to depict a bacterial cell and chromosome (e.g.

Escherichia coli). Note that the *E. coli* chromosome is 1300 mm long and is contained in a cell envelope of 2 μm × 1 μm; this is approximately equivalent to a 50 m length of cotton folded into a matchbox. (B) Chromosome folded around RNA core, and then (C) supercoiled by DNA gyrase (topoisomerase II). Quinolone antibacterials interfere with the action of this enzyme. Modified from Smith, J.T., 1985. In: Greenwood, D., O'Grady, F. (Eds). Scientific Basis of Antimicrobial Therapy. Cambridge University Press, Cambridge, p. 69.

The Formed Structures of The Cell as Potential Targets

The Membrane

Several important antimicrobials act on cell membranes. The plasma membrane of bacterial cells is similar to that in mammalian cells in that it consists of a phospholipid bilayer in which proteins are embedded, but it can be more easily disrupted in certain bacteria and fungi.

Polymyxins are cationic peptide antibiotics, containing both hydrophilic and lipophilic residues, which have a selective effect on bacterial cell membranes. They act as detergents, disrupting the phospholipid components of the membrane structure, thus killing the cell.

Unlike mammalian and bacterial cells, fungal cell membranes contain large amounts of *ergosterol*. This facilitates the attachment

of *polyene antibiotics* (e.g. **nystatin** and **amphotericin**; see **Ch. 54**), which act as ionophores and cause leakage of cations from the cytoplasm.

Azoles such as **itraconazole** kill fungal cells by inhibiting ergosterol synthesis, thereby disrupting the function of membrane-associated enzymes. The azoles also affect gram-positive bacteria, their selectivity being associated with the presence of high levels of free fatty acids in the membrane of susceptible organisms (see **Ch. 54**).

Biochemical reactions as potential targets for chemotherapy

- Class I reactions are poor targets.
- Class II reactions are better targets:
  - *folate synthesis* in bacteria is inhibited by sulfonamides;
  - *folate utilisation* is inhibited by folate antagonists, for example **trimethoprim** (bacteria), **pyrimethamine** (malarial parasite).
- Class III reactions are important targets:
  - *peptidoglycan synthesis* in bacteria can be selectively inhibited by β-lactam antibiotics (e.g. **penicillin**);
  - *bacterial protein synthesis* can be selectively inhibited by antibiotics that prevent binding of tRNA (e.g. tetracyclines), promote misreading of mRNA (e.g., aminoglycosides), inhibit transpeptidation (e.g. **chloramphenicol**) or inhibit translocation of tRNA (e.g. **erythromycin**); antisense RNA biopharmaceuticals

can selectively prevent the expression of particular proteins;

– *nucleic acid synthesis* can be inhibited by altering base pairing of DNA template (e.g. the antiviral **vidarabine**), by inhibiting DNA polymerase (e.g. the antivirals **aciclovir** and **foscarnet**) or by inhibiting DNA gyrase (e.g. the antibacterial **ciprofloxacin**).

Intracellular Organelles

Mitochondria

Mitochondria probably originated as a result of a symbiotic relationship between a prokaryotic and a eukaryotic cell during evolution. Since prokaryotes do not contain mitochondria, drugs such as **atovaquone** (see **Ch. 55**) that target these organelles in parasites are ineffective in bacteria. However, they can damage the host mitochondria, and this can contribute to the host toxicity encountered during their use.

Microtubules and/or microfilaments

The benzimidazoles (e.g. **albendazole**) exert their antihelminthic action by binding selectively to parasite tubulin and preventing microtubule formation (see **Ch. 56**).

Food vacuoles

The erythrocytic form of the malaria plasmodium feeds on host haemoglobin, which is digested by proteases in the parasite food vacuole, the final product, haem, being detoxified by

polymerisation. **Chloroquine** and several other antimalarials exert their antimalarial actions by inhibiting plasmodial haem polymerase (see **Ch. 55**).

Ion channels and receptors

Some antihelminthic drugs have a selective action on helminth muscle cells (see **Ch. 56**). **Piperazine** acts as an agonist on parasite-specific chloride channels gated by GABA in nematode muscle, hyperpolarising the muscle fibre membrane and paralysing the worm; avermectins increase Cl^- permeability in helminth muscle – possibly by a similar mechanism. **Pyrantel** and **levamisole** are agonists at nematode acetylcholine nicotinic receptors on muscle, causing contraction followed by paralysis (see **Ch. 56**).

Formed structures of the cell that are targets for chemotherapy

- The bacterial cell wall may be affected by several classes of antibiotics, including the β-lactams.
- The plasma membrane is affected by:
  - **amphotericin**, which acts as an ionophore in fungal cells
  - azoles, which inhibit fungal membrane ergosterol synthesis
- Microtubule function is disrupted by:
  - benzimidazoles (antihelminthics)
- Muscle fibres are affected by:

– avermectins (antihelminthics), which increase Cl^- permeability
– **pyrantel** (antihelminthic), which stimulates nematode nicotinic receptors, eventually causing muscle paralysis by depolarising neuromuscular block

Resistance to Antibacterial Drugs

The development and use of sulfonamides in the 1930s, and of antibiotics proper in the 1940s, to treat bacterial and other infections have revolutionised medical treatment, and the morbidity and mortality associated with these diseases have been dramatically reduced. Unfortunately, this welcome development has been accompanied by the spread of drug-resistant organisms and, with it, the fear that we are moving towards a 'post antibiotic' era. It is worth noting here that 'resistance' to therapeutic intervention is a general problem which is not restricted to antibiotics: vaccines too can lose efficacy either because of mutation and natural selection within the target organisms or random 'antigenic drift'.

The WHO has termed antimicrobial (especially antibiotic) resistance '…one of the biggest threats to global health, food security, and development today' and the growing concern has prompted several supra-national and domestic political responses. The WHO has formulated a *Global Action Plan on Antibiotic Resistance* and regularly issues updated fact sheets on the problem. Other organisations supported by the WHO include the *Global Antibiotic Resistance Development Partnership* (GARDP), the *Global Antimicrobial Resistance Surveillance System* (GLASS) and

the *Interagency Coordination Group on Antimicrobial Resistance* (IACG). These bodies have been monitoring the emergence of resistant strains around the world since 2009 and advising on local treatment strategies. There have been domestic initiatives too: in the United States, a national action plan was announced in 2015 and many other countries have introduced similar, if less formal, strategies to implement the advice arising from the WHO, GARDP and other organisations. Developing countries often struggle to introduce such measures and, because they are often burdened with large numbers of immunocompromised patients, lack of access to clean water, drugs and healthcare systems, lack of enforceable policies, poor hygiene and infection control, poverty and overcrowding, are (as always) faring less well.

So, what is the cause of this problem? The prevailing view used to be that antibiotic resistance was a phenomenon unique to our age and which arose largely through human mismanagement of antibiotic resources. This 'anthropogenic' view seemed to be supported by the relative absence of resistance elements in samples of bacteria taken from remote locations (such as the Galapagos islands) or from ancient samples that predated the antibiotic era. On the other hand, sequencing of recovered DNA from Pleistocene fossils (around 30,000 years old) suggested that at least some of the antibiotic resistance elements had a very ancient origin (see **Bhullar et al., 2012**). This presumption was dramatically confirmed by (among others) the discovery, in New Mexico, of multidrug-resistant bacteria in a deep cave system, which had been isolated from human and animal contact for 4–7 million years (**Bhullar et al., 2012**). A detailed analysis of one of the species

recovered, *Paenibacillus*, which is resistant to most clinically used antibiotics, found that resistance genes in this bacterium had evidently been conserved for millions of years. Not only that, but this study also uncovered several hitherto-unknown resistance mechanisms (**Pawlowski et al., 2016**).

Interestingly, while resistance to naturally occurring antibiotics (e.g. penicillin) was extensive among these organisms, little resistance to synthetic drugs such as **linezolid** was observed. Furthermore, none of these genes were expressed in samples of this bacterium collected from the nearby cave surface, suggesting that the organisms in the cave expressed these under some selection pressure. Findings such as these have led to a reappraisal of the origin and role of the bacterial 'resistome' (the pool of genes involved in antibiotic resistance) and the issue of antibiotic resistance in general and it is now clear that we have to take a more nuanced view of the problem.

Many clinically used antibiotics are complex, naturally occurring chemicals derived from bacteria or fungi. These are released as part of a defensive strategy by these organisms. Obviously, organisms which release antibiotics must also protect themselves against the effects of these substances, perhaps explaining, at least in part, why the resistome is so significant in soil-dwelling organisms. In addition, it is now thought that these endogenous antibiotics together with their resistance mechanisms may also have a 'physiological' role: perhaps regulating metabolic pathways, acting as communication molecules or as part of bacterial 'quorum sensing' mechanisms. [4] Many of the resistance genes are located on mobile elements of DNA, and transfer between organisms in the

soil by *horizontal gene transfer* (as opposed to the *vertical gene transfer* that occurs during reproduction) is common. This in part explains why the incidence of resistance is high in sites where bacteria proliferate and antibiotic usage is high, such as in agriculture or in hospitals.

Under the 'selection pressure' of intense clinical usage (and especially *mis*-usage) of antibiotics, multiple resistance elements have accumulated in pathogens. This obviously imposes serious constraints on the options available for the medical treatment of many bacterial infections. While resistance to chemotherapeutic agents can also develop in protozoa and multicellular parasites (and in populations of malignant cells; see **Ch. 57**), we will confine our discussion here mainly to the mechanisms of resistance in bacteria as this is the most studied.

The Spread of Antibiotic Resistance

Antibiotic resistance may be *innate* – pre-existing in a particular strain – or *acquired* in some way from other bacterial cells. In either case, *natural selection* works to favour resistant strains when the antibiotic is prevalent in the environment. Fundamental to the whole issue is how bacterial resistance genes are moved around between chromosomal DNA and mobile elements both *within* and *between* bacteria.

Several basic mechanisms have been identified:

- By transfer of resistance genes between genetic elements *within* bacteria, on transposons.
- By transfer of resistance genes *between* bacteria by mobile elements (such as plasmids).

- By transfer of resistant bacteria between people or animals.

An understanding of these mechanisms is crucial for the sensible clinical use of existing medicines ('antibiotic stewardship') as well as in the design of new antibacterial drugs. We look first at the mechanisms whereby genetic information can be exchanged and then at how these transferred genes undermine the activity of antibiotics.

Movement Of Genetic Information

Plasmids and mobile elements

In addition to chromosomal DNA, many species of bacteria contain *extrachromosomal* genetic elements called plasmids that exist free in the cytoplasm. These genetic elements can replicate independently. Structurally, they are closed loops of DNA that may comprise a single gene, as many as 500, or in some cases even more. Only a few plasmid copies may exist in the cell, but often multiple copies are present, and there may also be more than one type of plasmid in each bacterial cell. Plasmids that carry genes for resistance to antibiotics (*r genes*) are referred to as *R plasmids*. Much of the drug resistance encountered in clinical medicine is plasmid-determined.

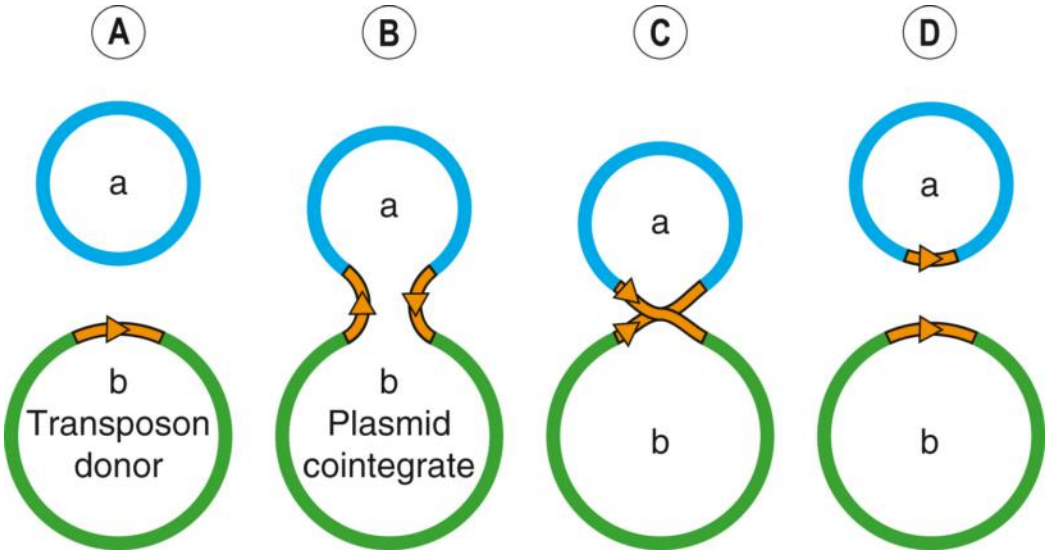

FIG. 51.7 An example of the transfer and replication of a transposon (which may carry genes coding for resistance to antibiotics). (A) Two plasmids, *a* and *b*, with plasmid *b* containing a transposon *(shown in brown)*. (B) An enzyme encoded by the transposon cuts DNA of both donor plasmid and target plasmid a to form a cointegrate. During this process, the transposon replicates. (C) An enzyme encoded by the transposon resolves the cointegrate. (D) Both plasmids now contain the transposon DNA.

The whole process can occur with frightening speed. *S. aureus*, for example, is a past master of the art of antibiotic resistance. Having become completely resistant to **penicillin** through plasmid-mediated mechanisms, this organism, within only 1–2 years, was able to acquire resistance to its β-lactamase-resistant (see later) descendant, **meticillin** (**de Lencastre et al., 2007**).

Transposons

Some stretches of DNA are readily transferred (transposed) from one plasmid to another and also from plasmid to chromosome or vice versa. [5] This is because integration of these segments of DNA, which are called *transposons*, into the acceptor DNA can occur independently of the normal mechanism of homologous genetic recombination. Unlike plasmids, transposons are not able to replicate independently, although some may replicate during the process of integration (**Fig. 51.7**), resulting in a copy in both the donor and the acceptor DNA. Transposons may carry one or more resistance genes and can 'hitch-hike' on a plasmid to a new species of bacterium. Even if the plasmid is unable to replicate in the new host, the transposon may integrate into its chromosome or into its indigenous plasmids. This probably accounts for the widespread distribution of certain resistance genes on different R plasmids and among unrelated bacteria.

Gene cassettes and integrons

Plasmids and transposons do not complete the tally of mechanisms that natural selection has provided to confound the hopes of the microbiologist/chemotherapist. Resistance – in fact, multidrug resistance – can also be spread by another mobile element, the *gene cassette*, which consists of a resistance gene attached to a small recognition site. Several cassettes may be packaged together in a *multi-cassette array*, which can, in turn, be integrated into a larger mobile DNA unit termed an *integron*. The integron (which may be located on a transposon) contains a gene for an enzyme, *integrase* (recombinase), which inserts the cassette(s) at unique sites into the

host DNA. This system – transposon/integron/multi-resistance cassette array – allows particularly rapid and efficient transfer of multidrug resistance between genetic elements both within and between bacteria.

The Transfer of Resistance Genes Between Bacteria

Horizontal gene transfer between bacteria of the same, or indeed of different, species is considered the most significant mechanism whereby antibiotic resistance is spread. There are several important mechanisms including conjugation, transduction, transformation and vesiduction, with the former being the most important. These mechanisms have assumed new significance in the light of the discovery that antibiotic resistance genes are abundant in the environment especially in the soil, in wastewater and in agricultural waste.

Conjugation

Conjugation is the main mechanism for the spread of resistance genes. It involves cell-to-cell contact during which chromosomal or extrachromosomal DNA is transferred from one bacterium to another. The ability to conjugate is encoded in *conjugative plasmids*: these are plasmids that contain transfer genes that, in (for example) coliform bacteria, code for the production by the host bacterium of proteinaceous surface tubules termed *sex pili*, which connect the two cells. The conjugative plasmid then passes across from one bacterial cell to another (generally of the same species).

Many gram-negative and some gram-positive bacteria can conjugate. Some promiscuous plasmids can even cross the species barrier, adopting one host as readily as another. Many R plasmids

are conjugative. Non-conjugative plasmids, if they co-exist in a 'donor' cell with conjugative plasmids, can hitchhike from one bacterium to the other with the conjugative plasmids. The transfer of resistance by conjugation is particularly significant in populations of bacteria that are normally found at high densities, as in the gut.

Transduction

Transduction is a process by which plasmid DNA is enclosed in a virus that infects bacteria (termed a *phage*) and transferred to another bacterium of the same species. It is a relatively ineffective means of transfer of genetic material but is clinically important in the transmission of resistance genes between strains of *staphylococci* and of *streptococci*.

Transformation

Under natural conditions a few species of bacteria can undergo transformation by taking up DNA from the environment and incorporating it into their genome by normal homologous recombination. Astonishingly, bacteria able to do this can import just a single strand of the DNA through special pili on their surface, subsequently degrading the unwanted strand (**Ellison et al., 2018**).

Vesiduction

Another, recently proposed mechanism for DNA transfer is termed *vesiduction* (**Soler and Forterre, 2020**). This refers to a well-studied process whereby vesicles containing various cargoes are released from (e.g.) bacterial cells and fuse with the membranes of

nearby cells releasing their contents intracellularly. Notably, this can occur between cells of different species, including from prokaryote to eukaryote. These vesicles can include DNA and thus can spread their genetic payload.

Resistance to antibiotics

- Antibiotic resistance is a naturally occurring phenomenon which plays a role in the normal bacterial ecology.
- In many bacterial species, resistance genes (*r* genes) are of ancient origin and are normally expressed in the presence of the antibiotic.
- R genes may be moved around between genetic elements within individual bacteria. There are several mechanisms:
  - Plasmids are extrachromosomal genetic elements that can replicate independently and can carry genes coding for resistance to antibiotics.
  - Transposons are stretches of DNA that can be transposed from one plasmid to another, from a plasmid to a chromosome or vice versa. A plasmid containing an r gene–bearing transposon may code for enzymes that cause the plasmid to be integrated with another. Following their separation, this transposon replicates so that both plasmids then contain the r gene.
- R genes, including *multi-cassette arrays* of drug resistance genes, can also be transferred to other bacteria of the same, or different, species. There are several mechanisms:

– The main method of transfer of r genes from one bacterium to another is by conjugative plasmids. The bacterium forms a connecting tube with other bacteria through which the plasmids pass.
– A less common method of transfer is by transduction, i.e. the transmission by a bacterial virus (phage) of a plasmid bearing an r gene into another bacterium.

Chromosomal Mutations

The spontaneous mutation rate in bacterial populations for any particular gene is very low: only approximately one cell in 10 million will bear a mutation and pass it on. However, as there are likely to be very many more cells than this over the course of an infection, the probability of a mutation causing a change from drug sensitivity to drug resistance can be quite high. Fortunately, the presence of a few mutants is not generally sufficient to produce resistance: despite the selective advantage that the resistant mutants possess, the drastic reduction of the population by the antibiotic usually enables the host's natural defences (see **Ch. 7**) to prevail at least in acute, if not chronic, infections. However, the outcome may not be quite so desirable if the primary infection is caused by a drug-resistant strain.

Gene Amplification

Gene duplication and *amplification* are important mechanisms for resistance in some organisms (**Sandegren and Andersson, 2009**). According to this idea, treatment with antibiotics can induce

an increased number of copies for pre-existing resistance genes such as antibiotic-destroying enzymes and efflux pumps.

Biochemical Mechanisms of Resistance to Antibiotics

Resistance genes are translated into proteins that subvert the action of antibiotics in several ways. Here we discuss several of these, but new mechanisms are constantly being uncovered (**Pawlowski et al., 2016**). **Fig. 51.8** illustrates the main mechanisms by which resistance can occur.

The Production of Enzymes That Inactivate Drugs

Inactivation of β-lactam antibiotics

Perhaps the most important example of resistance caused by inactivation is that of the β-lactam antibiotics. The enzymes concerned are *β-lactamases*, which cleave the β-lactam ring of penicillins and cephalosporins (see **Ch. 52**). Cross-resistance between the two classes of antibiotic is not complete, because some β-lactamases have a preference for penicillins and some for cephalosporins.

Staphylococci are the principal bacterial species producing β-lactamase, and the genes coding for the enzymes are on plasmids that can be transferred by transduction. In this species, the enzyme is inducible and is barely expressed in the absence of the drug. Minute, sub-inhibitory, concentrations of antibiotics de-repress the gene and result in a 50- to 80-fold increase in expression. The enzyme passes through the bacterial envelope and inactivates antibiotic molecules in the surrounding medium. The grave clinical

problem posed by resistant staphylococci secreting β-lactamase was tackled by developing semisynthetic penicillins (such as **meticillin**) and new β-lactam antibiotics (the monobactams and carbapenems), and cephalosporins (such as **cefamandole**), that are less susceptible to inactivation. In addition to acquiring resistance to β-lactams, some strains of *S. aureus* have even become resistant to some antibiotics that are not significantly inactivated by β-lactamase (e.g. **meticillin**), because they express an additional β-lactam-binding protein coded for by a mutated chromosomal gene. See **Lambert (2005)** for other examples of this type of action.

Gram-negative organisms can also produce β-lactamases, and this is a significant factor in their resistance to the semisynthetic broad-spectrum β-lactam antibiotics. In these organisms, the enzymes may be coded by either chromosomal or plasmid genes. In the former case, the enzymes may be inducible, but in the latter, they are produced constitutively. When this occurs, the enzyme does not inactivate the drug in the surrounding medium but instead remains attached to the cell wall, preventing access of the drug to membrane-associated target sites. Many of these β-lactamases are encoded by transposons, some of which may also carry resistance determinants to several other antibiotic classes.

Inactivation of chloramphenicol

Chloramphenicol is inactivated by *chloramphenicol acetyltransferase*, an enzyme produced by resistant strains of both gram-positive and gram-negative organisms, the resistance gene being plasmid borne. In gram-negative bacteria, the enzyme is produced constitutively, resulting in levels of resistance five-fold

higher than in gram-positive bacteria, in which the enzyme is inducible.

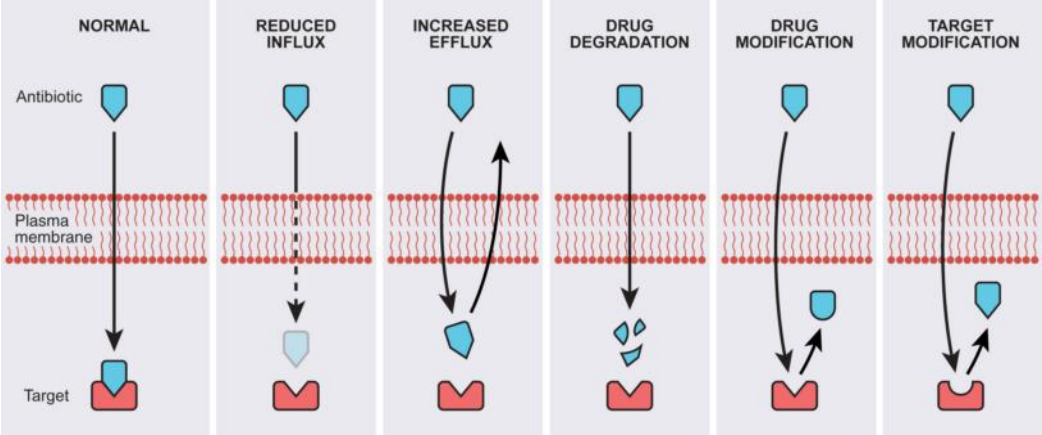

FIG. 51.8 The principal mechanisms of biochemical resistance to antibiotics. Adapted and modified from Wilson, D.N., 2014. Ribosome-targeting antibiotics and mechanisms of bacterial resistance. Nat. Rev. Microbiol. 12, 35–48.

Inactivation of aminoglycosides

Aminoglycosides are inactivated by phosphorylation, adenylation or acetylation, and the requisite enzymes are found in both gram-negative and gram-positive organisms. The resistance genes are carried on plasmids, and several are found on transposons. Many other examples of this kind are given by **Wright (2005)** and **Giedraitiene et al. (2011)**.

Alteration of Drug-Binding Site

The aminoglycoside-binding site on the 30S subunit of the ribosome may be altered by chromosomal mutation. A plasmid-mediated alteration of the binding site protein on the 50S subunit also underlies resistance to **erythromycin**, and decreased binding of fluoroquinolones because of a point mutation in DNA gyrase A has also been described. An altered DNA-dependent RNA polymerase determined by a chromosomal mutation is reported to be the basis for **rifampicin** resistance.

Decreased Accumulation of Drugs by Bacteria

An important example of decreased drug accumulation is the plasmid-mediated resistance to tetracyclines encountered in both gram-positive and gram-negative bacteria. In this case, resistance genes in the plasmid code for inducible protein pumps in the bacterial membrane, which promote energy-dependent efflux of the tetracyclines, and hence resistance. This type of resistance is common and has greatly reduced the therapeutic value of the tetracyclines in human and veterinary medicine. Resistance of *S. aureus* to **erythromycin** and other macrolides, and to fluoroquinolones, is also brought about by energy-dependent efflux. Notably, these pumps may be selective for one antibiotic class or may be more promiscuous in their action – an important problem in multidrug resistance of cancer cells (see **Ch. 57**). Inhibitors of such pumps may be useful adjuncts to antibiotics (**Thakur et al., 2021**) .

There is also recent evidence of plasmid-determined inhibition of porin synthesis, which could affect those hydrophilic antibiotics that enter the bacterium through these water-filled channels in the

outer membrane. Altered permeability as a result of chromosomal mutations involving the polysaccharide components of the outer membrane of gram-negative organisms may also confer enhanced resistance to ampicillin. Mutations affecting envelope components have been reported to affect the accumulation of aminoglycosides, β-lactams, **chloramphenicol**, peptide antibiotics and **tetracycline**.

Alteration of Enzyme Selectivity

Resistance to **trimethoprim** is the result of plasmid-directed synthesis of a *dihydrofolate reductase* with low or zero affinity for trimethoprim. It is transferred by transduction and may be spread by transposons.

Sulfonamide resistance in many bacteria is plasmid mediated and results from the production of a form of *dihydropteroate synthetase* with a low affinity for sulfonamides but no change in affinity for PABA. Bacteria causing serious infections and carrying plasmids with resistance genes to both sulfonamides and **trimethoprim** have been reported.

Biochemical mechanisms of resistance to antibiotics

The principal mechanisms are as follows:

- *Production of enzymes that inactivate the drug*: for example, β-lactamases, which inactivate **penicillin**; acetyltransferases, which inactivate **chloramphenicol**; kinases and other enzymes, which inactivate aminoglycosides.

- *Alteration of the drug-binding sites*: this occurs with aminoglycosides, **erythromycin**, **penicillin.**
- *Reduction of drug uptake by the bacterium or enhanced efflux*: for example, tetracyclines.
- *Alteration of enzyme sensitivity*: for example, dihydrofolate reductase becomes insensitive to **trimethoprim.**

Current Status of Antibiotic Resistance in Bacteria

The latest WHO assessment (2020) stresses that antibiotic resistance is now found in every country. Estimates of the global burden of this problem vary but one (Antibiotic Research UK) cites a figure of 700,000 deaths per annum rising to 10 million by 2050. Without effective antibiotics, many routine surgical procedures and other medical interventions are impossible. The WHO also highlights the following cases as being of special significance:

- *Klebsiella pneumoniae*. Resistance of this intestinal organism to 'last-resort' antibiotics such as carbapenem drugs has spread around the world and in many countries, treatment fails in about half of all cases.
- *Escherichia coli*. In many countries this organism has become resistant to fluoroquinolone antibiotics and again, treatment fails in about half of the patients in some parts of the world. Resistance to the last-resort treatment, **colistin**, is also spreading.

- *Neisseria gonorrhoea*. In many countries this organism has acquired resistance to almost all common antibiotics, with the last-resort drug, **ceftriaxone**, being the final remaining hope for treating resistant strains.
- *S. aureus*. Resistance of this skin organism to first-line drugs is now widespread and patients with **meticillin**-resistant *S. aureus* (MRSA) are more than twice as likely to die following infection. While mortality is declining in the North America and Europe, it is increasing in developing countries.
- *Enterobacteriaceae*. These organisms can cause life-threatening infections and recently resistance to the 'last-resort' drug **colistin** has been reported.
- *Mycobacterium tuberculosis*. This hitherto treatable disease has now become a major global health emergency. In 2018 WHO estimated that half a million new cases of **rifampicin**-resistant TB were seen annually and that the majority of these cases harboured multidrug-resistant strains of the disease. Cure rates are less than 60% in such cases.

Multidrug resistance

Some pathogenic bacteria have developed resistance to many or most commonly used antibiotics. Examples include the following:

- Some strains of staphylococci and enterococci that are resistant to virtually all current antibiotics, the resistance being transferred by transposons and/or plasmids; such

organisms can cause serious and virtually untreatable hospital-acquired (so-called nosocomial) infections.

- Some strains of *Mycobacterium tuberculosis* that have become resistant to most antituberculosis agents.

Resistance to Other Antimicrobials

While we have stressed bacterial resistance to antibiotics in this chapter, it is important to realise that this problem extends to all antimicrobial agents. The WHO has warned that resistance to most antiviral agents has developed. A particularly stark example is the emergence of a strain of HIV which is fully resistant to the current portfolio of antiretroviral drugs (see **Ch. 53**). More than half of all infants with HIV in sub-Saharan Africa are already infected with this resistant strain. Patients infected with HIV are immunocompromised and thus fungal infections are easily able to gain a foothold in their weakened immune systems. It is depressing to note that some *Candida* strains also have developed resistance to a battery of antifungal drugs including those in the azole group and **amphotericin** (see **Ch. 56**). The situation with antimalarial drugs is equally serious, with some parasite strains in Africa and Asia developing resistance to a key drug, **artemisinin**, as well as other conventional antimalarial agents.

So what is the way forward? Regardless of the ancient origin of bacterial resistance mechanisms, all parties agree that indiscriminate use of antibiotics in agriculture, human and veterinary medicine, and their use in animal foodstuffs, has undoubtedly encouraged the spread of resistant strains. The

situation is particularly acute in the developing world where poverty, overcrowding, lack of clean water and minimal sanitation exacerbate the problem.

The current trend is to tackle clinical drug resistance as part of a more holistic 'One Health' approach which embraces not only human health, but also that of plants and that of all animals, both land dwelling and aquatic, as well as agricultural, environmental and ecological practices (e.g. **Ben et al., 2019**). To support this the WHO has published numerous reports, updates, guidelines, policies and lists of 'priority pathogens' and launched several initiatives, most recently the annual *World Antimicrobial Awareness Week* in 2020 with its slogan 'Antimicrobials: Handle with Care'.

Prescribers and consumers alike must bear a measure of responsibility for the burgeoning problem of resistance. Most members of the general public have only a vague notion of the causes of the problem, its likely ultimate implications and their role in its development (**McCullough et al., 2016**). More worryingly, even many clinicians, while realising the scope of the problem, also seem unaware of their crucial role in its spread (**McCullough et al., 2015**).

Some authors (e.g.**Chaudhary, 2016**) have advocated tackling the problem at the point of diagnosis and prescription suggesting that bacterial susceptibility testing should be mandatory before the drug is dispensed. Unnecessary prescribing (e.g. for viral infections), inadequate dosing or inappropriate duration of treatment (which often leads to resistance) should all be scrupulously avoided and more rigorous adherence by patients to antibiotic regimes would help. Therapy using multiple antibiotics acting through different

mechanisms can be a useful strategy in some cases and a number of other unconventional therapies have been proposed (**Kumar et al., 2021**). Public health measures such as infection control procedures also play a key role. The removal of antibiotic resistance genes from the soil and wastewater is of particular importance and several innovative solutions have been proposed, including the construction of artificial wetlands and other measures (**Herraiz-Carbone et al., 2021**; **Liu et al., 2019**).

Another problem (which not only applies to antimicrobials but to other fields of medicine as well) is the funding model for such research. The antimicrobial drug 'pipeline' is depressingly slim, but the pharmaceutical industry is wary of investment in the field since the potential profits are unlikely to cover the huge development costs and most governments have no stomach for the eye-watering risks associated with investing in drug discovery either. Various techniques to counteract resistance have been proposed, including the repurposing of other drugs, combination therapies as well as the use of artificial Intelligence (AI) and associated techniques (**Alvarez-Martinez et al., 2020**) to predict likely candidate drugs. A number of public/private partnerships such as the *Antimicrobial Resistance Multi Partner Trust Fund* and the *Global Antibiotic Research & Development Partnership* have stepped in to fill the funding vacuum. Let's all hope that this action is not too late.

Useful web resources

34. The World Health Organisation (WHO) hosts web pages that deal with the global problem of microbial resistance, and the regularly updated *Antibiotic Resistance* Fact Sheet (see **https://www.who.int/news-room/fact-sheets/detail/antibiotic-resistance**) contains definitive information on the current situation around the world.

35. The AntiBiotic Research UK website also contains some interesting data relevant to this problem and also offers support for patients (see **https://www.antibioticresearch.org.uk**).

QUESTIONS

QUESTION 51.1

Humans are susceptible to a variety of diseases caused by microorganisms.

Which of the following are not classified as true microorganisms?

OPTIONS:

A. Viruses

B. Fungi

C. Bacteria

D. Helminths

E. Prions

QUESTION 51.2

Antibiotic resistance may be *innate* – pre-existing in a particular strain – or *acquired* in some way from other bacterial cells.

Which is the main mechanism by which microorganisms acquire antibiotic resistance?

OPTIONS:

A. Transformation

B. Vesiduction

C. Transduction

D. Conjugation

E. Mutation

QUESTION 51.3

Expression of specific bacterial enzymes and increased activity of efflux pumps often underpin the resistance to antibiotics.

Which of the following mechanisms of resistance to the specified antibiotic is incorrect?

OPTIONS:

A. Rifampicin resistance is due to a chromosomal mutation which reduces binding.

B. Aminoglycoside resistance is due altered permeability of the outer membrane.

C. Chloramphenicol is inactivated by enzymatic modifications.

D. Resistance to tetracyclines is mediated through an increase in protein pump-mediated efflux.

E. Resistance to trimethoprim is the result of altered enzyme affinity.

ANSWERS

ANSWER 51.1

RATIONALE:

A. Despite having a different mechanism for infection, viruses are still classified as microbial pathogens.

B. Fungi are eukaryotic microorganisms.

C. Bacteria are prokaryotic microorganisms.

D. Helminths are eukaryotic microorganisms.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Prions

Prions are infectious proteins, which cause disease but resist all attempts at classification and treatment.

ANSWER 51.2

RATIONALE:

A. Under natural conditions a few species of bacteria can undergo transformation by taking up DNA from the environment and incorporating it into their genome by normal homologous recombination.

B. Vesiduction is the process by which vesicles containing various cargoes are released from a variety of cells, including bacterial cells, and fuse with the membranes of nearby cells delivering releasing their contents intracellularly.

C. Transduction is a process by which plasmid DNA is enclosed in a virus that infects bacteria (termed a phage) and transferred to another bacterium of the same species. It is a relatively ineffective means of transfer of genetic material but is clinically important in the transmission of resistance genes between strains of staphylococci and of streptococci.

D.

E. The spontaneous mutation rate in bacterial populations for any particular gene is very low: only approximately 1 cell in 10 million will bear a mutation and pass it on.

CORRECT ANSWER WITH EXPLANATION:

D. Conjugation

Conjugation is the main mechanism for the spread of resistance genes. It involves cell-to-cell contact during which chromosomal or extrachromosomal DNA is transferred from one bacterium to another.

ANSWER 51.3

RATIONALE:

A. Rifampicin resistance is due to an altered DNA-dependent RNA polymerase determined by a chromosomal mutation.

B.

C. Chloramphenicol is inactivated by *chloramphenicol acetyltransferase*, an enzyme produced by resistant strains of

both Gram-positive and Gram-negative organisms, the resistance gene being plasmid borne.

D. Resistance genes in plasmids code for inducible protein pumps in the bacterial membrane, which promote energy-dependent efflux of the tetracyclines.

E. Resistance to trimethoprim is the result of plasmid-directed synthesis of a *dihydrofolate reductase* with low or zero affinity for trimethoprim. It is transferred by transduction and may be spread by transposons.

CORRECT ANSWER WITH EXPLANATION:

B. Aminoglycoside resistance is due altered permeability of the outer membrane.

Aminoglycosides are inactivated by phosphorylation, adenylation or acetylation, and the requisite enzymes are found in both Gram-negative and Gram-positive organisms. The resistance genes are carried on plasmids, and several are found on transposons.

---

[1] Toxic mercury-containing compounds were also once commonly used for treating syphilis. 'One night with Venus, a lifetime with Mercury' was a common saying prior to the advent of the antibiotic era.

[2] Humans harbour about 2 kg of bacteria in the gut, comprising a large 'forgotten organ' in the body which has important metabolic functions. Together with the commensals living on our skin and other organs, these are collectively known as the *microbiome*.

[3] You query whether 30S + 50S = 70S? Yes, it does, because we are talking about *Svedberg units*, which measure sedimentation *rate*, which is only partly dependent on *mass*.

[4] Quorum sensing is a mechanism by which bacterial colonies can regulate their gene expression (and other metabolic activity) according to their population density.

[5] According to one school of thought, viruses may have arisen as transposons that escaped from cells and now continued to ply their trade independently.

52: Antibacterial drugs

OVERVIEW

In this chapter we discuss antibacterial drugs. Bacteriology is a vast subject and a detailed discussion is beyond the scope of this book, but information about some clinically significant pathogens is included to provide necessary context. The pharmacological properties and therapeutic effects of the major classes of antibacterial drugs are described. We conclude with an assessment of the prospects for new antibacterials and the attendant risks if we fail to do so.

INTRODUCTION

Working at St Mary's Hospital in London in 1928, Alexander Fleming discovered that a culture plate on which staphylococci were being grown had become contaminated with a mould of the genus *Penicillium*. He made the crucial observation that bacterial growth in the vicinity of the mould had been inhibited. He subsequently isolated the mould in pure culture and demonstrated that it produced an antibacterial substance, which he named **penicillin**. This substance was subsequently prepared in bulk, extracted and its antibacterial effects analysed by Florey, Chain, Heatley and their colleagues at Oxford in 1940. They demonstrated that **penicillin** was non-toxic to the host but killed the pathogens in infected mice

and in doing so they ushered in the ‘antibiotic era’. Since then, many new types of antibiotics have been discovered and the practice of medicine today would be unthinkable without them.

GRAM STAINING AND ITS SIGNIFICANCE FOR DRUG ACTION

Most bacteria can be classified as being either *gram-positive* or *gram-negative*, depending on whether they stain with *Gram stain*. [1] This reflects fundamental differences in the structure of their cell walls and has important implications for the action of antibiotics (**Table 52.1**).

The cell wall of gram-positive organisms is a relatively simple structure. It is some 15–50 nm thick and comprises about 50% peptidoglycan (see **Ch. 51**), 40%–45% acidic polymer together with 5%–10% proteins and polysaccharides. The cell surface is highly polar and negatively charged and this influences the penetration of some drugs.

The cell wall of gram-negative organisms is much more complex. From the plasma membrane outwards, it consists of the following:

- A *periplasmic space* containing enzymes and other components.
- A *peptidoglycan layer* 2 nm in thickness, forming 5% of the cell wall mass. This is often linked to outwardly projecting lipoprotein molecules.
- An *outer membrane* consisting of a lipid bilayer, similar in some respects to the plasma membrane, that contains protein molecules and (on its inner aspect) lipoproteins linked to the peptidoglycan. Other proteins form

transmembrane water-filled channels, termed *porins*, through which some hydrophilic antibiotics can move freely (see also **Ch. 9**).

- *An outer surface rich in complex polysaccharides*. These differ between strains of bacteria and are the main determinants of their antigenicity. They are also the source of *endotoxin*, a lipopolysaccharide which, when shed in vivo, triggers various aspects of the inflammatory reaction by activating complement and releasing cytokines, causing fever, etc. (see **Ch. 7**).

The cell wall lipopolysaccharide is a major barrier to penetration of some antibiotics, including **benzylpenicillin**, **meticillin**, the macrolides, **rifampicin**, **fusidic acid** and **vancomycin** and difficulty in penetrating this complex outer layer explains why some antibiotics are less active against gram-negative than gram-positive bacteria. It is also one reason for the extraordinary antibiotic resistance exhibited by *Pseudomonas aeruginosa*, a pathogen that can cause life-threatening infections in neutropenic patients and those with burns and wounds, as well as a chronic bronchial infection in patients with cystic fibrosis.

BACTERIOSTATIC AND BACTERICIDAL DRUGS

Antibiotics that interfere with bacterial cell wall synthesis (e.g. penicillins) or inhibit crucial enzymes (such as the quinolones) generally kill bacteria (i.e. they are *bactericidal*), while those that inhibit protein synthesis, such as the tetracyclines, are generally *bacteriostatic*, that is they do not kill cells but rather prevent growth and replication. This distinction is not especially clinically

significant, as the therapeutic outcome of antibiotic therapy depends critically on the host response in dealing with compromised bacterial load.

In discussing the pharmacology of antibacterial drugs, it is convenient to divide them into different groups based upon their mechanism of action.

ANTIBACTERIAL AGENTS THAT INTERFERE WITH FOLATE SYNTHESIS OR ACTION

(See **Figs 52.1** and **52.2**.)

SULFONAMIDES

In a landmark discovery in the 1930s, prior to the advent of penicillin into the clinic, Domagk demonstrated that it was possible for a drug to suppress a bacterial infection. The drug was a dye called **prontosil rubrum**, [2] which proved to be an inactive prodrug that was metabolised in vivo to an active product, **sulfanilamide** (see **Fig. 52.1**). Many sulfonamides have been developed since, but their importance has declined in the face of increasing resistance. The only sulfonamide drugs still commonly used as *systemic* antibacterials are **sulfamethoxazole** (usually in combination with **trimethoprim** as **co-trimoxazole**) and **sulfasalazine**, which is poorly absorbed by the gastrointestinal (GI) tract but is widely used to treat ulcerative colitis and Crohn's disease (see Chs **25** and **30**). **Silver sulfadiazine** is another sulfonamide; it is used topically to treat infected burns. Some drugs with quite different clinical uses (e.g. the antiplatelet drug **prasugrel**, see **Ch. 23**, and the carbonic

anhydrase inhibitor **acetazolamide**, see **Ch. 30**) are also sulfonamides and share some of the off-target adverse effects of this class (see later).

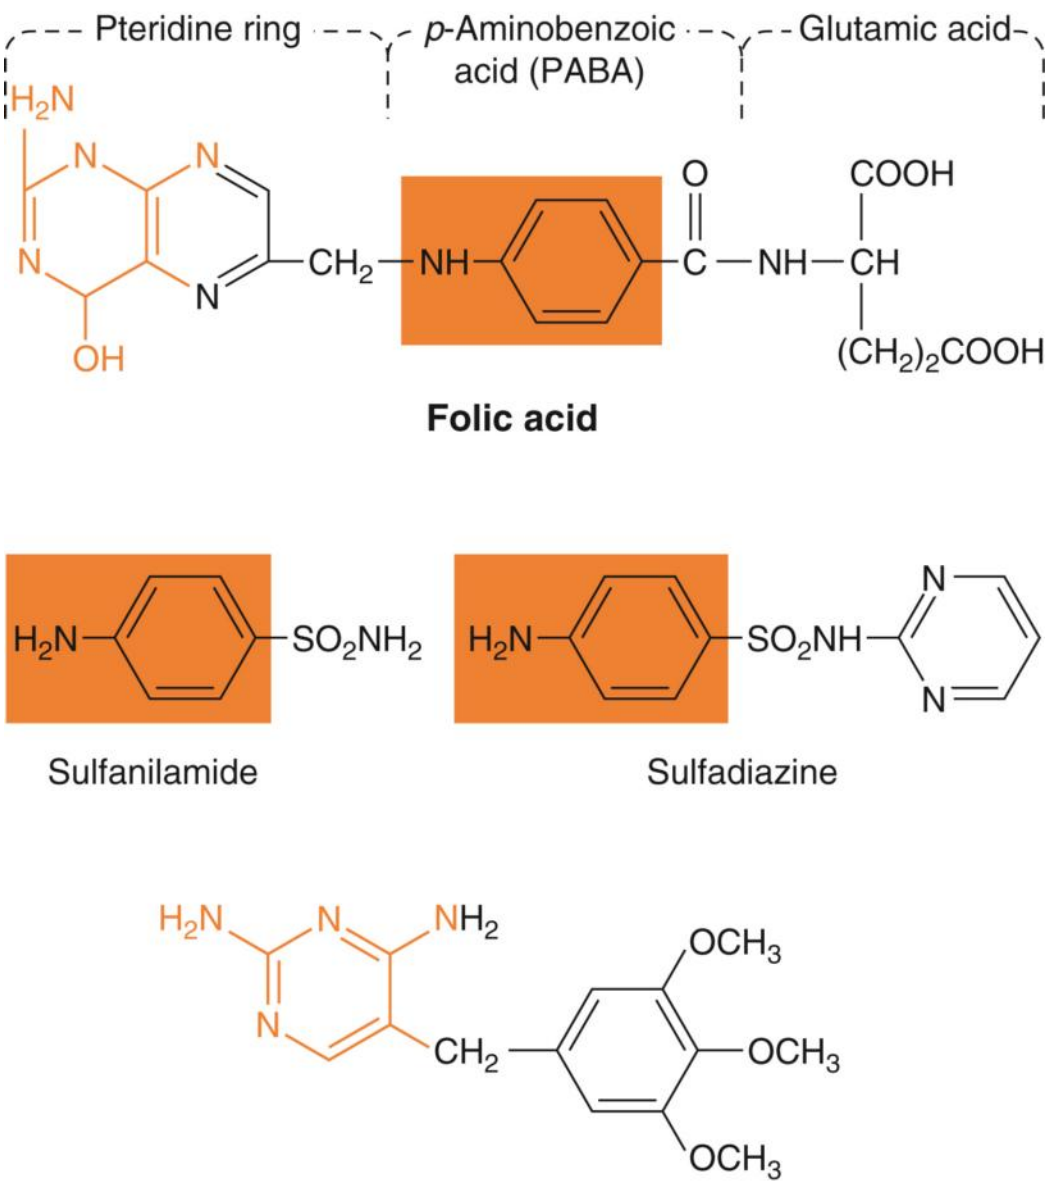

FIG. 52.1 Structures of two representative sulfonamides and trimethoprim.The structures illustrate the relationship between the sulfonamides and the *p*-aminobenzoic acid moiety in folic acid *(orange box)*, as well as between the antifolate drugs and the pteridine

moiety *(orange)*. Co-trimoxazole is a mixture of sulfamethoxazole and trimethoprim.

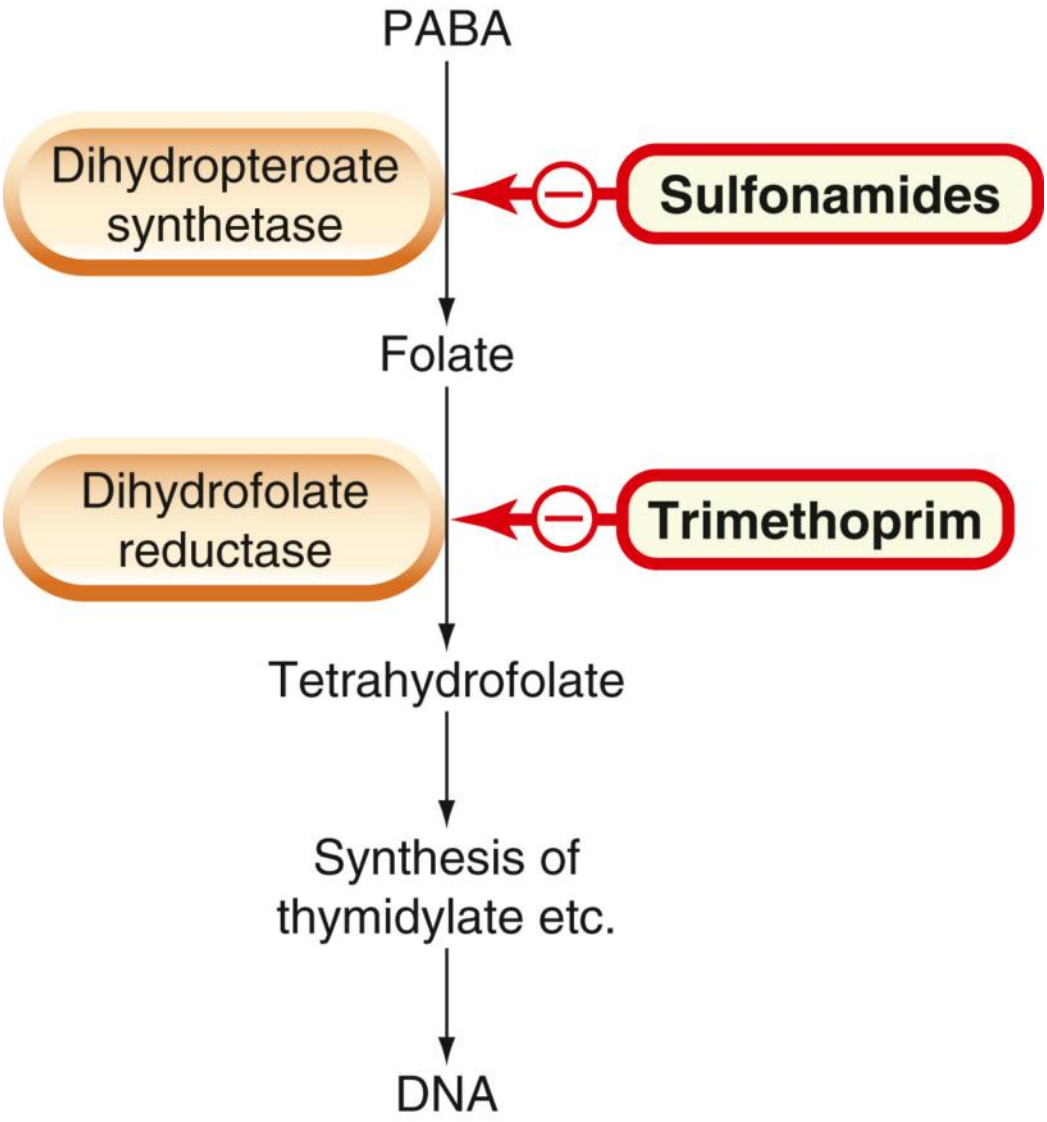

FIG. 52.2 The action of sulfonamides and trimethoprim on bacterial folate synthesis.See **Chapter 24** for more detail of tetrahydrofolate synthesis, and **Chapter 51** for comparisons of antifolate drugs. *PABA*, *p*-aminobenzoic acid.

Clinical uses of sulfonamides

- Combined with **trimethoprim** (**co-trimoxazole**) for *Pneumocystis carinii* (now known as *P. jirovecii*), for toxoplasmosis and nocardiasis.
- Combined with **pyrimethamine** for drug-resistant malaria (see **Ch. 55**) and for toxoplasmosis.
- In inflammatory bowel disease: **sulfasalazine** (sulfapyridine–aminosalicylate combination) is used (see **Ch. 30**).
- For infected burns (silver **sulfadiazine)** given topically

Mechanism of action

Sulfanilamide, the active metabolite of **prontosil**, is a structural analogue of *p*-aminobenzoic acid (PABA; see **Fig. 52.1**), which is an essential precursor in the biosynthesis of folic acid and is required for the synthesis of DNA and RNA in bacteria (see **Ch. 51**). Sulfonamides compete with PABA for the enzyme *dihydropteroate synthetase*, and the effect of the sulfonamide may be overcome by adding excess PABA. This is why local anaesthetics which are PABA esters (such as **procaine**; see **Ch. 44**) antagonise the antibacterial effect of these agents.

Sulfonamide action is vitiated in the presence of pus or products of tissue breakdown, because these contain thymidine and purines which bacteria utilise directly, bypassing the requirement for folic acid. Resistance to sulfonamides, which is common, is plasmid

mediated (see **Ch. 51**) and results from the synthesis of a bacterial enzyme insensitive to the drugs.

Pharmacokinetic aspects

Most sulfonamides can be given orally and, apart from **sulfasalazine** and **silver sulfadiazine** (see earlier), are well absorbed and widely distributed in the body. The drugs pass into inflammatory exudates and cross both placental and blood–brain barriers. They are metabolised mainly in the liver, the major product being an acetylated derivative that lacks antibacterial action. There is a risk of sensitisation or allergic reactions when these drugs are given topically.

Table 52.1

UTI, Urinary tract infection.

Unwanted effects

Serious adverse effects necessitating cessation of therapy include hepatitis, hypersensitivity reactions (rashes including severe forms of erythema multiforme, fever, anaphylactoid reactions – see **Ch. 58**), bone marrow depression and acute renal failure due to interstitial nephritis or crystalluria. This last effect results from the precipitation of acetylated metabolites in the urine (see **Ch. 29**). Cyanosis caused by methaemoglobinaemia may occur but is a lot less alarming than it looks. Mild to moderate side effects include nausea and vomiting, headache and mental depression.

TRIMETHOPRIM

Mechanism of action

Trimethoprim is chemically related to the antimalarial drug **pyrimethamine** (see **Ch. 55**), both being folate antagonists. Structurally it resembles the pteridine moiety of folate and the similarity is close enough to fool the bacterial *dihydrofolate reductase*, which is many times more sensitive to **trimethoprim** than is the equivalent enzyme in humans.

Trimethoprim is active against most common bacterial pathogens as well as protozoa, and is used to treat various urinary, pulmonary and other infections. It is sometimes given in combination with **sulfamethoxazole** as **co-trimoxazole**. Because sulfonamides inhibit a different stage on the same bacterial metabolic pathway, they can potentiate the action of **trimethoprim,** but to be effective, they must have a similar *pK* to the drug. **Sulfamethoxazole** has this property. In the United Kingdom, the use of **co-trimoxazole** is generally restricted to the treatment of Pneumocystis pneumonia, an opportunistic infection with which AIDS may present (see **Ch. 53**), caused by the fungus *Pneumocystis carinii* (now known as *Pneumocystis jirovecii*), toxoplasmosis (a protozoan infection) or nocardiasis (a bacterial infection).

Pharmacokinetic aspects

Trimethoprim is well absorbed orally, and widely distributed throughout the tissues and body fluids. It reaches high concentrations in the lungs and kidneys, and fairly high concentrations in the cerebrospinal fluid (CSF). When given with **sulfamethoxazole**, the only sulfonamide with similar *p*K to

trimethoprim, about half the dose of each is excreted within 24 h. Because **trimethoprim** is a weak base, its elimination by the kidney increases with decreasing urinary pH.

Unwanted effects

Folate deficiency can result from long-term administration of **trimethoprim** resulting in megaloblastic anaemia (see **Ch. 24**). Other unwanted effects include nausea, vomiting, blood disorders and rashes.

Antimicrobial agents that interfere with the synthesis or action of folate

- Sulfonamides are bacteriostatic; they act by interfering with folate synthesis and thus with nucleotide synthesis. Unwanted effects include crystalluria and hypersensitivities.
- **Trimethoprim** is bacteriostatic. It acts by antagonising folate.
- **Co-trimoxazole** is a mixture of **trimethoprim** with **sulfamethoxazole**, which affects bacterial nucleotide synthesis at two points in the pathway.
- **Pyrimethamine** and **proguanil** are also antimalarial agents (see **Ch. 55**).

β-LACTAM ANTIBIOTICS AND OTHER AGENTS THAT INTERFERE WITH BACTERIAL WALL OR MEMBRANE SYNTHESIS

(See **Ch. 51** and **Fig. 52.3** and **Table 52.2**.)

PENICILLINS

The remarkable antibacterial effects of systemic penicillin in humans were clearly demonstrated in 1941. A small amount of **penicillin**, extracted laboriously from crude cultures in the laboratories of the Dunn School of Pathology in Oxford, was given to a desperately ill policeman with septicaemia and multiple abscesses. Although sulfonamides were available, they would have had no effect in the presence of pus. Intravenous injections of **penicillin** were given every 3 h. All of the patient's urine was collected, and each day the bulk of the excreted **penicillin** was extracted and reused. After 5 days, the patient's condition was vastly improved, and there was obvious resolution of the abscesses. Furthermore, there seemed to be no toxic effects of the drug. Unfortunately, when the supply of **penicillin** was finally exhausted his condition gradually deteriorated and he died a month later.

Penicillins, often combined with other antibiotics, remain crucially important in antibacterial chemotherapy, but regrettably they are destroyed by bacterial *amidases* and *β-lactamases* (*penicillinases*) which limits their effectiveness. This is one of the principal types of antibiotic resistance.

Clinical uses of the penicillins

- Penicillins are given by mouth or, in more severe infections, intravenously, and often in combination with other antibiotics.
- Uses are for sensitive organisms and may (but may not: individual sensitivity testing is often appropriate depending on local conditions) include:
  - *bacterial meningitis* (e.g. caused by *Neisseria meningitidis*, *Streptococcus pneumoniae*): **benzylpenicillin**, high doses intravenously;
  - *bone* and *joint infections* (e.g. with *Staphylococcus aureus*): **flucloxacillin**;
  - *skin* and *soft tissue infections* (e.g. with *Streptococcus pyogenes* or *S. aureus*): **benzylpenicillin**, **flucloxacillin**; animal bites: **co-amoxiclav**;
  - *pharyngitis* (from *S. pyogenes*): **phenoxymethylpenicillin**;
  - *otitis media* (organisms commonly include *S. pyogenes*, *Haemophilus influenzae*): **amoxicillin**;
  - *bronchitis* (mixed infections common): **amoxicillin**;
  - *pneumonia*: **amoxicillin**;
  - *urinary tract infections* (e.g. with *Escherichia coli*): **amoxicillin**;
  - *gonorrhoea*: **amoxicillin** (plus **probenecid**);
  - *syphilis*: **procaine benzylpenicillin**;
  - *endocarditis* (e.g. with *Streptococcus viridans* or *Enterococcus faecalis*): high-dose intravenous

benzylpenicillin sometimes with an aminoglycoside;
– serious infections with *P. aeruginosa*: **ticarcillin**, **piperacillin.**

This list is not exhaustive. In severe infection, especially sepsis, treatment with penicillins, often in combination with an aminoglycoside, is often started empirically while awaiting the results of laboratory tests to identify the organism and determine its antibiotic susceptibility.

Mechanisms of action

All β-lactam antibiotics interfere with the synthesis of the bacterial cell wall peptidoglycan. After attachment to **penicillin**-binding proteins on bacteria (there may be seven or more types in different organisms), they inhibit the transpeptidation enzyme that cross-links the peptide chains attached to the backbone of the peptidoglycan.

The final bactericidal event is the inactivation of an inhibitor of autolytic enzymes in the cell wall, leading to lysis of the bacterium. Some organisms, referred to as 'tolerant', have defective autolytic enzymes in which case lysis does not occur in response to the drug. Resistance to **penicillin** may result from a number of different causes and is discussed in detail in **Chapter 51**.

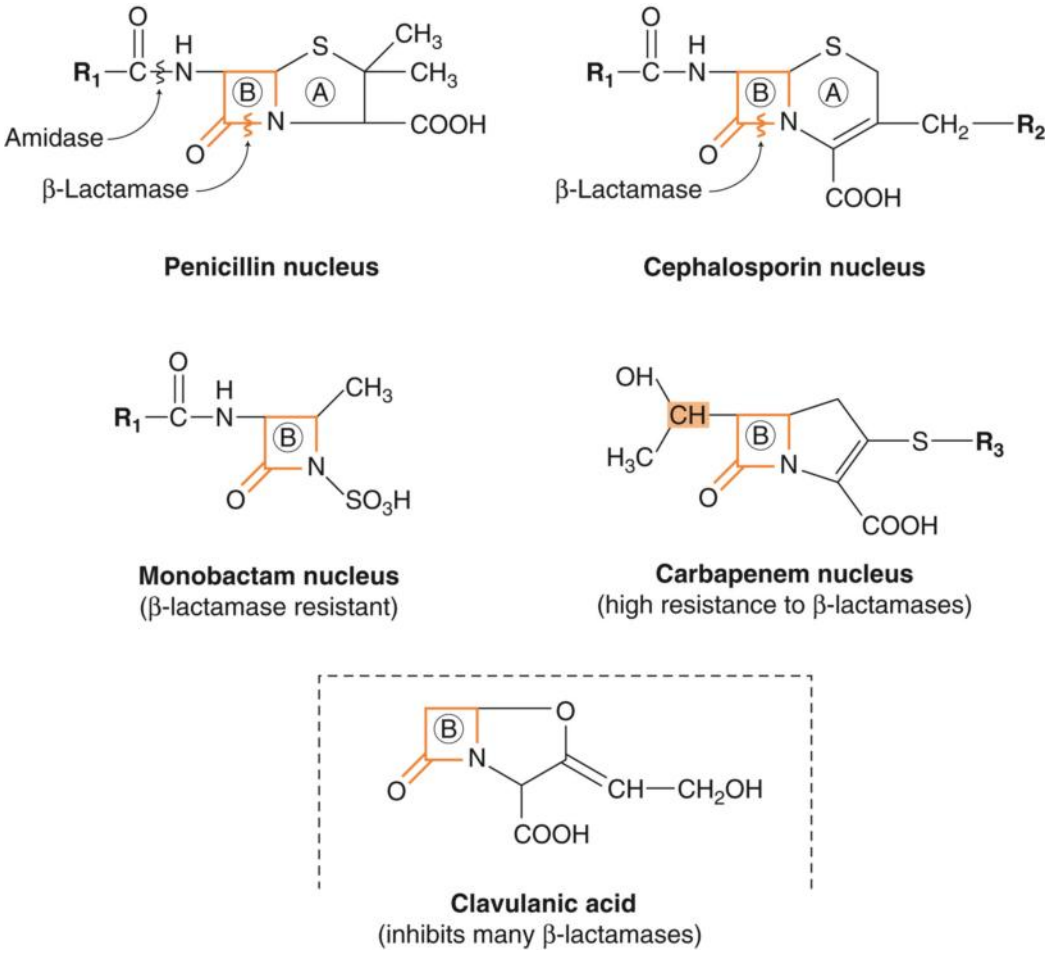

FIG. 52.3 Basic structures of four groups of β-lactam antibiotics and clavulanic acid.The structures illustrate the β-lactam ring (marked B; outlined in orange) and the sites of action of bacterial enzymes that inactivate these antibiotics (*A*, thiazolidine ring). Various substituents are added at R1, R2 and R3 to produce agents with different properties. In carbapenems, the stereochemical configuration of the part of the β-lactam ring shown shaded in *orange* here is different from the corresponding part of the penicillin and cephalosporin

molecules; this is probably the basis of the β-lactamase resistance of the carbapenems. The β-lactam ring of clavulanic acid is thought to bind strongly to β-lactamase, meanwhile protecting other β-lactams from the enzyme.

Types of penicillin and their antimicrobial activity

The first penicillins were the naturally occurring **benzylpenicillin** (**penicillin G**) and its congeners, including **phenoxymethylpenicillin** (**penicillin V**). **Benzylpenicillin** is active against a wide range of organisms and is still the drug of first choice for many infections (see clinical box). Its main drawbacks are inactivation by gastric acid and hence generally poor absorption in the GI tract (which means it must be given by injection).

Semisynthetic penicillins, incorporating different side-chains attached to the penicillin nucleus (at R1 in **Fig. 52.3**), include β-lactamase-resistant penicillins (e.g. **meticillin**,[3] **flucloxacillin**, **temocillin**) and broad-spectrum penicillins (e.g. **ampicillin**, **amoxicillin**). Extended-spectrum penicillins (e.g. **ticarcillin**, **piperacillin**) with activity against *Pseudomonas* have gone some way to overcoming the problem of serious infections caused by *P. aeruginosa*. **Amoxicillin** and **ticarcillin** are sometimes given in combination with the β-lactamase inhibitor **clavulanic** acid (e.g. **co-amoxiclav**). **Pivmecillinam** is a prodrug of **mecillinam**, which also has a wide spectrum of action.

Pharmacokinetic aspects

Oral absorption of penicillins varies, depending on their stability in acid and their adsorption to foodstuffs in the gut. Penicillins can also be given by intravenous injection. Preparations for intramuscular injection are also available, including slow-release preparations such as **benzathine benzylpenicillin** which is useful for treating syphilis since *Treponema pallidum* is a very slowly dividing organism. Intrathecal administration of **benzylpenicillin** (used historically to treat meningitis) is no longer used as penicillin is not excluded by the inflamed blood–brain barrier (see **Ch. 9**), and overdosage via the intrathecal route causes convulsions. [4]

The penicillins are widely distributed in other body fluids, passing into joints; into pleural and pericardial cavities; into bile, saliva and milk and across the placenta. Being lipid-insoluble, they do not enter mammalian cells.

Table 52.2

Drug mixtures (e.g. co-fluampicil – flucloxacillin with ampicillin) are not shown.

MRSA, Methicillin-resistant staphylococcus aureus; *UTI,* urinary tract infection.

Sources: BNF (2021) and others.

Elimination of most penicillins occurs rapidly and is mainly renal, 90% being through tubular secretion. The relatively short plasma half-life is a potential problem in the clinical use of **benzylpenicillin**, although because **penicillin** works by

preventing cell wall synthesis in dividing organisms, intermittent rather than continuous exposure to the drug can be an advantage.

Unwanted effects

Penicillins are relatively free from direct toxic effects (other than their proconvulsant effect when given intrathecally). The main unwanted effects are hypersensitivity reactions caused by the degradation products of penicillin, which combine with host protein and become antigenic. Rashes and fever are common; a delayed type of serum sickness occurs infrequently. Much more serious is *acute anaphylactic shock* which, although rare, may be fatal. When given orally, penicillins, particularly the broad-spectrum type, also alter the bacterial flora in the gut. This very commonly causes diarrhoea, and predisposes to suprainfection by other, ***penicillin*** *-insensitive*, microorganisms leading less commonly to serious problems such as *pseudomembranous colitis* (caused by *Clostridium difficile*; see later).

CEPHALOSPORINS AND CEPHAMYCINS

First isolated from fungi in seawater near a sewage outlet in Sardinia, cephalosporins and cephamycins are also β-lactam antibiotics and have the same mechanism of action as penicillins. Semisynthetic broad-spectrum cephalosporins have been produced by addition, to the cephalosporin C nucleus, of different side-chains at R_1 and/or R_2 (see **Fig. 52.3**). This group of agents is water soluble and relatively acid stable. They vary in susceptibility to β-lactamases.

Many cephalosporins and cephamycins are now available for clinical use. Resistance to this group of drugs has increased because

of plasmid-encoded or chromosomal β-lactamase. The latter is present in nearly all gram-negative bacteria, and it is more active in hydrolysing cephalosporins than penicillins. In several organisms a single mutation can result in high-level constitutive production of this enzyme. Resistance also occurs when there is decreased penetration of the drug as a result of alterations to outer membrane proteins, or mutations of the binding-site proteins.

Pharmacokinetic aspects

Some cephalosporins are given orally, but most are given parenterally, intramuscularly (which may be painful) or intravenously. After absorption, they are widely distributed in the body and some, such as **cefotaxime**, **cefuroxime** and **ceftriaxone**, cross the blood–brain barrier. Excretion is mostly via the kidney, largely by tubular secretion, but 40% of **ceftriaxone** is eliminated in the bile.

Unwanted effects

Hypersensitivity reactions, very similar to those seen with penicillin, may occur, and there may be some cross-sensitivity; about 10% of penicillin-sensitive individuals will also have allergic reactions to cephalosporins. Nephrotoxicity has been reported (especially with **cefradine**), as has drug-induced alcohol intolerance – a ***disulfiram*** -like effect (see **Ch. 50**) because the methylthiotetrazole moiety inhibits aldehyde dehydrogenase. Diarrhoea is common and can be due to *C. difficile*.

Clinical uses of the cephalosporins

Cephalosporins are used to treat infections caused by sensitive organisms. As with other antibiotics, patterns of sensitivity vary geographically, and treatment is often started empirically. Many different kinds of infection may be treated, including:

- *septicaemia* (e.g. **cefuroxime**, **cefotaxime**)
- *pneumonia* caused by susceptible organisms
- *meningitis* (e.g. **ceftriaxone**, **cefotaxime**)
- *biliary tract infection*
- *urinary tract infection* (especially in pregnancy or in patients unresponsive to other drugs)
- *sinusitis* (e.g. **cefadroxil**)

OTHER β-LACTAM ANTIBIOTICS

Carbapenems and monobactams (see **Fig. 52.3**) were developed to deal with β-lactamase-producing gram-negative organisms resistant to penicillins. Most carbapenems are not orally active and are used only in special situations.

CARBAPENEMS

Imipenem, an example of a carbapenem, acts in the same way as the other β-lactams. It has a very broad spectrum of antimicrobial activity, being active against many aerobic and anaerobic gram-positive and gram-negative organisms. However, many of the '**meticillin**-resistant' staphylococci are less susceptible, and resistant strains of *P. aeruginosa* have emerged during therapy. Resistance to **imipenem** was initially low but is increasing as some

organisms now have chromosomal genes that code for **imipenem**-hydrolysing β-lactamases.

Imipenem is sometimes given together with **cilastatin**, which inhibits its inactivation by renal enzymes. **Meropenem** is similar but is not metabolised by the kidney. **Ertapenem** has a broad spectrum of antibacterial actions but is licensed only for a limited range of indications.

Unwanted effects

are generally similar to those seen with other β-lactams, nausea and vomiting being the most frequently seen. Neurotoxicity can occur with high plasma concentrations.

MONOBACTAMS

The main monobactam is **aztreonam**, which is resistant to most β-lactamases. It is given by injection and has a plasma half-life of 2 h. **Aztreonam** has an unusual spectrum of activity and is effective only against gram-negative aerobic bacilli such as *Pseudomonas* species, *Neisseria meningitidis* and *Haemophilus influenzae*. It has no action against gram-positive organisms or anaerobes.

Unwanted effects

are, in general, similar to those of other β-lactam antibiotics, but this agent does not necessarily cross-react immunologically with **penicillin** and its products and does not usually cause allergic reactions in **penicillin**-sensitive individuals.

Bactericidal because they inhibit peptidoglycan synthesis.

Penicillins

- The first choice for many infections.
- **Benzylpenicillin**:
  - given by injection, has a short half-life and is destroyed by β-lactamases;
  - spectrum: gram-positive and gram-negative cocci and some gram-negative bacteria;
  - many staphylococci are now resistant.
- β-Lactamase-resistant penicillins (e.g. **flucloxacillin**):
  - given orally;
  - spectrum: as for **benzylpenicillin**;
  - many staphylococci are now resistant.
- Broad-spectrum penicillins (e.g. **amoxicillin**):
  - given orally; they are destroyed by β-lactamases;
  - spectrum: as for **benzylpenicillin** (although less potent); they are also active against gram-negative bacteria.
- Extended-spectrum penicillins (e.g. **ticarcillin**):
  - given orally; they are susceptible to β-lactamases;
  - spectrum: as for broad-spectrum penicillins; they are also active against pseudomonads.
- Unwanted effects of penicillins: mainly hypersensitivities.
- A combination of **clavulanic acid** plus **amoxicillin** or **ticarcillin** is effective against many β-lactamase-producing organisms.

Cephalosporins and cephamycins

- Second choice for many infections.
- Oral drugs (e.g. **cefaclor**) are used in urinary infections.
- Parenteral drugs (e.g. **cefuroxime**, which is active against *S. aureus*, *H. influenzae*, Enterobacteriaceae).
- Unwanted effects: mainly hypersensitivities.

Carbapenems

- **Imipenem** is a broad-spectrum antibiotic.
- **Imipenem** is used with **cilastatin**, which prevents its breakdown in the kidney.

Monobactams

- **Aztreonam**: active only against gram-negative aerobic bacteria and resistant to most β-lactamases.

(See **Table 52.2** for further examples.)

OTHER ANTIBIOTICS THAT INHIBIT BACTERIAL CELL WALL PEPTIDOGLYCAN SYNTHESIS

GLYCOPEPTIDES

Vancomycin is a glycopeptide antibiotic, and **teicoplanin** is similar but longer lasting. **Vancomycin** inhibits cell wall synthesis. It is effective mainly against gram-positive bacteria. **Vancomycin** is not absorbed from the gut and is only given by the oral route for treatment of GI infection with *C. difficile*.

The main clinical use of **vancomycin** is the treatment of **meticillin**-resistant *Staphylococcus aureus* (MRSA). It is often the drug of last resort for this condition, an alarming consideration since **vancomycin**-resistant *S. aureus* (VRSA) has now emerged. **Vancomycin** is also valuable in some other serious infections including severe staphylococcal infections in patients allergic to both penicillins and cephalosporins.

Pharmacokinetic aspects

For systemic use, it is given intravenously and has a plasma half-life of about 8 h.

Unwanted effects

include fever, rashes and phlebitis at the infusion site. Ototoxicity and nephrotoxicity can occur, and hypersensitivity reactions are occasionally seen.

Daptomycin is a lipopeptide antibacterial with a similar spectrum of actions to **vancomycin**. It is used, in combination with other drugs, for the treatment of MRSA. **Telavancin** (another lipopeptide) is also active against MRSA and has a longer duration of action than **vancomycin**.

POLYMYXINS

The polymyxin antibiotics include **polymyxins B** and **E**, **colistitin** and **colistimethate** (its sulphomethate salt). They have cationic detergent properties and disrupt the bacterial outer cell membrane. They have a selective, rapidly bactericidal action on gram-negative bacilli, especially pseudomonads and coliform organisms, and can

bind to, and neutralise, some bacterial endotoxins. They are increasingly used to treat multidrug-resistant (MDR) organisms.

Pharmacokinetic aspects

They are not absorbed from the GI tract and must therefore be given systemically. Clinical use of these drugs is limited by their toxicity and is generally confined to intestinal infections and topical treatment of ear, eye or skin infections caused by susceptible organisms.

Unwanted effects

include neurotoxicity and nephrotoxicity which may be serious.

Also related to this group is **fosfomycin,** a small organic molecule originally found in *Streptomyces*, which blocks peptidoglycan synthesis by inactivating a key enzyme *Mur A*. It has a good spectrum of activity but, currently, fairly limited use in the treatment of urinary tract infections.

Miscellaneous antibacterial agents that prevent cell wall or membrane synthesis

- *Glycopeptide antibiotics*. **Vancomycin** is bactericidal, acting by inhibiting cell wall synthesis. It is used intravenously for multiresistant staphylococcal infections and orally for pseudomembranous colitis. Unwanted effects include ototoxicity and nephrotoxicity.
- *Polymyxins* (e.g. **colistimethate**). By disrupting bacterial cell membranes these are bactericidal. They are highly neurotoxic

and nephrotoxic and are only used topically.

(See **Table 52.2** for further examples.)

ANTIMICROBIAL AGENTS AFFECTING BACTERIAL PROTEIN SYNTHESIS

(See **Table 52.3**.)

TETRACYCLINES

The tetracyclines are broad-spectrum antibiotics. The group includes **tetracycline**, **oxytetracycline**, **demeclocycline**, **lymecycline**, **doxycycline**, **minocycline** and **tigecycline**.

Clinical uses of tetracyclines

- The use of tetracyclines declined because of widespread drug resistance, but has staged a comeback, e.g. for respiratory infections, as resistance has receded with reduced use. Most members of the group are microbiologically similar; **doxycycline** is given once daily and may be used in patients with renal impairment. Uses (sometimes in combination with other antibiotics) include:
  - rickettsial and chlamydial infections, brucellosis, anthrax and Lyme disease;
  - as useful second choice, for example in patients with allergies, for several infections (see **Table 52.3**), including mycoplasma and leptospira;

– respiratory tract infections (e.g. exacerbations of chronic bronchitis, community-acquired pneumonia);
– acne;
– inappropriate secretion of antidiuretic hormone (e.g. by some malignant lung tumours), causing hyponatraemia: **demeclocycline** inhibits the action of this hormone by an entirely distinct action from its antibacterial effect (see **Ch. 33**).

Mechanism of action

Following uptake into susceptible organisms by active transport, tetracyclines exert a bacteriostatic effect by inhibiting protein synthesis as explained in **Chapter 51**.

Antibacterial spectrum

The spectrum of antimicrobial activity of the tetracyclines is very wide and includes gram-positive and gram-negative bacteria, *Mycoplasma*, *Rickettsia*, *Chlamydia* spp., spirochaetes and some protozoa (e.g. amoebae). **Minocycline** is also effective against *N. meningitidis* and has been used to eradicate this organism from the nasopharynx of carriers. However, widespread resistance to these agents has decreased their usefulness. This is transmitted mainly by plasmids and, because the genes controlling resistance to tetracyclines are closely associated with genes for resistance to other antibiotics, organisms may develop resistance to many drugs simultaneously.

Pharmacokinetic aspects

The tetracyclines are generally given orally but can also be administered parenterally. **Minocycline** and **doxycycline** are well absorbed orally. The absorption of most other tetracyclines is irregular and incomplete but is improved in the absence of food. Because tetracyclines chelate metal ions (calcium, magnesium, iron, aluminium), forming non-absorbable complexes, absorption is decreased in the presence of milk, certain antacids and iron preparations.

Table 52.3

MRSA, Methicillin-resistant staphylococcus aureus.

Sources: BNF (2021) and others.

Unwanted effects

The commonest unwanted effects are GI disturbances caused initially by direct irritation and later by modification of the gut flora. Vitamin B complex deficiency can occur, as can suprainfection. Because they chelate Ca^{2+}, tetracyclines are deposited in growing bones and teeth, causing staining and sometimes dental hypoplasia and bone deformities. They should therefore not be given to children, pregnant women or nursing mothers. Another hazard to pregnant women is hepatotoxicity. Phototoxicity (sensitisation to sunlight) has also been seen, particularly with **demeclocycline**. **Minocycline** can produce vestibular disturbances (dizziness and nausea). High doses of tetracyclines can decrease protein synthesis in host cells, an anti-anabolic effect that may result in renal damage. Long-term therapy can cause disturbances of the bone marrow.

CHLORAMPHENICOL

Chloramphenicol was originally isolated from cultures of *Streptomyces*. It inhibits bacterial protein synthesis by inhibiting peptide bond formation and chain termination (**Ch. 51**).

Antibacterial spectrum

Chloramphenicol has a wide spectrum of antimicrobial activity, including gram-negative and gram-positive organisms and rickettsiae. It is bacteriostatic for most organisms but kills *H. influenzae*. Resistance, caused by the production of *chloramphenicol acetyltransferase*, is plasmid-mediated.

Pharmacokinetic aspects

Given orally, chloramphenicol is rapidly and completely absorbed and reaches its maximum concentration in the plasma within 2 h. It can also be given parenterally. The drug is widely distributed throughout the tissues and body fluids including the CSF. Its half-life is approximately 2 h. About 10% is excreted unchanged in the urine, and the remainder is inactivated in the liver.

Unwanted effects

The most important unwanted effect of **chloramphenicol** is severe, idiosyncratic depression of the bone marrow, resulting in *pancytopenia* (a decrease in all blood cell elements) – an effect that, although rare, can occur even with low doses in susceptible individuals. **Chloramphenicol** must be used with great care in newborns, with monitoring of plasma concentrations, because inadequate inactivation and excretion of the drug can result in the 'grey baby syndrome' – vomiting, diarrhoea, flaccidity, low

temperature and an ashen-grey colour – which carries 40% mortality. Hypersensitivity reactions can occur, as can GI disturbances secondary to alteration of the intestinal microbial flora.

Clinical uses of chloramphenicol

- Systemic use should be reserved for serious infections in which the benefit of the drug outweighs its uncommon but serious haematological toxicity. Such uses may include:
  - infections caused by *H. influenzae* resistant to other drugs;
  - *meningitis* in patients in whom penicillin cannot be used;
  - *typhoid fever*, but **ciprofloxacin** or **amoxicillin** and **co-trimoxazole** are similarly effective and less toxic.
- Topical use: safe and effective in bacterial conjunctivitis.

AMINOGLYCOSIDES

The aminoglycosides are a group of antibiotics of complex chemical structure, resembling each other in antimicrobial activity, pharmacokinetic characteristics and toxicity. The main agents are **gentamicin**, **streptomycin**, **amikacin**, **tobramycin** and **neomycin**.

Mechanism of action

There are several possible sites of action by which aminoglycosides inhibit bacterial protein synthesis. Their penetration through the

cell membrane of the bacterium depends partly on oxygen-dependent active transport by a polyamine carrier system (which, incidentally, is blocked by **chloramphenicol**) and they have minimal action against anaerobic organisms. The effect of the aminoglycosides is bactericidal and is enhanced by agents that interfere with cell wall synthesis (e.g. penicillins).

Resistance

Resistance to aminoglycosides is becoming a problem. It occurs through several different mechanisms, the most important being inactivation by microbial enzymes, of which nine or more are known. **Amikacin** was designed to be a poor substrate for these enzymes, but some organisms can inactivate this agent as well. Resistance as a result of failure of penetration can be largely overcome by the concomitant use of **penicillin** and/or **vancomycin**, at the cost of an increased risk of severe adverse effects.

Antibacterial spectrum

The aminoglycosides are effective against many aerobic gram-negative and some gram-positive organisms. They are most widely used against gram-negative enteric organisms and in sepsis. They may be given together with a penicillin in streptococcal infections and those caused by *Listeria* spp. and *P. aeruginosa*. **Gentamicin** is the aminoglycoside most commonly used, although **tobramycin** is slightly more active against *P. aeruginosa* infections. **Amikacin** has the widest antimicrobial spectrum and can be effective in infections with organisms resistant to **gentamicin** and **tobramycin**. **Streptomycin**, the first aminoglycoside to be

discovered, is active against *Mycobacterium tuberculosis*, and is seldom used for other indications.

Pharmacokinetic aspects

The aminoglycosides are polycations and therefore polar at neutral pH. They are not absorbed from the gastrointestinal tract and are usually given intramuscularly or intravenously. They cross the placenta but do not cross the blood–brain barrier, although high concentrations can be attained in joint and pleural fluids. The plasma half-life is 2–3 h. Elimination is by glomerular filtration in the kidney, 50%–60% of a dose being excreted unchanged within 24 h. If renal function is impaired, accumulation occurs rapidly, with a resultant increase in those toxic effects (such as ototoxicity and nephrotoxicity) that are dose related.

Unwanted effects

Serious, dose-related toxic effects, which may increase as treatment proceeds, can occur with the aminoglycosides, the main hazards being ototoxicity and nephrotoxicity. The former involves progressive damage to, and eventually destruction of, the sensory cells in the cochlea and vestibular organ of the ear. The result, usually irreversible, may manifest as vertigo, ataxia and loss of balance in the case of vestibular damage, and auditory disturbances or deafness in the case of cochlear damage. Any aminoglycoside may produce both types of effect, but **streptomycin** and **gentamicin** are more likely to interfere with vestibular function, whereas **neomycin** and **amikacin** mostly affect hearing. Ototoxicity is potentiated by the concomitant use of other ototoxic drugs (e.g. loop diuretics, see **Ch. 29**, and **vancomycin,** see

earlier) and susceptibility is genetically determined via mitochondrial DNA (see **Ch. 12**). Unlike nephrotoxicity, regular monitoring of plasma aminoglycoside concentration does not mitigate the risk of ototoxicity reliably.

The nephrotoxicity consists of damage to the kidney tubules and may necessitate dialysis, although function usually recovers if administration ceases as soon as renal toxicity is detected. Nephrotoxicity is more likely to occur in patients with pre-existing renal disease or in conditions in which urine volume is reduced, and concomitant use of other nephrotoxic agents (e.g. first-generation cephalosporins, **vancomycin**) increases the risk. As the elimination of these drugs is almost entirely renal, this nephrotoxic action can impair their own excretion and a vicious cycle may develop. Plasma concentrations should be monitored repeatedly, and the dose or dose interval adjusted accordingly.

A rare but serious toxic reaction is paralysis caused by long-lasting neuromuscular blockade. This is usually seen only if the agents are given concurrently with neuromuscular-blocking agents. It results from inhibition of the Ca^{2+} uptake necessary for the exocytotic release of acetylcholine (see **Ch. 14**).

MACROLIDES

The term *macrolide* relates to a structural feature of this group, a many-membered lactone ring to which one or more deoxy sugars are attached. The main macrolide and related antibiotics are **erythromycin**, **clarithromycin** and **azithromycin**. **Telithromycin** is of minor utility.

Mechanism of action

The macrolides inhibit bacterial protein synthesis by acting at different sites in the synthesis of new bacterial proteins (see **Ch. 51**).

Antimicrobial spectrum

The antimicrobial spectrum of **erythromycin** is very similar to that of **penicillin**, and it is a safe and effective alternative for **penicillin**-sensitive patients. **Erythromycin** is effective against gram-positive bacteria and spirochaetes but not against most gram-negative organisms, exceptions being *Neisseria gonorrhoeae* and, to a lesser extent, *H. influenzae*. *M. pneumoniae*, *Legionella* spp. and some chlamydial organisms are also susceptible (see **Table 52.3**). Resistance can occur and results from a plasmid-controlled alteration of the binding site for **erythromycin** on the bacterial ribosome.

Azithromycin is less active than **erythromycin** against gram-positive bacteria but is considerably more effective against *H. influenzae* and may be more active against *Legionella*. It can be used to treat *Toxoplasma gondii*, as it kills the cysts. **Clarithromycin** is as active, and its metabolite is twice as active, against *H. influenzae* as **erythromycin**. It is also effective against *Mycobacterium avium-intracellulare* (which can infect immunologically compromised individuals and elderly patients with chronic lung disease), and it may also be useful in leprosy and against *Helicobacter pylori* (see **Ch. 30**). Both these macrolides are also effective in *Lyme disease*.

Pharmacokinetic aspects

The macrolides are administered orally or parenterally, although intravenous injections can cause local thrombophlebitis. They diffuse readily into most tissues but do not cross the blood–brain barrier, and there is poor penetration into synovial fluid. The plasma half-life of **erythromycin** is about 90 min; that of **clarithromycin** is three times longer, and that of **azithromycin** is 8–16 times longer. Macrolides enter and indeed are concentrated within phagocytes – **azithromycin** concentrations in phagocyte lysosomes can be 40 times higher than in the blood – and they can enhance intracellular killing of bacteria by phagocytes.

Erythromycin is partly inactivated in the liver; **azithromycin** is more resistant to inactivation, and **clarithromycin** is converted to an active metabolite. Inhibition of the P450 cytochrome system by these agents can affect the bioavailability of other drugs leading to clinically important interactions, for example, with **theophylline** (see **Ch. 12**). The major route of elimination is in the bile.

Unwanted effects

GI disturbances are common and unpleasant but not serious. With **erythromycin**, the following have also been reported: hypersensitivity reactions such as rashes and fever, transient hearing disturbances and rarely, following treatment for longer than 2 weeks, cholestatic jaundice. Opportunistic infections of the GI tract or vagina can occur.

OXAZOLIDINONES

Following their discovery in the mid-1990s, the oxazolidinones were originally hailed as the ‘first truly new class of antibacterial agents

to reach the marketplace in several decades' (**Zurenko et al., 2001**). The group inhibits bacterial protein synthesis by a novel mechanism: inhibition of *N*-formylmethionyl-tRNA binding to the 70S ribosome. **Linezolid** was the first member of this new antibiotic family to be introduced. It is active against a wide variety of gram-positive bacteria and is particularly useful for the treatment of drug-resistant bacteria such as MRSA, **penicillin**-resistant *Streptococcus pneumoniae* and **vancomycin**-resistant enterococci. The drug is also effective against some anaerobes, such as *C. difficile*. Most common gram-negative organisms are not susceptible to the drug. **Linezolid** can be used to treat pneumonia, septicaemia and skin and soft tissue infections. Its use is restricted to serious bacterial infections where other antibiotics have failed, and there have so far been few reports of resistance.

Unwanted effects

include thrombocytopenia, diarrhoea, nausea and, rarely, rash and dizziness. **Linezolid** is a non-selective inhibitor of monoamine oxidase, and appropriate precautions need to be observed (see **Ch. 48**).

FUSIDIC ACID

Fusidic acid is a narrow-spectrum steroidal antibiotic active mainly against gram-positive bacteria. It acts by inhibiting bacterial protein synthesis, but resistance commonly emerges if it is used as a single agent. It is used in combination with other anti-staphylococcal agents in staphylococcal sepsis, and also used topically for staphylococcal infections (e.g. as eye drops or cream).

Pharmacokinetic aspects

As the sodium salt, the drug is well absorbed from the gut and is distributed widely in the tissues. Some is excreted in the bile and some metabolised.

Unwanted effects

such as GI disturbances are fairly common. Skin eruptions and jaundice can occur. Resistance occurs if it is used systemically as a single agent, so it is always combined with other antibacterial drugs when used systemically.

STREPTOGRAMINS

Dalfopristin and **quinupristin** are cyclic peptides used in combination. They inhibit bacterial protein synthesis by binding to the 50S subunit of the bacterial ribosome. Other members of the family include **pristinamycin** and **virginiamycin**. **Dalfopristin** changes the structure of the ribosome so as to promote the binding of **quinupristin**. Individually, they exhibit only very modest bacteriostatic activity, but combined together as an intravenous injection they have good activity against many gram-positive bacteria. The combination is used to treat serious infections, usually where no other antibacterial is suitable being effective, for example, against MRSA and **vancomycin**-resistant *Enterococcus faecium*.

Pharmacokinetic aspects

Both drugs undergo extensive first-pass hepatic metabolism and must therefore be given by intravenous infusion. The half-life of each compound is 1–2 h.

Unwanted effects

include inflammation and pain at the infusion site, arthralgia, myalgia and nausea, vomiting and diarrhoea. To date, resistance to **quinupristin** and **dalfopristin** does not seem to be a major problem.

CLINDAMYCIN

The lincosamide **clindamycin** is active against gram-positive cocci, including many penicillin-resistant staphylococci and many anaerobic bacteria such as *Bacteroides* spp. It acts in the same way as macrolides and **chloramphenicol**. In addition to its use in infections caused by *Bacteroides* organisms, it is used to treat staphylococcal infections of bones and joints. It is also given topically, as eye drops, for staphylococcal conjunctivitis and used as an anti-protozoal drug (see **Ch. 55**).

Unwanted effects

consist mainly of GI disturbances, ranging from uncomfortable diarrhoea to potentially lethal pseudomembranous colitis, caused by a toxin-forming *C. difficile*. [5]

Antimicrobial agents affecting bacterial protein synthesis

- *Tetracyclines* (e.g. **minocycline**). These are orally active, bacteriostatic, broad-spectrum antibiotics. Resistance is increasing. GI disorders are common. They also chelate

calcium and are deposited in growing bone. They are contraindicated in children and pregnant women.

- ***Chloramphenicol.*** This is an orally active, bacteriostatic, broad-spectrum antibiotic. Serious toxic effects are possible, including bone marrow depression and 'grey baby syndrome'. Systemic use should be reserved for life-threatening infections.
- *Aminoglycosides* (e.g. **gentamicin**). These are given by injection. They are bactericidal, broad-spectrum antibiotics (but with low activity against anaerobes, streptococci and pneumococci). Resistance is increasing. The main unwanted effects are dose-related nephrotoxicity and ototoxicity. Serum levels should be monitored. (**Streptomycin** is an aminoglycoside used to treat tuberculosis.)
- *Macrolides* (e.g. **erythromycin**). Can be given orally and parenterally. They are bactericidal/bacteriostatic. The antibacterial spectrum is the same as for **penicillin**. **Erythromycin** can cause jaundice. Newer agents are **clarithromycin** and **azithromycin.**
- *Lincosamides* (e.g. **clindamycin**). Can be given orally and parenterally. It can cause pseudomembranous colitis.
- *Streptogramins* (e.g. **quinupristin/dalfopristin**). Given by intravenous infusion as a combination. Considerably less effective when administered separately. Active against several strains of drug-resistant bacteria.
- ***Fusidic acid.*** This is an anti-staphylococcal antibiotic that acts by inhibiting protein synthesis. It penetrates bone. Unwanted effects include GI disorders. It is used systemically

in combination with other anti-staphylococcal drugs (e.g. **flucloxacillin**), and topically for staphylococcal conjunctivitis.

- ***Linezolid.*** Given orally or by intravenous injection. Active against several strains of drug-resistant bacteria.

(See **Table 52.3** for further examples.)

ANTIMICROBIAL AGENTS AFFECTING TOPOISOMERASE

QUINOLONES

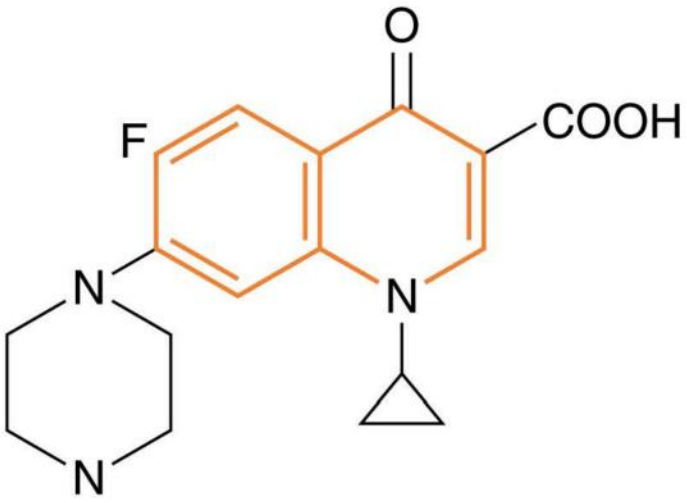
The quinolones include the broad-spectrum agents **ciprofloxacin**, **levofloxacin**, **ofloxacin**, **norfloxacin** and **moxifloxacin** as well as **nalidixic acid**, a narrow-spectrum drug used in urinary tract infections. Most are fluorinated (fluoroquinolones). These agents inhibit *topoisomerase II*, a bacterial DNA gyrase that produces a negative supercoil in DNA and thus permits transcription or replication (see **Fig. 52.4** and **Table 52.3**).

Antibacterial spectrum and clinical use

Ciprofloxacin is widely used and is typical of the group. It is a broad-spectrum antibiotic effective against both gram-positive and gram-negative organisms, including the Enterobacteriaceae (enteric gram-negative bacilli), many organisms resistant to penicillins, cephalosporins and aminoglycosides, and against *H. influenzae*, penicillinase-producing *N. gonorrhoeae*, *Campylobacter* spp. and pseudomonads. Of the gram-positive organisms, streptococci and pneumococci are only weakly inhibited, and there is a high

incidence of staphylococcal resistance. **Ciprofloxacin** should be avoided in MRSA infections. Clinically, the fluoroquinolones are best reserved for infections with facultative and aerobic gram-negative bacilli and cocci. [6] Resistant strains of *S. aureus* and *P. aeruginosa* have emerged.

A



Ciprofloxacin

B

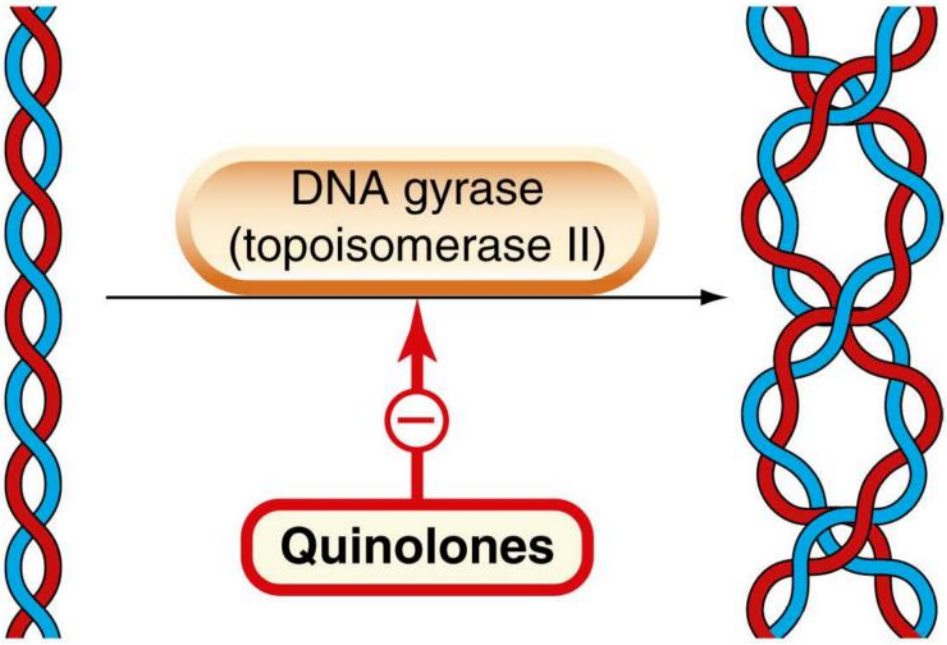


FIG. 52.4 A simplified diagram of the mechanism of action of the fluoroquinolones.(A) An example of a quinolone (the quinolone moiety is shown in *orange*). (B) Schematic diagram of *(left)* the double helix and *(right)* the double helix in supercoiled form (see also **Ch. 51**). In essence, the DNA gyrase unwinds the RNA-induced positive supercoil (not shown) and introduces a negative supercoil.

Pharmacokinetic aspects

Fluoroquinolones are well absorbed following oral administration. The drugs accumulate in several tissues, particularly in the kidney, prostate and lung. All quinolones are concentrated in phagocytes. Most fail to cross the blood–brain barrier, but **ofloxacin** does so. Aluminium and magnesium antacids interfere with the absorption of the quinolones. Elimination of **ciprofloxacin** and **norfloxacin** is partly by hepatic metabolism by P450 enzymes (which they can inhibit, giving rise to interactions with other drugs) and partly by renal excretion. **Ofloxacin** is excreted in the urine.

Unwanted effects

In hospitals, infection with *C. difficile* may prove hazardous. *Tendonitis* is commoner in children and adults over 60 years old and can lead to tendon rupture so treatment must be discontinued immediately if tendonitis is suspected; co-treatment with corticosteroids is a risk factor. There is also a risk of aortic dissection and aortic aneurysm. GI disorders are common and

rashes can occur. Central nervous system (CNS) symptoms – headache and dizziness – have occurred, as have, less frequently, convulsions associated with CNS pathology or concurrent use of a non-steroidal anti-inflammatory drug (NSAID; see **Ch. 25**).

There is a clinically important interaction between **ciprofloxacin** and **theophylline** (through inhibition of P450 enzymes), which can lead to **theophylline** toxicity (including convulsions) in asthmatics treated with the fluoroquinolones. The topic is discussed further in **Chapter 28**. **Moxifloxacin** prolongs the electrocardiographic QT interval and is used extensively, following FDA guidance, as a positive control in studies in healthy volunteers examining possible effects of new drugs on cardiac repolarisation.

Antimicrobial agents affecting DNA topoisomerase II

- The quinolones interfere with the supercoiling of DNA.
- **Ciprofloxacin** has a wide antibacterial spectrum, being especially active against gram-negative enteric coliform organisms, including many organisms resistant to penicillins, cephalosporins and aminoglycosides; it is also effective against *H. influenzae*, penicillinase-producing *N. gonorrhoeae*, *Campylobacter* spp. and pseudomonads. There is a high incidence of staphylococcal resistance.
- Unwanted effects include tendonitis, tendon rupture, rarely aortic dissection and aortic aneurysm; GI tract upsets are

common, hypersensitivity reactions and, rarely, CNS disturbances can occur.

(See **Table 52.3** for further examples.)

MISCELLANEOUS ANTIBACTERIAL AGENTS

Fidaxomicin was originally discovered in actinomycetes. It inhibits bacterial RNA polymerase. It is not used to treat systemic infections as it is poorly absorbed from the gut but has a role in treating *C. difficile* infections.

METRONIDAZOLE

Metronidazole was introduced as an antiprotozoal agent (see **Ch. 55**), but it is also active against anaerobic bacteria such as *Bacteroides*, *Clostridia* spp. and some streptococci. It is effective in the therapy of pseudomembranous colitis and is important in the treatment of serious anaerobic infections (e.g. sepsis secondary to bowel disease). It has a disulfiram-like action (see **Ch. 50**), so patients must avoid alcohol during treatment.

NITROFURANTOIN

Nitrofurantoin is a synthetic compound active against a range of gram-positive and gram-negative organisms. The development of resistance in susceptible organisms is rare, and there is no cross-resistance. Its mechanism of action is probably related to its ability to damage bacterial DNA.

Pharmacokinetic aspects

Nitrofurantoin is given orally and is rapidly and totally absorbed from the GI tract and just as rapidly excreted by the kidney. Its use is confined to the treatment of bladder infections ('cystitis') and prophylactically in the prevention of such infections in patients with recurrent cystitis.

Unwanted effects

GI disturbances are relatively common, and hypersensitivity reactions involving the skin and the bone marrow (e.g. leukopenia) can occur. Hepatotoxicity and peripheral neuropathy have been reported.

ANTIMYCOBACTERIAL AGENTS

(See **Table 52.4**.)

The main mycobacterial infections in humans are tuberculosis (TB) and leprosy, which are chronic infections caused by *M. tuberculosis* and *Mycobacterium leprae*, respectively. Another mycobacterial infection is *M. avium-intracellulare* (actually two organisms), which can infect some AIDS patients. A particular problem with mycobacteria is that they can survive inside macrophages after phagocytosis, unless these cells are 'activated' by cytokines produced by T-helper (Th) 1 lymphocytes (see **Ch. 7**). Drugs in this section are usually considered separately since some of them are specific for mycobacteria or used only to treat these infections for other reasons.

DRUGS USED TO TREAT TUBERCULOSIS

For centuries, TB was a major killer disease, but the introduction of **streptomycin** in the late 1940s followed by **isoniazid** and, in the 1960s, of **rifampicin** and **ethambutol** revolutionised therapy and TB came to be regarded as an easily treatable condition. Regrettably, this is no longer true. Strains with increased virulence or exhibiting multidrug resistance are now common (**Bloom and Small, 1998**), and at the time of writing, TB now causes more deaths than any other single infectious agent apart from COVID-19. Even though infection rates are falling at a rate of about 2% annually, some 10 million people fell ill with the disease in 2020 (including 1.1 million children) and there were 1.5 million deaths from the disease according to the latest WHO figures. While TB is a global disease, about 86% of new infections can be accounted for by 30 countries with India and China being the worst affected. MDR TB is common and because of an ominous synergy between mycobacteria (e.g. *M. tuberculosis*, *M. avium-intracellulare*) and HIV, infections with the latter increase the risk of catching the disease some 20-fold and about a quarter of HIV-associated deaths are caused by TB.

Treatment is usually initiated with **isoniazid**, **rifampicin**, **rifabutin**, **ethambutol** and **pyrazinamide**. Second-line drugs include **capreomycin**, **cycloserine**, **streptomycin** (rarely used for this purpose now in the United Kingdom), **clarithromycin** and **ciprofloxacin**. These are used to treat infections likely to be resistant to first-line drugs, or when the first-line agents have to be abandoned because of adverse effects. Two newer drugs, **bedaquiline** and **delamanid**, have been introduced for use in MDR cases of TB, usually in conjunction with other agents.

Table 52.4

UTI, Urinary tract infection.

[a] These drugs are often used in combination.

Sources: BNF (2021) and others.

To decrease the probability of the emergence of resistant organisms, combination drug therapy is usually mandatory. [7] This commonly involves:

- an initial phase of treatment (about 2 months) with a combination of **isoniazid**, **rifampicin** and **pyrazinamide** (plus **ethambutol** if the organism is suspected to be resistant);
- a second, continuation phase (about 4 months) of therapy, with **isoniazid** and **rifampicin.** Longer-term treatment is needed for patients with meningitis, bone/joint involvement or drug-resistant infection.

ISONIAZID

The antibacterial activity of **isoniazid** is limited to mycobacteria. It halts the growth of resting organisms (i.e. is bacteriostatic) but can also kill dividing bacteria. It passes freely into mammalian cells and is thus effective against intracellular organisms. **Isoniazid** is a prodrug that must be activated by bacterial enzymes before it can exert its inhibitory activity on the synthesis of *mycolic acids*, important constituents of the cell wall peculiar to mycobacteria. Resistance to the drug, secondary to reduced penetration into the

bacterium, may be present, but cross-resistance with other tuberculostatic drugs does not occur.

Pharmacokinetic aspects

Isoniazid is readily absorbed from the gastrointestinal tract and is widely distributed throughout the tissues and body fluids, including the CSF. An important point is that it penetrates well into 'caseous' tuberculous lesions (i.e. necrotic lesions with a cheese-like consistency). Metabolism, which involves acetylation, depends on genetic factors that determine whether a person is a slow or rapid acetylator of the drug (see **Ch. 12**), with slow inactivators enjoying a better therapeutic response. The half-life in slow inactivators is 3 h and in rapid inactivators, 1 h. **Isoniazid** is excreted in the urine partly as unchanged drug and partly in the acetylated or otherwise inactivated form.

Unwanted effects

depend on the dosage and occur in about 5% of individuals, the commonest being allergic skin eruptions. A variety of other adverse reactions have been reported, including fever, hepatotoxicity, haematological changes, arthritic symptoms and vasculitis. Adverse effects involving the central or peripheral nervous systems are largely consequences of pyridoxine deficiency and were common in malnourished patients before supplementation of this vitamin during isoniazid treatment became routine. **Isoniazid** may cause haemolytic anaemia in individuals with glucose 6-phosphate dehydrogenase deficiency, and it decreases the metabolism of the antiepileptics **phenytoin**, **ethosuximide** and **carbamazepine**,

resulting in an increase in the plasma concentration and toxicity of these drugs.

RIFAMPICIN

Rifampicin (also called **rifampin**) acts by binding to, and inhibiting, *DNA-dependent RNA polymerase* in prokaryotic but not in eukaryotic cells (see **Ch. 51**). It is one of the most active antituberculosis agents known and is also effective against leprosy and most gram-positive bacteria as well as many gram-negative species, but it is usually reserved for the treatment of TB and leprosy. It enters phagocytic cells and kills intracellular tubercle bacilli. Resistance can develop rapidly in a one-step process in which a chromosomal mutation changes its target site on microbial DNA-dependent RNA polymerase, so it is used in combination with other antituberculous antibiotics.

Pharmacokinetic aspects

Rifampicin is given orally and is widely distributed in the tissues and body fluids (including CSF), giving an orange tinge to saliva, sputum, tears and sweat. It is excreted partly in the urine and partly in the bile, some of it undergoing enterohepatic cycling. The metabolite retains antibacterial activity but is less well absorbed from the GI tract. The half-life is 1–5 h, becoming shorter during treatment because of induction of hepatic microsomal enzymes.

Unwanted effects

are relatively infrequent. The commonest are skin eruptions, fever and GI disturbances. Liver damage with jaundice has been reported and has proved fatal in a very small proportion of patients, so liver

function should be assessed before treatment is started. **Rifampicin** induces hepatic metabolising enzymes (see **Ch. 11**), increasing the degradation of **warfarin**, glucocorticoids, narcotic analgesics, oral antidiabetic drugs, **dapsone** and oestrogens, the last effect leading to failure of oral contraception.

ETHAMBUTOL

Ethambutol has no effect on organisms other than mycobacteria. It is taken up by the bacterial cells and exerts a bacteriostatic effect after a period of 24 h, probably by inhibiting mycobacterial cell wall synthesis. Resistance emerges rapidly if the drug is used alone.

Pharmacokinetic aspects

Ethambutol is given orally and is well absorbed. It can reach therapeutic concentrations in the CSF in tuberculous meningitis. In the blood, it is taken up by erythrocytes and slowly released. **Ethambutol** is partly metabolised and is excreted in the urine.

Unwanted effects

These are uncommon, the most significant being optic neuritis, which is dose related and is more likely to occur if renal function is decreased. This results in visual disturbances manifesting initially as red–green colour blindness progressing to a decreased visual acuity. Colour vision should be monitored before and during prolonged treatment.

To avoid the emergence of resistant organisms, combination therapy is used (e.g. three drugs initially, followed by a two-drug regimen later).

First-line drugs

- **Isoniazid** kills actively growing mycobacteria within host cells. Given orally, it penetrates necrotic lesions, also the CSF. 'Slow acetylators' (genetically determined) respond well. It has low toxicity. Pyridoxine deficiency increases risk of neurotoxicity. No cross-resistance with other agents.
- **Rifampicin** is a potent, orally active drug that inhibits mycobacterial RNA polymerase. It penetrates CSF. Unwanted effects are infrequent (but serious liver damage has occurred). It induces hepatic drug-metabolising enzymes. Resistance can develop rapidly.
- **Ethambutol** inhibits growth of mycobacteria. It is given orally and can penetrate CSF. Unwanted effects are uncommon, but optic neuritis can occur. Resistance can emerge rapidly.
- **Pyrazinamide** is tuberculostatic against intracellular mycobacteria. Given orally, it penetrates CSF. Resistance can develop rapidly. Unwanted effects include increased plasma urate and liver toxicity with high doses.

Second-line drugs

- **Capreomycin** is given intramuscularly. Unwanted effects include damage to the kidney and to the auditory nerve.

- **Cycloserine** is a broad-spectrum agent. It inhibits an early stage of peptidoglycan synthesis. Given orally, it penetrates the CSF. Unwanted effects affect mostly the CNS.
- **Streptomycin**, an aminoglycoside antibiotic, acts by inhibiting bacterial protein synthesis. It is given intramuscularly. Unwanted effects are ototoxicity (mainly vestibular) and nephrotoxicity.

(See **Table 52.4** for further examples.)

PYRAZINAMIDE

Pyrazinamide is inactive at neutral pH but tuberculostatic at acid pH. It is effective against the intracellular organisms in macrophages because, after phagocytosis, the organisms are contained in phagolysosomes where the pH is low. The drug probably inhibits bacterial fatty acid synthesis. Resistance develops rather readily, but cross-resistance with **isoniazid** does not occur.

Pharmacokinetic aspects

The drug is well absorbed after oral administration and is widely distributed, penetrating the meninges. It is excreted through the kidney, mainly by glomerular filtration.

Unwanted effects

include gout, which is associated with high concentrations of plasma uric acid with which pyrazinamide competes for the renal tubular OAT (see Chs **9** and **10**). GI upsets, malaise and fever have also been reported. Serious hepatic damage due to high doses was once a problem but is less likely with lower dose/shorter course

regimens now used; nevertheless, liver function should be assessed before treatment.

CAPREOMYCIN

Capreomycin is a peptide antibiotic given by intramuscular injection. Its principal mechanism of action is thought to be through inhibition of translocation thereby inhibiting protein synthesis, but it may also have other effects on the bacterial cell membrane.

Unwanted effects

are many and the drug should be used with great caution. They include kidney damage and injury to the auditory nerve, with consequent deafness and ataxia. The drug should not be given at the same time as **streptomycin** or other drugs that may cause deafness. It is usually reserved for patients with disease due to drug-resistant organisms.

CYCLOSERINE

Cycloserine is a broad-spectrum antibiotic that inhibits the growth of many bacteria, including coliforms and mycobacteria. It is water soluble and destroyed at acid pH. It acts by competitively inhibiting bacterial cell wall synthesis. It is an analogue of D-alanine and inhibits the formation of the D-Ala-D-Ala dipeptide that is added to the initial tripeptide side-chain on *N*-acetylmuramic acid; i.e. it prevents completion of the major building block of peptidoglycan. It is administered orally and distributed throughout the tissues and body fluids, including CSF. Its use is limited to the treatment of TB that is resistant to other drugs.

Pharmacokinetic aspects

Most of the drug is eliminated in active form in the urine, but approximately 35% is metabolised.

Unwanted effects

are mainly on the CNS possibly through an inhibitory effect on GABA-transaminase. A wide variety of disturbances may occur, ranging from headache and irritability to depression, convulsions and psychotic states.

DRUGS USED TO TREAT LEPROSY

Leprosy is one of the most ancient diseases known to mankind and has been mentioned in texts dating back to 600 BC. The causative organism is *M. leprae*. It is a chronic disfiguring illness with a long latency and, historically, sufferers have been ostracised and forced to live apart from their communities, even though the disease is not particularly contagious. Once viewed as incurable, the introduction in the 1940s of **dapsone**, and subsequently, in the 1960s, of **rifampicin** and **clofazimine**, completely changed our perspective on leprosy. It is now generally curable, and the global figures show that the prevalence rates for the disease have now fallen by about 99% as a result of public health measures and the **M**ulti**d**rug **T**reatment (MDT; essential to avoid drug resistance) regimens implemented by WHO since 1981 with support from some pharmaceutical companies. The disease has been now eliminated from all but a few small countries; nevertheless, the WHO reported some 127,000 new cases in 2020, mainly in Asia and Africa.

There are two forms:

- *Paucibacillary leprosy*, leprosy characterised by one to five numb patches, is mainly *tuberculoid* [8] in type and is generally treated for 6 months with **dapsone** and **rifampicin.**
- *Multibacillary leprosy*, characterised by more than five numb skin patches, is mainly *lepromatous* in type and is treated for at least 2 years with **rifampicin**, **dapsone** and **clofazimine.**

DAPSONE

Dapsone is chemically related to the sulfonamides. Its action is antagonised by PABA and so the drug probably acts through inhibition of bacterial folate synthesis. Resistance to **dapsone** has steadily increased since its introduction and treatment in combination with other drugs is now recommended.

Pharmacokinetic aspects

Dapsone is given orally; it is well absorbed and widely distributed through the body water and in all tissues. The plasma half-life is 24–48 h, but some drug persists in liver, kidney and, to some extent, skin and muscle for much longer periods. There is enterohepatic recycling of the drug, but some is acetylated and excreted in the urine. **Dapsone** is also used to treat *dermatitis herpetiformis*, a chronic blistering skin condition associated with coeliac disease.

Unwanted effects

occur fairly frequently and include haemolysis of red cells (although usually not severe enough to lead to frank anaemia),

methaemoglobinaemia, anorexia, nausea and vomiting, fever, allergic dermatitis and neuropathy. *Lepra reactions* (an exacerbation of lepromatous lesions) can occur, and a potentially fatal syndrome resembling infectious mononucleosis has occasionally been seen.

CLOFAZIMINE

Clofazimine is a dye of complex structure. Its mechanism of action against leprosy bacilli may involve an action on DNA. It also has anti-inflammatory activity and is useful in patients in whom **dapsone** causes inflammatory side effects.

Pharmacokinetic aspects

Clofazimine is given orally and accumulates in the body, being sequestered in the mononuclear phagocyte system. The plasma half-life may be as long as 8 weeks. The anti-leprotic effect is delayed and is usually not evident for 6–7 weeks.

Unwanted effects

may be related to the fact that **clofazimine** is a dye. The skin and urine can develop a reddish colour and the lesions a blue–black discoloration. Dose-related nausea, giddiness, headache and GI disturbances can also occur.

Antileprosy drugs

- For *tuberculoid leprosy*: **dapsone** and **rifampicin** (**rifampin**).

  - **Dapsone** is sulfonamide-like and inhibits folate synthesis. It is given orally. Unwanted effects are fairly frequent; a few are serious. Resistance is increasing.
  - **Rifampicin** (see *Antituberculosis drugs* box).
- For *lepromatous leprosy*: dapsone, **rifampicin** and **clofazimine.**
  - **Clofazimine** is a dye that is given orally and can accumulate by sequestering in macrophages. Action is delayed for 6–7 weeks, and its half-life is 8 weeks. Unwanted effects include red skin and urine, sometimes GI disturbances.

(See **Table 52.4** for further examples.)

PROSPECTS FOR NEW ANTIBACTERIAL DRUGS

During the 5 years ending in 2020, only 12 'new' antibiotics were approved by the FDA and, as a recent review has made plain, virtually all of these were essentially variations upon existing antibiotic structures with only one **cephalosporin** derivative acting through a novel mechanism (**Provenzani et al., 2020**).

Historically, antibiotics were one of the mainstays of the pharmaceutical industry. The rapid discoveries and developments that characterised the 'heroic' years of antibiotic research, which spanned approximately 1930–1960, led to the discovery of some 20 novel classes of antibiotics which even today constitute the core of our arsenal of antibacterial drugs. The depressing message is that to compensate for the loss of drug efficacy to resistance mechanisms,

we would need another 20 new classes of antibiotics within the next 50 years. Despite the emergence of isolated reports of new antibiotic mechanisms in the scientific literature, there is, at present, little prospect of achieving this goal.

Hubris is partly to blame. The antibiotics originally discovered were so successful that by 1970, it was thought that infectious diseases had been effectively vanquished. [9] Many pharmaceutical companies scaled down their efforts in the area, despite the continuing need for compounds acting by novel mechanisms to keep pace with the adaptive potential of pathogens.

One might legitimately ask how this has been allowed to happen given the cardinal importance of this group of drugs. The reasons are multifactorial. Innovation by the pharmaceutical industry has been beset by regulatory problems and ethical issues with the clinical trials of new antibiotics. Perhaps most important though is the financial backing for new drug discovery. The private sector is the major initiator of drug discovery but with an eye-watering outlay currently estimated at about US$2.9 billion (**Provenzani et al., 2020**) required to develop such drugs, the payback to the pharmaceutical industry is seldom sufficient to recoup such a massive investment. Evidence of antibiotic efficacy is difficult to generate and 'success' is rewarded by a product that will used for the shortest duration possible to minimise the emergence of resistance, and which probably cannot be afforded by the peoples in poor countries who often have the greatest need for such drugs. These and other complex reasons for the failure to develop new antibiotics have been analysed in detail by **Coates et al. (2011)**.

Legislation and government initiatives have been introduced in some countries (e.g. United States) which promise fast-track regulatory approval and extended patent life for those wishing to take the huge financial risks. These, and other potentially useful strategies, have been reviewed by **Renwick et al. (2016)** but have seemingly made little impact thus far.

At the same time, drug resistance has been increasing and can develop with shocking rapidity. **Bax et al. (2000)** noted the appearance of resistant strains within 2 years or so of the introduction of a new agent and **Costelloe et al. (2010)** concluded that most patients prescribed antibiotics for a respiratory or urinary tract infection develop individual resistance to the drug within a few weeks and that this may persist for up to a year after treatment. In fact, deaths from drug-resistant bacteria now exceed those caused by HIV/AIDS or malaria with *Escherichia coli*, *S. aureus* and *Klebsiella pneumoniae* topping the list of frequent killers (**Murray, 2022**). [10] Since about half the antibiotic use is for veterinary purposes, it is not just human medicine that is compromised by this phenomenon.

The stark reality is that unless substantial progress is made, we will soon be entering the 'post-antibiotic' era and medicine, as we know it today, will not be possible. But perhaps we should not underestimate the collective ingenuity of biomedical scientists. Many labs, both academic and commercial, are utilising the power of high-throughput screens to search for, and assess, new naturally occurring antibiotic candidates. Others are exploring different types of antibacterials such as biopharmaceuticals (see **Ch. 5**) or devising increasingly sophisticated ways of defeating bacterial resistance

mechanisms. In all cases their endeavours are informed by the latest conceptual tools such as bioinformatic analysis of pathogen genomes. In the meantime, the world awaits further therapeutic developments with bated breath.

QUESTIONS

QUESTION 52.1

Gram-negative bacteria often show increased levels of resistance to antibiotics compared to Gram-positive bacteria.

The main characteristic of Gram-negative bacteria responsible for their increased resistance is…

OPTIONS:

A. The presence of enzymes in the periplasmic space

B. A peptidoglycan layer

C. An outer membrane

D. An outer surface rich in complex polysaccharides

E. Secretion of endotoxin

QUESTION 52.2

Following the serendipitous discovery of penicillin, a range of β-lactam antibiotics has been developed, although growing resistance to these antibiotics is limiting their current use.

Which of the following statements about β-lactam antibiotics is incorrect?

OPTIONS:

A. β-Lactam antibiotics interfere with the synthesis of the bacterial cell wall peptidoglycan.

B. β-Lactam antibiotics are bacteriostatic.

C. Monobactam antibiotics are resistant to β-lactamases.

D. Cephalosporins are more readily hydrolysed by β-lactamases than penicillins.

E. The main side effect of β-lactam antibiotics is hypersensitivity.

QUESTION 52.3

The use of many antibiotics is limited by resistance or side effects.

Which of the following would be suitable for the given indication?

OPTIONS:

A. Co-trimoxazole for *Pneumocystis* pneumonia

B. Tetracyclines for urinary tract infections in pregnancy

C. Benzylpenicillin for methicillin-resistant *Staphylococcus aureus* (MRSA) infections

D. Isoniazid for meningitis

E. Chloramphenicol for bacterial throat infections

ANSWERS

ANSWER 52.1

RATIONALE:

A. The periplasmic space contains enzymes and other components but do not target antibiotics.

B. The peptidoglycan layer is 2 nm in thickness, forming 5% of the cell wall mass. This is often linked to outwardly projecting lipoprotein molecules but does not form a significant barrier to antibiotic uptake.

C. An outer membrane consisting of a lipid bilayer, similar in some respects to the plasma membrane, that contains protein molecules and lipoproteins linked to the peptidoglycan but does not affect antibiotic action.

D.

E. Endotoxin is a lipopolysaccharide which, when shed in vivo, triggers various aspects of the inflammatory reaction by activating complement and cytokines but once shed no longer blocks antibiotic entry.

CORRECT ANSWER WITH EXPLANATION:

D. An outer surface rich in complex polysaccharides

The cell wall lipopolysaccharide is a major barrier to penetration of some antibiotics, and difficulty in penetrating this complex outer layer explains why some antibiotics are less active against Gram-negative than Gram-positive bacteria.

ANSWER 52.2

RATIONALE:

A. They bind to penicillin-binding proteins and inhibit the transpeptidation enzyme that cross-links the peptide chains attached to the backbone of the peptidoglycan.

B.

C. The structure and associated side groups of the β-lactam ring in monobactam antibiotics have made them resistant to most β-lactamases.

D. Chromosomal β-lactamase is now present in most Gram-negative bacteria and is more active in hydrolysing cephalosporins than penicillins.

E. Hypersensitivity caused by the degradation of β-lactam antibiotics, which combine with host proteins to form antigenic fragments, limits the use of these agents in some patients.

CORRECT ANSWER WITH EXPLANATION:

B. β-Lactam antibiotics are bacteriostatic.

β-Lactam antibiotics interfere with cell wall synthesis, resulting in the killing of the bacteria, and are therefore classed as bactericidal.

Which agent(s)…

ANSWER 52.3

RATIONALE:

A.

B. Tetracyclines are contraindicated in children and during pregnancy due to the risk of bone deformities and hepatotoxicity.

C. MRSA demonstrates multiresistance to a large number of antibiotics including the penicillins. Vancomycin is one of the few active agents but even resistance to this agent has been observed.

D. The antimicrobial activity of isoniazid is limited to mycobacterium and it is therefore used as an antituberculosis agent.

E. Due to the risk of bone marrow depression, the use of chloramphenicol is restricted to severe life-threatening infections.

CORRECT ANSWER WITH EXPLANATION:

A. Co-trimoxazole for *Pneumocystis* pneumonia

Co-trimoxazole (trimethoprim and sulfamethoxazole) is generally restricted to the treatment of *Pneumocystis* pneumonia, an opportunistic infection with which AIDS may present.

[1] Named after its inventor, Hans Christian Gram, a 19th century Danish bacteriologist.

[2] Domagk believed, wrongly as it happens, that the staining property of azo dyes, such as prontosil, was responsible for their antibacterial selectivity. He used **prontosil** – a red dye – to treat his young daughter for a life-threatening streptococcal infection. She survived but was left with permanently red-stained skin – a testament to its lack of selectivity for the invading bacteria.

[3] **Meticillin** (previous name: **methicillin**) was the first ß-lactamase-resistant **penicillin**. It is not now used clinically because it was associated with interstitial nephritis, but is remembered in the acronym 'MRSA' – **meticillin**-resistant *S. aureus*, which are resistant to other ß-lactamase-resistant penicillins as well as **meticillin**.

[4] Indeed, penicillins applied topically to the cortex are used to induce convulsions in an animal model of epilepsy (see Ch. 46).

[5] This may also occur with broad-spectrum penicillins and cephalosporins as a result of cross-infection (usually within hospital) by *C. difficile* in patients susceptible because of the disturbance caused to their gut microbiome by the broad-spectrum antibiotic. Hand washing by staff with soap and water can prevent this (alcohol rub is less effective as it does not kill bacterial spores).

[6] When **ciprofloxacin** was introduced, clinical pharmacologists and microbiologists sensibly suggested that, to prevent emergence of resistance, it should be reserved for organisms already refractory to the effects of other drugs. However, by 1989 it was already estimated that it was prescribed for 1 in 44 of Americans, so it would seem that the horse had not only left the stable but had bolted into the therapeutic blue!

[7] An exception is the use of **isoniazid** monotherapy in selected healthy people with latent tuberculosis. This is diagnosed by a positive whole blood test based on interferon gamma release in response to mycobacterial antigens ('IGRA' test).

[8] The difference between *tuberculoid* and *lepromatous* disease appears to be that the T cells from patients with the former vigorously produce interferon-?, which enables macrophages to kill intracellular microbes, whereas in the latter case the immune response is dominated by interleukin-4, which blocks the action of interferon-? (see Ch. 17).

[9] In 1967 the US Surgeon General announced (in effect) that infectious diseases had been vanquished, and that the researchers should turn their attention to chronic diseases instead.

[10] The worst offenders are sometimes collectively referred to, rather fittingly, as 'ESKAPE pathogens'. The acronym is formed of the initial letters of *E. faecium*, *S. aureus*, *K. pneumonia*, *A. baumanii*, *P. aeruginosa* and *Enterobacter* spp.

53: Antiviral drugs

OVERVIEW

This chapter deals with drugs used to treat infections caused by viruses. We first provide some basic information about viruses, including a simple outline of their structure and classification as well as a brief summary of their life cycle. We continue with a consideration of the host–virus interaction: the defences deployed by the human host against viruses and the strategies employed by viruses to evade these measures. We next discuss the various types of antiviral drugs and their mechanisms of action. We illustrate this discussion with particular reference to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, which causes COVID-19, and the human immunodeficiency virus (HIV), which is responsible for a dangerous acquired immunodeficiency syndrome (AIDS).

Background Information About Viruses

An Outline of Virus Structure

Viruses are small infective agents which range in size between the tiny parvovirus (~20 nm) and the (relatively) giant Ebola virus (>900 nm). Their distinguishing feature is that they lack any metabolic machinery or capacity and which must therefore infect other cells in order to replicate. The ‘free-living’ virus particle is

termed a *virion* and consists of segments of nucleic acid enclosed in a protein coat comprised of symmetrical repeating structural units and called a *capsid* (**Fig. 53.1**). The viral coat, together with the nucleic acid core, is termed the *nucleocapsid*. Some viruses have a further external lipoprotein envelope, which may be decorated with antigenic viral glycoproteins or phospholipids acquired from its host when the nucleocapsid buds through the membranes of the infected cell. [1] Nobody knows how many individual species of viruses exist, but they probably number in the millions (at least). [2] It is now thought that they play a crucial role in the planetary ecosystem and that they have been instrumental in the evolution of living beings – so not all the news is bad. [1]

Viruses can infect virtually all living organisms. Whilst by no means all are pathogenic – the human genome itself is estimated to contain 8%–10% viral material – they are nevertheless a common and important cause of disease in humans. Some important examples are as follows:

- *DNA viruses*: poxviruses (smallpox), herpesviruses (chickenpox, shingles, cold sores, glandular fever), adenoviruses (sore throat, conjunctivitis) and papillomaviruses (warts, cervical carcinoma).
- *RNA viruses*: orthomyxoviruses (influenza), paramyxoviruses (measles, mumps), coronaviruses (respiratory tract infections including COVID-19), rubella virus (German measles), rhabdoviruses (rabies), picornaviruses (colds, meningitis, poliomyelitis), retroviruses (AIDS, T-cell leukaemia), arenaviruses (meningitis, Lassa fever), hepadnaviruses (serum hepatitis)

and arboviruses (various **ar**thropod-**bo**rne illnesses, e.g. encephalitis, yellow fever).

Despite being so numerous, only some 9000 viruses have been characterised and classified. Unlike animals or plants, viruses have not descended from a common ancestry and so classification is therefore a problem. Two systems are in use: one is based upon their morphology (e.g. rotaviruses, coronaviruses etc.), the other on their mode of replication. From the pharmacologist's viewpoint, the latter is the more useful scheme because it suggests useful drug targets.

The Lifecycle of Viruses

To replicate, viruses must first attach to and penetrate a living host cell – be it an animal, plant or bacterial cell – and hijack its metabolic capability. The first step in this process is facilitated by polypeptide binding sites on the envelope or capsid which interact with corresponding attachment points on the host cell. These viral 'receptors' are actually normal membrane constituents, receptors for cytokines, neurotransmitters or hormones, ion channels or other integral membrane glycoproteins. COVID-19, for example, uses *angiotensin converting enzyme 2* (ACE2) for this purpose while the virus that produces AIDS utilises the CD4 protein. Sometimes other accessory proteins are co-opted to aid viral entry. In the former case, the transmembrane protease, serine 2 (TMPRSS2) is used while in the latter case, chemokine receptors are involved. Some other examples of cellular viral receptors are listed in **Table 53.1**.

Following attachment, the receptor–virus complex enters the cell, often utilising receptor-mediated endocytosis (though some viruses bypass this route). The virus coat is removed by host cell enzymes (often lysosomal in nature) and the virion is dismantled, thereby liberating the genetic material together with any other viral enzymes or other factors important for replication. What follows is known as the *eclipse phase* of viral infection because individual virus particles can no longer be observed within the host cell.

The viral nucleic acid then utilises the host cellular machinery to synthesise viral proteins and further copies of the viral genetic material. Following processing, these components are then assembled into new virus particles in specialised complexes in the Golgi membranes and released from the cell during the final *shedding* (or *budding*) phase. The new viral particles are then free to infect further cells.

Mechanisms of Viral Replication

When they infect cells, viruses have to solve two problems: they must produce more viral proteins, but they must also regenerate and synthesise further copies of their genetic material.

Since viruses lack ribosomes, the host cell cannot directly translate their genetic information to make further viral proteins and several enzymatic steps may be required to transform the viral genetic material into a form that can be 'read' by the host. How this is achieved depends upon whether their genetic material comprises either *DNA* or *RNA*, whether this is in a single- or double-stranded configuration and whether these are in a (+) sense or (-) sense form (in other words whether they are the same as (+), or

complementary to (-), the final mRNA molecule). The actual enzymology is complex, sometimes involving viral and sometimes host enzymes, but the manner in which viruses produce a readable mRNA is the basis for commonly used classification system known as the *Baltimore system*.[3] **Fig. 53.2** and the text later provide a simplified summary of this system

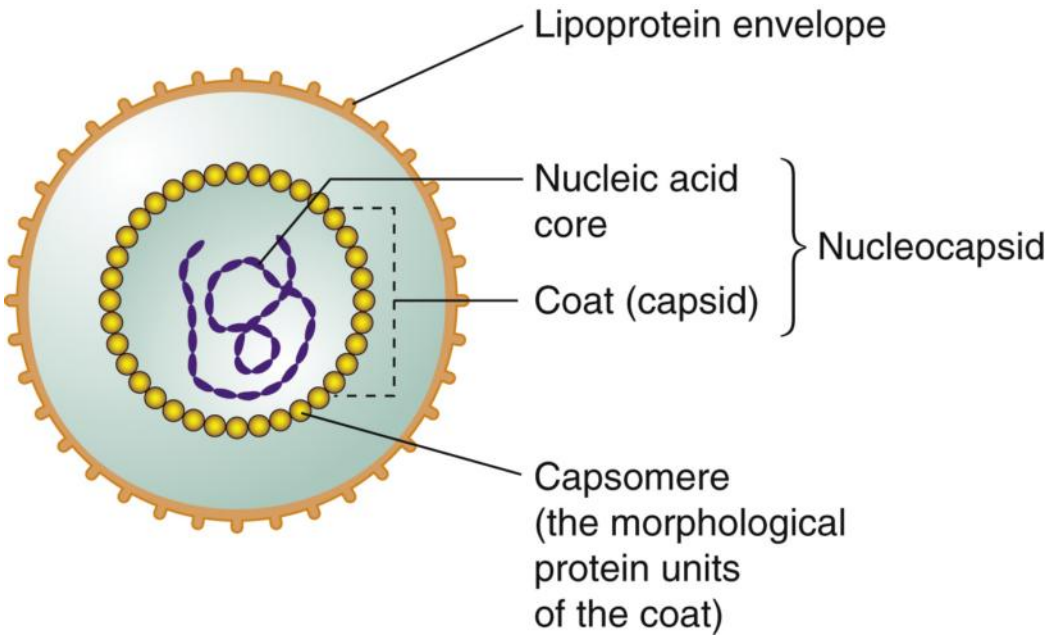

FIG. 53.1 Schematic diagram of the components of a virus particle or virion.

Replication of DNA Viruses

The mechanisms by which viral DNA replication occurs depends upon its configuration. In some cases, a conventional DNA–mRNA–protein pathway can be utilised. The double-stranded DNA of poxviruses or herpesviruses for example is transcribed directly by a host or viral *DNA-dependent RNA polymerase* into mRNA which can then be translated by the host cell to make viral proteins in the

usual way. Some of these proteins are enzymes while others are structural proteins which comprise the viral coat and envelope. To synthesise further copies of viral DNA a separate *DNA-dependent DNA polymerase* must be used, and again, this may originate from the virus or the host.

The final assembly of coat proteins around the new viral DNA takes place in specialised structures in the Golgi and the mature virions are released by shedding or following host cell lysis.

In the case of viruses such as those of the parvovirus family, the DNA is in a single stranded (+) form, so a complementary (-) species must first be produced to form a replicative form of dsDNA which can then be transcribed into viral mRNA and thence translated into viral proteins by the host ribosomes. This dsRNA species is also used to regenerate the viral genomic material.

The dsDNA hepadnaviruses, such as the hepatitis virus utilise yet another method. Because their dsDNA genome contains stretches of single-stranded DNA, leaving ‘gaps’ in the coding sequence, enzymes in the host nucleus must first add additional bases to produce a replication-capable dsRNA copy. From this, a (+) ssRNA is synthesised so that a dsRNA species can be produced. A *reverse transcriptase* enzyme (an *RNA-dependent DNA polymerase* enzyme) uses this template to synthesise dsDNA which can then be utilised by the host to produce mRNA for subsequent translation.

Table 53.1

Some host cell surface structures that can function as receptors for virus entry

Host cell structure [a]	Virus(es)
Acetylcholine receptor on skeletal muscle	Rabies virus
Angiotensin converting enzyme 2 (ACE2)	Coronaviruses including SARS-CoV and SARS-CoV-2 (COVID-19 [b])
β-Adrenoceptors	Infantile diarrhoea virus
B lymphocyte complement C3d receptor	Glandular fever virus
CCR5 receptor for chemokines MCP-1 and RANTES	HIV (causing AIDS)
CXCR4 chemokine receptor for cytokine SDF-1	HIV (causing AIDS)
Helper T lymphocytes CD4 glycoprotein	HIV (causing AIDS)
MHC molecules	Adenoviruses (causing sore throat and conjunctivitis) T-cell leukaemia viruses

Host cell structure [a]	Virus(es)
T lymphocyte interleukin-2 receptor	T-cell leukaemia viruses

MCP-1, Monocyte chemoattractant protein-1; *MHC,* major histocompatibility complex; *RANTES,* regulated on activation normal T cell expressed and secreted; *SDF-1,* stromal cell-derived factor-1.

[a] For more detail on complement, interleukin-2, the CD4 glycoprotein on helper T lymphocytes, MHC molecules, etc., see **Chapter 7**.

[b] COVID-19 also utilises TMPRSS2 (transmembrane serine protease 2).

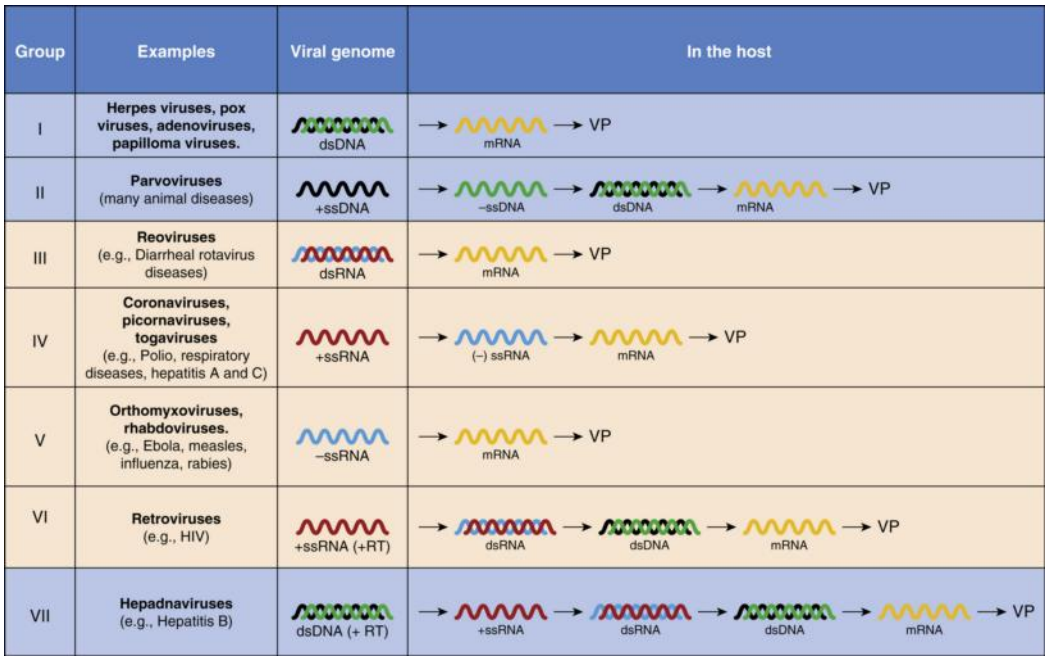

FIG. 53.2 A simplified schematic diagram of the Baltimore system of virus classification.This system categorises viruses depending on how they produce a readable mRNA from their genomes. Note that the regeneration of viral genomic material, which is obviously essential for viral reproduction, is not shown here. *VP,* Viral protein.

Replication of RNA Viruses

The replication of RNA viruses again reflects the complexity of the different configurations adopted by the viral genome. Reoviruses, such as the rotaviruses for example, contain dsRNA which can be transcribed into a useable mRNA for the host cell to translate and also copied by an *RNA-dependent RNA polymerase* to replicate the viral genome. This must occur within the viral capsid itself because cells can detect and destroy dsRNA species.

(+) ssRNA viruses such as coronaviruses or rabies virus can be modified by the attachment of a poly A tail and a 5' cap to furnish a source of useable mRNA but this (+) ssRNA is amplified by a viral *RNA-dependent RNA polymerase*, producing a (-) ssRNA copy as a template for producing more (+) ssRNA which can then be used to synthesise further proteins as well as to replenish the viral genome. In the case of (-) ssRNA viruses, such as the influenza virus, this can be transcribed directly into mRNA and copied to produce a (+) ssRNA strand using the viral *RNA-dependent RNA polymerase*. This is used as a template for producing further (-) ssRNA species for the nascent viruses.

The human immunodeficiency virus (HIV) bears a (+) ssRNA genome. In this case, however, a viral *reverse transcriptase* uses this to synthesise a dsDNA species via a dsRNA intermediate. In addition to using this source for mRNA, the dsDNA can be inserted into the host genome forming a stable *provirus*; it can remain in the host indefinitely, becoming activated under certain circumstances. RNA viruses such as HIV which utilise reverse transcriptase in this fashion are known as *retroviruses*.

Like some DNA viruses, retroviruses may remain associated with the host genome and in some cases (e.g. HIV) replicated together with host genetic material when the cell divides. This accounts for the periodic nature of some viral diseases, such as those caused by *herpes labialis* (cold sores) or *varicella zoster* – another type of herpes virus (which causes chickenpox and shingles), which can recur when viral replication is reactivated by some factor (or when the immune system is compromised in some way). Other RNA retroviruses (e.g. the *Rous sarcoma* virus) can transform normal

cells into malignant cells (a serious concern with use of retroviral vectors for gene therapy, see **Ch. 5**).

The Host–Virus Interaction

Host Defences Against Viruses

The host's first line of defence is the simple barrier function of intact skin, which most viruses are unable to penetrate. Mucous membranes and broken skin (e.g. at sites of wounds or insect bites) are another matter and are more vulnerable to viral attack. Should the virus gain entry to the body, then the host will deploy both an innate and, subsequently, an adaptive immune response (see **Ch. 7**) to limit the incursion. An infected cell presents viral peptides, complexed with major histocompatibility complex (MHC) class I molecules on its surface. This is recognised by T lymphocytes, which then kill the infected cell (**Fig. 53.3**). Killing may be accomplished by the release of lytic proteins (such as perforins, granzymes) or by triggering the apoptotic pathway of the infected cell by activation of its Fas receptor ('death receptor', see **Ch. 6**). The latter may also be triggered indirectly through the release of a cytokine such as tumour necrosis factor (TNF)-α. Natural killer (NK) cells will also react to the absence of normal MHC molecules by killing the cell. This is called the 'mother turkey' strategy (kill everything that does not sound exactly like a baby turkey; see **Ch. 7**). The virus may escape immune detection by cytotoxic lymphocytes by modifying the expression of the peptide–MHC complex, but still fall victim to NK cells, although some viruses have also developed ways of evading NK cells (see later).

Within the cell itself, *gene silencing* provides a further level of protection (see **Schutze, 2004**). Short double-stranded fragments of RNA, such as those that could arise as a result of the virus's attempts to recruit the host's transcription/translational machinery, actually cause the gene coding for the RNA to be 'silenced' – to be switched off. The gene is then no longer able to direct further viral protein synthesis and replication is halted. This mechanism can be exploited for experimental purposes in many areas of biology, and tailored siRNA (*small- or short-interfering RNA*) is a cheap [4] and useful technique to suppress the expression of a particular gene of interest. Attempts to harness the technique for viricidal and more general therapeutic purposes have met with some success (see **Barik, 2004**; **Bo et al., 2020**), and are beginning to find their way into clinical use (see **Ch. 5**).

Viral Ploys to Circumvent Host Defences

Viruses have evolved a variety of strategies to ensure successful infection, some entailing redirection of the host's response to the advantage of the virus (see **Xu et al., 2021**; **Konig and Munk, 2021**, for recent reviews).

Subversion of the immune response

Viruses can inhibit the synthesis or action of cytokines, such as interleukin-1, TNF-α and antiviral interferons (IFNs), the chemical signals that normally coordinate innate and adaptive immune responses. For example, following infection, some poxviruses express proteins that mimic the extracellular ligand-binding domains of cytokine receptors. These pseudoreceptors bind cytokines, preventing them from reaching their natural targets on

cells of the immune system and thus inhibiting the normal immune response to virus-infected cells. Other viruses that can interfere with cytokine signalling include human cytomegalovirus, Epstein–Barr virus, herpesvirus and adenovirus.

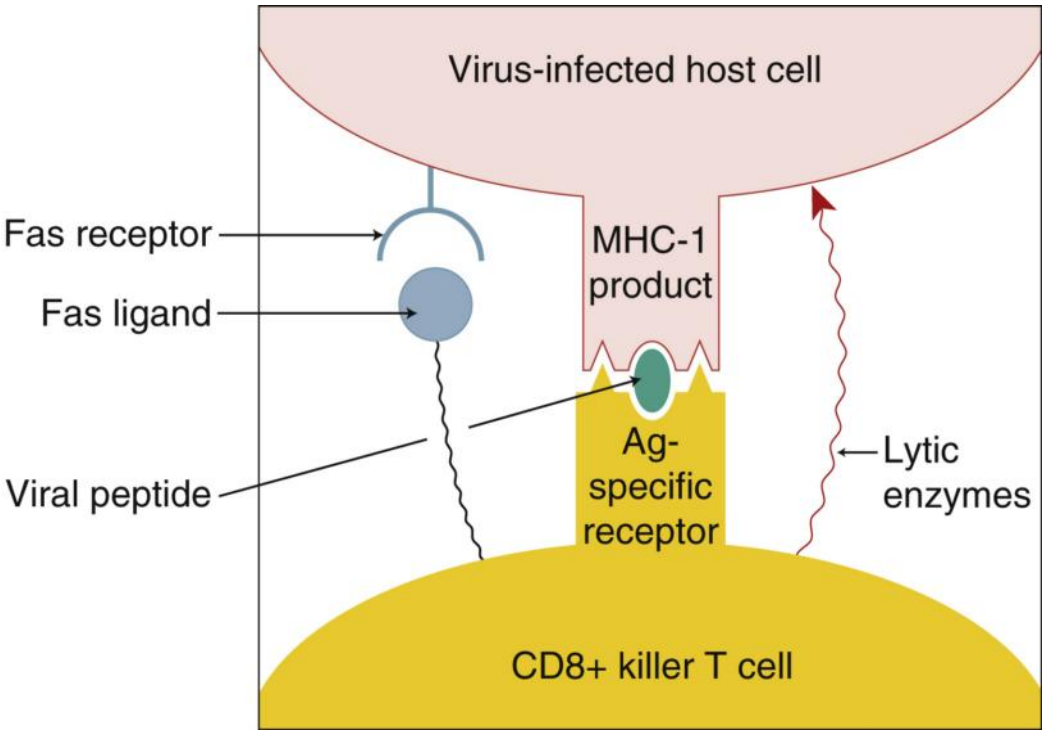

FIG. 53.3 How a $CD8^+$ T cell kills a virus-infected host cell. The virus-infected host cell expresses a complex of virus peptides plus major histocompatibility complex class I product (MHC-I) on its surface. This is recognised by the $CD8^+$ T cell, which then releases lytic enzymes into the virus-infected cell. The killer T cell also expresses a Fas ligand which triggers apoptosis in the infected cell by stimulating its Fas 'death receptor'.

Evasion of immune detection and attack by killer cells

Once within host cells, viruses may also escape immune detection and evade lethal attack by cytotoxic lymphocytes and NK cells in various ways, these include:

- *Interference with the surface protein markers on the infected cells essential for killer cell recognition and attack*. Some viruses inhibit generation of the antigenic peptide and/or the presentation of MHC–peptide molecules that signals that the cells are infected. In this way, they can remain undetected. Examples include adenovirus, herpes simplex virus, human cytomegalovirus, Epstein–Barr virus and influenza virus.
- *Interference with the apoptotic pathway*. Adenovirus, human cytomegalovirus and Epstein–Barr virus can also subvert this pathway to ensure their own survival.
- *Fooling the 'baby turkey' ploy*. Other viruses (e.g. cytomegalovirus) get round the 'mother turkey strategy' of NK cells by expressing a homologue of MHC class I (the equivalent of a turkey chick's chirping) that is close enough to the real thing to hoodwink NK cells.

It is evident that natural selection has equipped pathogenic viruses with many efficacious tactics for circumventing host defences, and understanding these in more detail is likely to suggest new types of antiviral therapy. Fortunately, the biological arms race is not one sided, and evolution has also equipped the host with sophisticated countermeasures. In the majority of cases these prevail, and most viral infections eventually resolve spontaneously,

except in immunocompromised hosts. The situation does not always end happily though; some viral infections, such as Lassa fever and Ebola virus infection, have a high mortality or can lead to chronic ill health and we now discuss a two further examples of hazardous viruses: HIV and the COVID-19 coronavirus. Whilst different in many ways, these examples exhibit many of the features common to other viral infections. The scale of the global AIDS problem pushed HIV up the priority list of antiviral targets and at the time or writing, the world is in the grip of a COVID-19 pandemic which, as well as inflicting illness on a huge number of people, has had a profound effect on the global economy and has halted research into, and diverted precious healthcare resources from, the treatment of other diseases.

Viruses

- Viruses are small infective agents consisting of nucleic acid (RNA or DNA) enclosed in a protein coat.
- They are not cells and, having no metabolic machinery of their own, are obligate intracellular parasites, utilising the metabolic processes of the host cell to replicate.
- *DNA viruses* (e.g. herpes virus) usually enter the host cell nucleus and direct the generation of new viruses.
- *RNA viruses* (e.g. COVID-19 virus) usually direct the generation of new viruses without involving the host cell nucleus (the influenza virus is an exception).
- *RNA retroviruses* (e.g. HIV, T-cell leukaemia virus) contain an enzyme, reverse transcriptase, which makes a DNA copy of

the viral RNA. This DNA copy is integrated into the host cell genome and directs the generation of new virus particles. The infection may remain latent in the host genome becoming reactivated during periods of stress or immunosuppression.

HIV and AIDS

HIV is an RNA retrovirus. Two forms are known: *HIV-1* is the principal organism responsible for human AIDS. The *HIV-2* organism is similar to the HIV-1 virus in that it also causes immune suppression, but it is less virulent. HIV-1 is distributed around the world, whereas HIV-2 is confined to parts of Africa. While it was first identified in the West in the 1960s, it is thought that the virus actually passed from chimpanzees to humans sometime in the late 19th or early 20th century. Since then almost 80 million people have become infected with the virus and over 36 million have died. Recent assessments by the The Joint United Nations Programme on HIV/AIDS (UNAIDS, 2021) suggest that over 37 million people are presently living with HIV, including over 1.7 million children (a particularly horrid thought), and that new infections are appearing at the rate of about 1.5 million per year.

The search for effective drugs to treat patients with HIV was responsible for dramatic advances in antiviral pharmacotherapy and thanks to the current availability of antiviral medicines, the global situation is improving, and the number of AIDS-related deaths is declining. HIV/AIDS is currently overwhelmingly centred on sub-Saharan Africa, which accounts for two-thirds of the total global number of infected persons, and where the adult prevalence is over

10 times greater than in Europe. It is estimated that there are currently some 28 million people receiving these drugs – approximately three quarters of all those suffering from the disease. Overall, mortality has fallen by over half since the peak of the pandemic and by a third in the last decade. For a review of the pathogenesis (and many other aspects) of AIDS, see **Moss (2013)**.

Induction of the Disease

The interaction of HIV with the host's immune system is complex; cytotoxic T lymphocytes (CTLs; $CD8^+$ T cells) and $CD4^+$ helper T lymphocytes ($CD4^+$ cells) are the main targets although other cells may be involved. The HIV virion cannily attaches to CD4 (the glycoprotein marker of a particular group of helper T lymphocytes) and CCR5 (a co-receptor for certain chemokines, including monocyte chemoattractant protein-1 and RANTES; see **Ch. 7** and **Fig. 53.4A**). Antibodies are produced by the host to various HIV components, but it is the action of the CTLs and $CD4^+$ cells that initially prevents the spread of HIV within the host. CTLs directly kill virally infected cells and produce and release antiviral cytokines. The lethal event is lysis of the target cell, but induction of apoptosis by interaction of Fas ligand (see **Ch. 6**) on the CTL with Fas receptors on the virally infected cell also plays a part. $CD4^+$ cells have an important role as helper cells and may have a direct role in the control of HIV replication (e.g. lysis of target cells: **Norris et al., 2004**). It is the progressive loss of these cells that is the defining characteristic of HIV infection.

The CTLs are effective during the initial stages of the infection but are not able to stop the progression of the disease. It is believed

that this is because they become ‘exhausted’ and unable to maintain their protective function. Different mechanisms may be involved (see **Jansen et al., 2004**, and **Barber et al., 2006**, for further details).

CD4+ cells normally orchestrate the immune response to viruses, but HIV virtually cripples this aspect of the immune response. Evidence from exposed individuals who somehow evade infection indicates that CCR5 also has a central role in HIV pathogenesis. Drugs that inhibit the entry of HIV into cells by blocking CCR5 are now used clinically.

When immune surveillance finally breaks down, other mutated strains of HIV arise within an individual patient which recognise other host cell surface molecules. For example, gp120, a surface glycoprotein on the HIV envelope binds to CD4 and also to the T-cell chemokine co-receptor CXCR4. Another viral glycoprotein, gp41, then causes fusion of the viral envelope with the plasma membrane of the cell.

Progress OF Infection

New HIV virions produced following infection (usually within 48 h) can lead to the release of a staggering 10^{10} new virus particles each day.

Viral replication is highly error prone. Many mutations occur daily at each site in the HIV genome, so HIV soon escapes recognition by the original cytotoxic lymphocytes (a particularly virulent new strain is currently circulating in Europe at the time of writing). Although other cytotoxic lymphocytes arise that recognise the altered virus protein(s), further mutations eventually allow

escape from surveillance by these cells too. It is suggested that wave after wave of cytotoxic lymphocytes act against new mutants as they arise, gradually depleting a T-cell repertoire already seriously compromised by the loss of $CD4^+$ helper T cells, until eventually the immune response falters or completely fails.

Intracellular HIV may remain ‘silent’ (latent) for a long time before clinical signs emerge and there is considerable variability in the progress of the disease, but the usual clinical course of an untreated HIV infection is shown in **Fig. 53.5**. An initial acute influenza-like illness is associated with an increase in the number of virus particles in the blood, their widespread dissemination through the tissues and the seeding of lymphoid tissue with the virion particles. Within a few weeks, this viraemia is reduced by the action of cytotoxic lymphocytes as explained earlier.

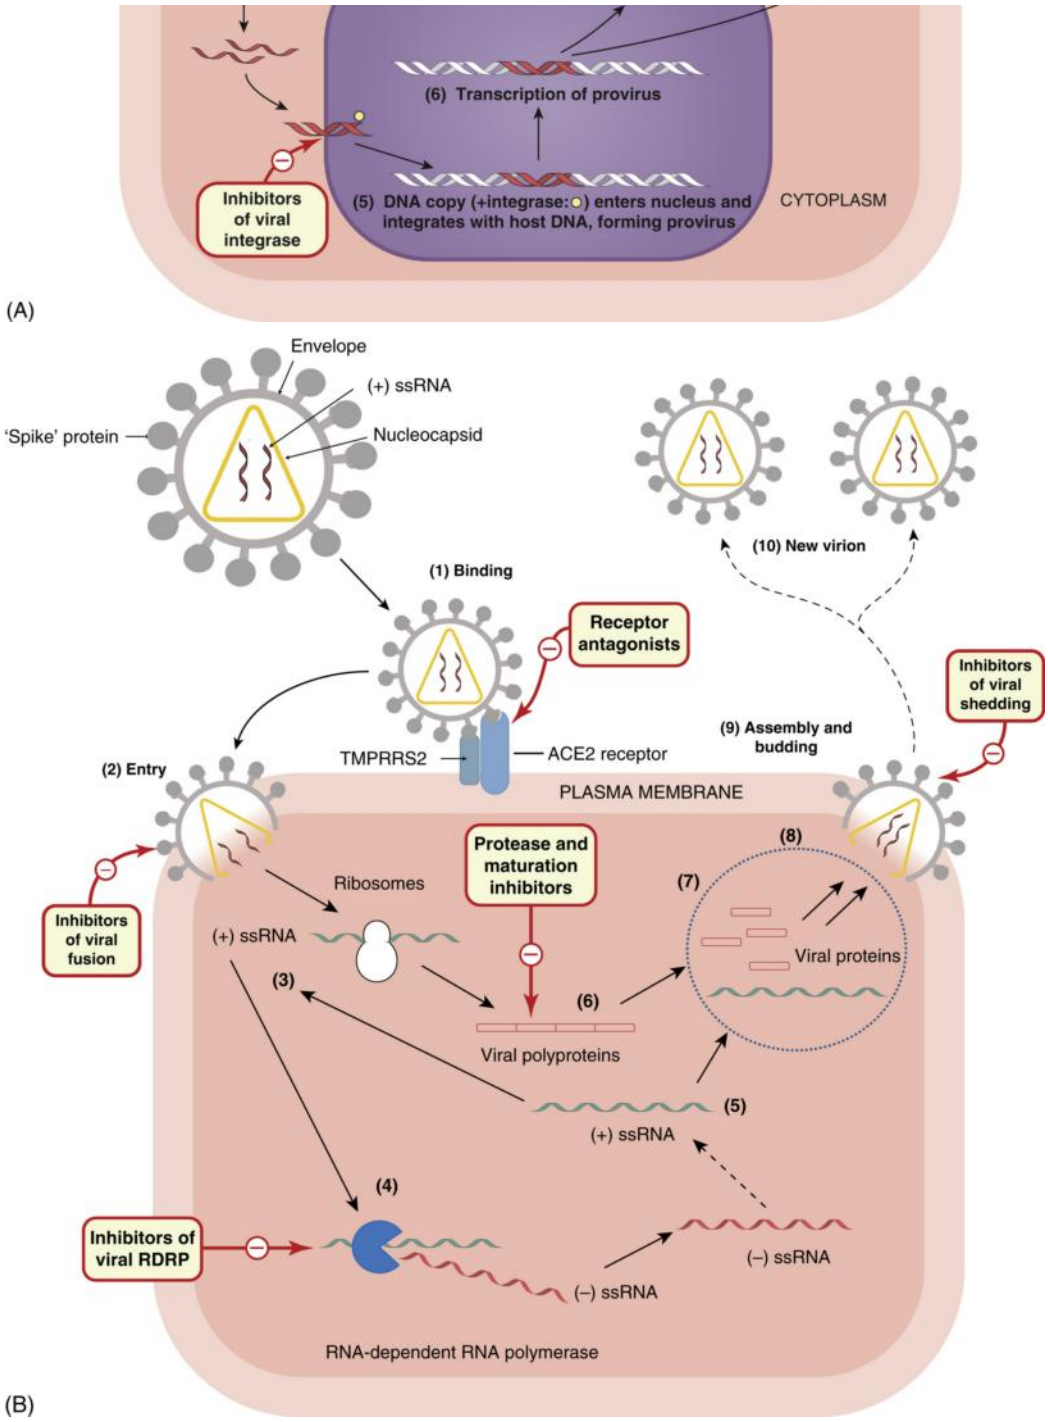

FIG. 53.4 Schematic diagrams of infection by (A) the HIV virion and (B) the COVID-19 coronavirus, with the sites of action of the main classes of antiviral drugs.(A) The HIV virus uses the CD4 co-receptor and the chemokine (ck)

receptors CCR5/CXCR4 as binding sites to facilitate entry into the cell, where it becomes incorporated into host DNA (steps *1–5*). When transcription occurs (step *6*), the T cell itself is activated and the transcription factor nuclear factor κB initiates transcription of both host cell and provirus DNA. A viral protease cleaves the nascent viral polypeptides (steps *7* and *8*) into enzymes (integrase, reverse transcriptase, protease) and structural proteins for new virions. These are assembled and released from the cells, initiating a fresh round of infection (steps *9* and *10*). The sites of action of anti-HIV drugs are shown.(B) Infection of respiratory epithelial cell by the COVID-19 coronavirus virion. The virus attaches to the ACE2 receptor using its 'spike' protein *(1)*. This may be modified by the transmembrane protease TMPRSS2 which facilitates fusion and entry of the virion into the cell *(2)*. The (+) ssRNA viral genome may be used as mRNA *(3)* but it also is used as a template for synthesis (by RNA-dependent RNA polymerase) of (-) ssRNA *(4)* which can be used as a template to produce further (+) ssRNA for protein synthesis or for packaging into new virions *(5)*. Host ribosomes produce viral polyproteins *(6)* which are cleaved *(7)* into viral proteins. These are packaged *(8)* together with

copies of (+) ssRNA into new virions *(9)* and released *(10)*. Note that some organelles and other cellular components have been omitted to improve clarity.

The acute initial illness is followed by a symptom-free period during which there is reduction in the viraemia accompanied by silent virus replication in the lymph nodes, associated with damage to lymph node architecture and the loss of $CD4^+$ lymphocytes and dendritic cells. Clinical latency (median duration 10 years) comes to an end when the immune response finally fails and the signs and symptoms of AIDS appear – opportunistic infections (e.g. *Pneumocystis* pneumonia or tuberculosis), neurological symptoms (e.g. confusion, paralysis, dementia) caused by direct infection of neuronal tissue by HIV or by opportunistic infections, bone marrow depression and malignancies such as lymphoma and Kaposi's sarcoma. [5] Chronic gastrointestinal (GI) infections contribute to the severe weight loss, and cardiovascular and kidney damage can also occur. In an untreated patient, death usually follows within 2 years. The advent of effective drug regimens has greatly improved the prognosis in countries that are able to deploy them, and patients thus treated may enjoy a near-normal life expectancy.

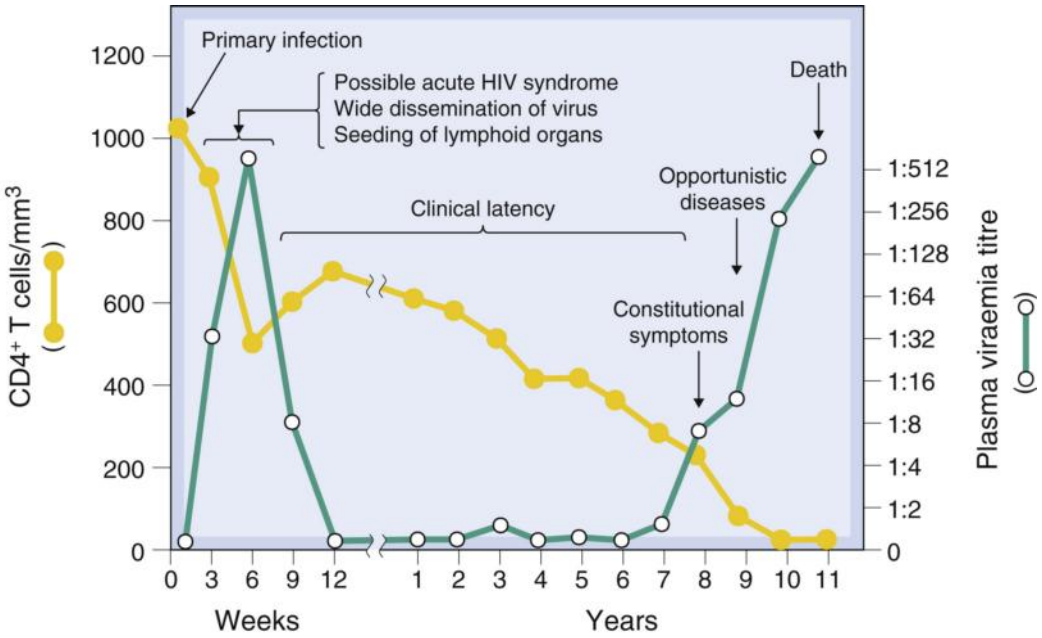

FIG. 53.5 Schematic outline of the course of HIV infection.The $CD4^+$ T-cell titre is often expressed as cells/mm^3. Adapted from Pantaleo, G., Graziosi, C., Fauci, A.S., 1993. New concepts in the immunopathogenesis of human immunodeficiency virus infection. N. Engl. J. Med. 328, 327–335.

There is evidence that genetic factors play an important role in determining the susceptibility – or resistance – to HIV (see **Flores-Villanueva et al., 2003**).

Drug mechanisms in HIV infections

- Reverse transcriptase inhibitors (RTIs):
  - *nucleoside (or nucleotide) analogue RTIs* are phosphorylated by host cell enzymes to give the 5′-

trisphosphate, which competes with the equivalent host cellular trisphosphates that are essential substrates for the formation of proviral DNA by viral reverse transcriptase (examples are **zidovudine** and **abacavir**); they are used in combination with protease inhibitors.
  - *non-nucleoside RTIs* are chemically diverse compounds that bind to the reverse transcriptase near the catalytic site and denature it; an example is **nevirapine.**
- Protease inhibitors inhibit cleavage of the nascent viral protein into functional and structural proteins. They are often used in combination with RTIs. An example is **saquinavir.**
- Combination therapy is essential in treating HIV; this characteristically comprises two nucleoside RTIs with either a non-nucleoside RTI or one or two protease inhibitors. Other drugs, such as the HIV integrase inhibitor **raltegravir**, the chemokine receptor antagonist **maraviroc** and the HIV fusion inhibitor **enfuvirtide**, may also be used in such combination therapy regimens. 'Once-daily' combination therapies greatly improve patient compliance and longer-lasting (e.g. once monthly, or longer) formulations are in prospect.

COVID-19

The first reports of this viral disease surfaced in December 2019 from the city of Wuhan in China prompted by cases of an unfamiliar type of pneumonia which progressed to serious respiratory disease. Whilst the origin of the initial infection is still uncertain – and

indeed the continuing subject of speculation and conspiracy theories – it may be significant that all of the original 10 victims were connected in some way with the Wuhan Seafood Wholesale Market which, in addition to fish, also sells live animals including bats, poultry and snakes.

The causative agent was soon identified as a novel coronavirus genomically similar (>95%) to a bat coronavirus, RaTG13 (**Wacharapluesadee et al., 2021**) suggesting that it was a zoonotic infection acquired through an intermediate animal host. At least seven other coronaviruses were known to be pathogenic in humans and two previous global epidemics of coronavirus-mediated respiratory disease were already well documented: SARS-CoV which was again first reported in China and MERS (Middle Eastern respiratory syndrome) which appeared in Saudi Arabia in 2012. The new agent was named SARS-CoV-2, and the disease it causes was termed COVID-19.

No doubt facilitated by the ease of international travel, the virus quickly spread around the world: according to the latest (2022) global data from the WHO, there have been an astonishing total of almost 316 million *confirmed* infections with the virus since it was first reported. There have also been some 5.5 million confirmed COVID-19-related deaths, but the true death toll is estimated to be 3–5 times higher. Europe and the Americas have seen the highest numbers of infections, followed by SE Asia, which experienced about a third as many.

The virus is spread from person to person primarily in exhaled respiratory droplets and any illness usually develops within a few days following infection. Although the symptomatology is varied,

those who do become ill usually present with a dry cough, fever, myalgia and fatigue and a change in the sensations of smell and taste, although many other effects of the virus have been described. In some people, these initial symptoms can progress to a severe respiratory illness characterised by widespread alveolar damage, and ARDS (acute respiratory distress syndrome) requiring intensive medical care including supplemental oxygen usually administered non-invasively but in the most severe cases, by mechanical ventilation. Most hospitalised patients are over 50 years old, and men are slightly more susceptible than women. Generally, children under the age of 15 years are unaffected. Between 10% and 20% of those who become ill may experience *long COVID* – which is usually taken to mean that their disease symptoms last more than 3 months. Many of those infected with the COVID-19 virus are asymptomatic and this cohort is probably mainly responsible for spreading the infection.

Since the initial detection of the disease, several variant forms, generally with mutations in the characteristic coronavirus 'spike' protein, have been identified around the world. The WHO has given these variants Greek names, with the *alpha* variant being the original virus identified, soon followed by a further *beta*, *gamma* and (until recently the dominant) *delta* strain. More recently (late 2021), a further rapidly spreading *omicron* variant was detected. Evolution of variants with even higher transmissibility is inevitable while global cases remain so high; virulence of such future variants is unpredictable.

The virus gains access to cells by binding to the cell surface receptor *angiotensin converting enzyme 2* (ACE-2), a protein which

is known to be used by other coronaviruses such as SARS-CoV as an entry point. This enzyme is expressed in many tissues around the body including the gut epithelium and ciliated cells of the lower and, particularly, the upper respiratory tract. A co-receptor, TMPRSS2 (a transmembrane serine protease mentioned previously), aids this binding by proteolytically modifying the spike protein such that the virus is more capable of fusing with the cell membrane. However, this latter enzyme is much less abundant in the lower respiratory tract perhaps explaining why the omicron variant, which is unable to enter cells without this cofactor, is less damaging to alveolar cells.

Fig. 53.4B shows how the COVID-19 virus infects cells. Like HIV, its genome is comprised of (+) single-strand RNA but, unlike HIV, it does not utilise a reverse transcriptase, its viral RNA itself acting as mRNA.

Antiviral Drugs

Because viruses hijack many of the metabolic processes of the host cell itself, it is difficult to find drugs that are selective for the pathogen. Happily, there are some enzymes that are (relatively or wholly) virus specific, and these have proved to be useful drug targets. Most currently available antiviral agents (excluding vaccines) are effective only while the virus is replicating. Because the initial phases of viral infection are often asymptomatic, treatment is characteristically not initiated until the infection is well established. This is unfortunate because, as is often the case with infectious diseases, an ounce of pharmacological prevention is

worth a pound of cure, hence the importance of pre-exposure prophylaxis wherever possible.

Antiviral drugs, of which many are now available, may be conveniently grouped according to their mechanisms of action. **Table 53.2** shows the commonest agents, together with some of the diseases they are used to treat. Since the antiviral pharmacology of HIV has been so well explored, **Table 53.3** separately lists the principal agents specifically used in this disease.

DNA Polymerase Inhibitors

Aciclovir

The development of the landmark drug **aciclovir** launched the era of effective selective antiviral therapy. Typical of drugs of this type, it is a guanosine derivative that is converted to the monophosphate by viral thymidine kinase. This viral enzyme is much more effective in carrying out the phosphorylation than the enzyme of the host cell, so **aciclovir** is predominantly activated in infected cells. Kinases in the host cell then convert the monophosphate to the trisphosphate, the active form that inhibits viral DNA polymerase, terminating the nucleotide chain. It is 30 times more potent against the herpes virus enzyme than the host enzyme. **Aciclovir trisphosphate** is inactivated within the host cells, presumably by cellular phosphatases. Resistance caused by changes in the viral genes coding for thymidine kinase or DNA polymerase has been reported, and **aciclovir**-resistant herpes simplex virus can cause pneumonia, encephalitis and mucocutaneous infections in immunocompromised patients.

Aciclovir can be given orally, intravenously or topically. When it is given orally, only 20% of the dose is absorbed. The drug is widely distributed and reaches effective concentrations in the cerebrospinal fluid (CSF). It is excreted by the kidneys, partly by glomerular filtration and partly by tubular secretion.

Unwanted effects

are minimal. Local inflammation can occur during intravenous injection if there is extravasation of the solution. Renal dysfunction has been reported when **aciclovir** is given intravenously but slow infusion reduces the risk. Nausea and headache can occur and, rarely, encephalopathy.

There are now other drugs with a similar action to **aciclovir** such as **famciclovir** and **valaciclovir** (see list in **Table 53.2**). **Foscarnet** achieves the same effect through a slightly different mechanism.

Table 53.2

NB some drugs are only used as components of combination therapies.

[a]Prodrug of **penciclovir**.

Nc, Nucleotide; *Ns*, nucleoside.

Data from various sources including BNF (2021).

Clinical uses of drugs for herpes viruses

- *Varicella zoster* infections (chickenpox, shingles):
  - orally (e.g. **famciclovir**) including in immunocompetent patients;
  - intravenously (e.g. in encephalitis, **aciclovir**) including in immunocompromised patients.
- *Herpes simplex* infections: *genital* herpes (systemic and/or topical treatment depending on severity, whether immunocompromised and whether or not a first attack), *mucocutaneous* herpes (e.g. **aciclovir** or, if unresponsive, **foscarnet**) and herpes *encephalitis* (e.g. intravenous aciclovir).
- Prophylactically:
  - patients who are to be treated with immunosuppressant drugs or radiotherapy and who are at risk of herpesvirus infection owing to reactivation of a latent virus;
  - in individuals who suffer from frequent recurrences of genital infection with herpes simplex virus.
- Cytomegalovirus (CMV)
  - CMV, while a herpes virus, is less sensitive to **aciclovir** than is *herpes simplex* or *herpes zoster*. **Valaciclovir** is licensed for prevention of CMV during immunosuppression following organ transplantation. **Ganciclovir** and **valganciclovir** are more active against CMV than **aciclovir**, but are more toxic; they are used by specialists for serious problems such as CMV retinitis in patients with AIDS.

Reverse Transcriptase Inhibitors

These include *nucleoside or nucleotide analogues*, exemplified by **zidovudine** and **tenofovir**, respectively. Nucleosides are first phosphorylated to the corresponding nucleotides and can then act as false substrates, being further phosphorylated by host cell enzymes and incorporated into the growing DNA chain but causing chain termination. While mammalian α-DNA polymerase is relatively resistant, the mitochondrial γ-DNA polymerase is susceptible to inhibition by these drugs, and unwanted effects may result at high doses. The main use of these drugs is the treatment of HIV, but several have useful activity against other viruses also (e.g. hepatitis B, which, though not a retrovirus, also uses reverse transcriptase for replication).

Zidovudine

Zidovudine (or **azidothymidine**, AZT) was the first drug to be introduced for the treatment of HIV and retains an important place in therapy. It can prolong life in HIV-infected individuals and diminish HIV-associated dementia. Given during pregnancy and then to the newborn infant, it can reduce mother-to-baby transmission by more than 20%. It is generally administered orally two to three times each day but can also be given by intravenous infusion. Its plasma half-life is 1 h, but the intracellular half-life of the active trisphosphate is 3 h. The concentration in CSF is 65% of the plasma level. Most of the drug is metabolised to the inactive glucuronide in the liver, only 20% of the active form being excreted in the urine.

Table 53.3

Some drugs used to treat HIV infection

Drug	Mechanism of action
Abacavir, bictegravir, didanosine, emtricitabine, lamivudine, stavudine, tenofovir, zidovudine	Ns or Nc reverse transcriptase inhibitors
Doravirine, efavirenz, etravirine, nevirapine, rilpivirine	Non-Ns reverse transcriptase inhibitors
Atazanavir, darunavir, fosamprenavir (PD), indinavir, lopinavir, ritonavir, saquinavir, tipranavir	Protease inhibitors
Enfuvirtide	Inhibitor of HIV fusion with host cells
Cabotegravir, dolutegravir, elvitegravir, raltegravir	HIV integrase inhibitor
Maraviroc	Chemokine receptor antagonist (CCR5)
Cobicistat [a]	Pharmacokinetic enhancer

NB some drugs are only used as components of combination therapies.

Nc, Nucleotide; *Ns,* nucleoside; *PD,* prodrug.

[a] No intrinsic antiviral activity but prolongs the action of **atazanavir** and **darunavir**.

Data from various sources including BNF (2021).

Because of rapid mutation, the virus is a constantly moving target, and resistance develops with long-term use of **zidovudine**, particularly in late-stage HIV infection. Furthermore, resistant strains can be transferred between individuals. Other factors that underlie loss of efficacy include decreased activation of **zidovudine** to the trisphosphate and increased virus load as the host immune response fails.

Unwanted effects

include GI disturbances (e.g. nausea, vomiting, abdominal pain), blood disorders (sometimes anaemia or neutropenia) and central nervous system (CNS) effects (e.g. insomnia, dizziness, headache), as well as the risk of lactic acidosis (possibly secondary to mitochondrial toxicity) in some patients; all these effects are shared by this entire group of drugs to a greater or lesser extent.

Other, currently approved, antiviral drugs in this group include **abacavir**, **adefovir**, **emtricitabine**, **entecavir**, **lamivudine**, **stavudine**, **telbivudine** and **tenofovir** which are used for hepatitis B as well as treatment of HIV infection.

Non-Nucleoside Reverse Transcriptase Inhibitors

Non-nucleoside reverse transcriptase inhibitors are chemically diverse compounds that bind to the reverse transcriptase enzyme near the catalytic site and inactivate it. Most are also, to varying degrees, inducers, substrates or inhibitors of the liver cytochrome P450 enzyme system (see **Ch. 10**). Currently available drugs include **efavirenz** and **nevirapine**, and the related compounds **etravirine** and **rilpivirine**.

Efavirenz (plasma half-life ~50 h) is given orally, once daily. It is 99% bound to plasma albumin, and its CSF concentration is ~1% of that in the plasma. Its major adverse effects are insomnia, bad dreams and sometimes psychotic symptoms. It is teratogenic.

Nevirapine has good oral bioavailability and penetrates into the CSF. It is metabolised in the liver, and the metabolite is excreted in the urine. **Nevirapine** can prevent mother-to-baby transmission of HIV.

Unwanted effects

include rash (common) as well as a cluster of other effects.

Protease Inhibitors

In many cases, the viral mRNA is initially translated into biochemically inert *polyproteins*. A virus-specific protease then converts the polyproteins into various structural and functional proteins by cleavage at the appropriate positions. Because this functionally critical protease does not occur in the host, it is a useful target for chemotherapeutic intervention. HIV infection generates two such polyproteins named *Gag* and *Gag-Pol*. Specific protease

inhibitors bind to the site where cleavage occurs, and their use, in combination with reverse transcriptase inhibitors, has transformed the therapy of AIDS. In the case of the hepatitis C virus, two protease targets have also been identified, *non-structural protein (NS) 3*, a serine protease, and *NS 5A*, which appears to act as an accessory protein for NS3. Examples of currently available protease inhibitors are shown in Tables **53.2** and **53.3**.

Darunavir, a typical example, binds tightly to the specific retropepsin proteases from HIV-1 or HIV-2, inactivating the catalytic site. **Ritonavir** acts in a similar way but also inhibits the P450 enzymes that metabolise these drugs potentiating their activity and for this reason is often given in combination with other protease inhibitors (e.g. **lopinavir**).

Unwanted effects

that are shared among this group include GI disturbances (e.g. nausea, vomiting, abdominal pain), blood disorders (sometimes anaemia or neutropenia) and CNS effects (e.g. insomnia, dizziness, headache) as well as the risk of hyperglycaemia.

Drug interactions

are numerous, clinically important and unpredictable. As with other antiretroviral drugs, it is essential to check possible interactions before prescribing any other drugs in patients receiving antiretroviral treatment.

Neuraminidase Inhibitors and Inhibitors of Viral Coat Disassembly

Viral neuraminidase is one of three transmembrane proteins coded by the influenza genome. Infection with these RNA viruses begins with the attachment of the viral haemagglutinin to neuraminic (sialic) acid residues on host cells. The viral particle then enters the cell by endocytosis. The endosome is acidified following influx of H^+ through another viral protein, the *M2 ion channel*. This facilitates the disassembly of the viral structure, allowing the RNA to enter the host nucleus, thus initiating a round of viral replication. Newly replicated virions escape from the host cell by budding from the cell membrane. Viral neuraminidase promotes this by severing the bonds linking the particle coat and host sialic acid.

The neuraminidase inhibitors **oseltamivir** and **zanamivir** are active against both influenza A and B viruses and are licensed for use at early stages in the infection or when use of the vaccine is impossible. **Zanamivir** is available as a powder for inhalation, and **oseltamivir** as an oral preparation. Although **oseltamivir** has in the past been 'stockpiled' by governments when flu pandemics (e.g. 'swine' flu – H1N1) are forecast, clinical trials suggest that its efficacy in reducing disease severity is very limited.

Unwanted effects

of **oseltamivir** include GI symptoms (nausea, vomiting, dyspepsia and diarrhoea), but these are less frequent and severe in the inhaled preparation. **Zanamivir** commonly causes a rash.

Drugs Acting Through Other Mechanisms

Enfuvirtide inhibits the fusion of HIV with host cells. It is generally given by subcutaneous injection in combination with

other drugs to treat HIV when resistance becomes a problem or when the patient is intolerant of other antiretroviral drugs.

Unwanted effects

include flu-like symptoms, central effects such as headache, dizziness, alterations in mood, GI effects and, sometimes, hypersensitivity reactions.

Raltegravir and related agents (see **Table 53.3**) act by inhibiting HIV DNA integrase, the enzyme that splices viral DNA into the host genome when forming the provirus. It is used for the treatment of HIV as part of combination therapy and is generally reserved for cases that are resistant to other antiretroviral agents.

Maraviroc. CCR5, together with CXCR4, are cell surface chemokine receptors that have been exploited by some strains of HIV to gain entry to the cell (see earlier). In patients who harbour 'R5' strains, the chemokine receptor antagonist **maraviroc** may be used, in combination with more conventional antiretroviral drugs (see **Dhami et al., 2009**). Its use, in combination with other antiretroviral drugs, is currently restricted to CCR5-tropic HIV infection in patients previously treated with other antiretrovirals.

Cobicistat is classed as a *pharmacokinetic enhancer*. It has no intrinsic activity but potentiates the actions of **atazanavir** and **darunavir** by inhibiting CYP3A enzymes and hence inhibiting drug metabolism.

Antiviral drugs

Most antiviral drugs generally fall into the following groups:

- *Nucleoside (or nucleotide) analogues* that inhibit the viral reverse transcriptase enzyme, preventing replication (e.g. **lamivudine**, **zidovudine**).
- *Non-nucleoside analogues* that have the same effect (e.g. **efavirenz**).
- *Inhibitors of proteases* that prevent viral protein processing (e.g. **saquinavir**, **indinavir**).
- *Inhibitors of viral DNA polymerase* that prevent replication (e.g. **aciclovir**, **famciclovir**).
- *Inhibitors of HIV integrase* that prevent the incorporation of viral DNA into the host genome (**raltegravir**).
- *Inhibitors of viral fusion with cells* (e.g. **enfuvirtide**).
- *Inhibitors of viral entry* that block the use of host cell surface receptors, which are used as entry points by viruses (**maraviroc**).
- *Inhibitors of neuraminidase* that prevent viral escape from infected cells (e.g. **oseltamivir**).
- *Immunomodulators* that generally enhance host defences (e.g. interferons and **inosine pranobex**).
- *Immunoglobulin and related preparations* that contain neutralising antibodies to various viruses.

Biopharmaceutical Antiviral Drugs

Biopharmaceuticals (see **Ch. 5**) that have been recruited in the fight against virus infections include immunoglobulin preparations, IFNs and monoclonal antibodies.

Immunoglobulins

Pooled immunoglobulin contains antibodies against various viruses present in the population. The antibodies are directed against the viral envelopes and can 'neutralise' some viruses and prevent their attachment to host cells. If used before the onset of signs and symptoms, it may attenuate or prevent measles, German measles, infectious hepatitis, rabies or poliomyelitis. *Hyperimmune* globulin, specific against particular viruses, is used against hepatitis B, varicella zoster and rabies and, more recently, COVID-19.

Palivizumab

Related in terms of its mechanism of action to immunoglobulins is **palivizumab**, a monoclonal antibody (see **Ch. 5**) directed against a glycoprotein on the surface of respiratory syncytial virus. Given by intramuscular injection under specialist supervision, it has proved useful in children at high risk to prevent infection by this organism.

Interferons

IFNs are a family of inducible proteins synthesised by mammalian cells and now generally produced commercially by recombinant DNA technology. There are at least three types, α, β and γ, constituting a family of hormones involved in cell growth and regulation and the modulation of immune reactions. IFN-γ, termed *immune interferon*, is produced mainly by T lymphocytes as part of an immunological response to both viral and non-viral antigens, the latter including bacteria and their products, rickettsiae, protozoa, fungal polysaccharides and a range of polymeric chemicals and other cytokines. IFN-α and IFN-β are produced by B and T

lymphocytes, macrophages and fibroblasts in response to the presence of viruses and cytokines. The general actions of the IFNs are described briefly in **Chapter 7**.

The IFNs bind to specific ganglioside receptors on host cell membranes. They induce, in host cell ribosomes, the production of enzymes that inhibit the translation of viral mRNA into viral proteins, thus halting viral replication. They have a broad spectrum of action and inhibit the replication of most viruses in vitro. Given intravenously, IFNs have a half-life of 2–4 h. They do not cross the blood–brain barrier.

IFN-α-2a is used for treatment of hepatitis B infections and AIDS-related Kaposi's sarcomas; **IFN-α-2b** is used for hepatitis C (a chronic viral infection which can progress insidiously in apparently healthy people, leading to end-stage liver disease or liver cancer). There are reports that IFNs can prevent reactivation of herpes simplex after trigeminal root section in animals and can prevent spread of herpes zoster in cancer patients. Preparations of IFNs conjugated with polyethylene glycol (pegylated IFNs) have a longer lifetime in the circulation.

Unwanted effects

are common and resemble the symptoms of influenza (which are mediated by cytokine release) including fever, lassitude, headache and myalgia. Repeated injections cause chronic malaise. Bone marrow depression, rashes, alopecia and disturbances in cardiovascular, thyroid and hepatic function can also occur.

Other Agents

Immunomodulators are drugs that act by modulating the immune response to viruses or use an immune mechanism to target a virus or other organism. **Inosine pranobex** may interfere with viral nucleic acid synthesis but also has immune-potentiating actions on the host. It is sometimes used to treat herpes infections of mucosal tissues or skin.

Tribavirin (**ribavirin**) is a synthetic nucleoside, similar in structure to guanosine. It interferes with the synthesis of viral mRNA although the exact mechanism of action is unclear. While it inhibits a wide range of DNA and RNA viruses, including many that affect the lower airways, it is used mainly to treat infections with *respiratory syncytial virus* (an RNA paramyxovirus) using an aerosol or tablet form. It has also been shown to be effective in hepatitis C as well as Lassa fever, an extremely serious *arenavirus* infection. When given promptly to victims of the latter disease, it has been shown to reduce to fatality rates (usually about 76%) by approximately eight-fold.

Combination Therapy For HIV

Because the two main classes of antiviral drugs used to treat HIV (reverse transcriptase inhibitors and protease inhibitors) have different mechanisms of action (see **Fig 53.4A**), they can usefully be deployed in synergistic combinations, and this has dramatically improved the prognosis of the disease. Such combination treatment was originally known as **h**ighly **a**ctive **a**nti**r**etroviral **t**herapy (HAART; sometimes simply abbreviated to ART). A typical HAART three- or four-drug combination would involve two nucleoside

reverse transcriptase inhibitors with either a non-nucleoside reverse transcriptase inhibitor or one or two protease inhibitors.

Using a HAART protocol, HIV replication is inhibited, the presence in the plasma of HIV RNA is reduced to undetectable levels and patient survival is greatly prolonged – so much so that near-normal life spans can now be achieved, given prompt diagnosis and treatment and good patient adherence. The latter is a key point – an adherence rate of 95% or higher is required to achieve this result and prevent treatment failure. This is difficult to achieve because the daily multiple dosing regimens are complex, and these drugs have many unwanted effects. Since lifelong treatment is necessary, 'treatment fatigue' is a real issue.

To circumvent at least some of these problems, several 'once-a-day' formulations have been devised. The first one to be approved, **Atripla**, comprised a fixed-dose mixture of nucleoside and non-nucleoside reverse transcriptase inhibitors (**tenofovir**, **emtricitabine** and **efavirenz**). Several other proprietary combinations have also been approved with different constituent drugs. It is estimated that switching to a 'once-daily' administration doubles the likelihood of maintaining the 95% adherence rate that is crucial to treatment success (see **Truong et al., 2015**). More recently, such three-drug combinations have been successfully replaced with two-drug combinations comprising a DNA integrase inhibitor such as **dolutegravir** together with the reverse transcriptase inhibitor **rilpivirine** for example. Perhaps the most important step forward for patients, however, is the use of long-lasting injectable drug combinations. At the time of writing (January 2022), the UK National Institute for Health and Care

Excellence has just approved the use of **cabotegravir** and **rilpivirine** for injectable use every 2 months in selected patients with a pre-existing good level of control. The use of combination therapy of this type has been successfully applied to other viral infections in addition to HIV.

Unwelcome interactions can occur between the component drugs of HAART combinations, and there may be inter-individual variations in absorption. Metabolic and cardiovascular complications attend the usage of these drugs and pose a problem to patients requiring lifelong therapy (see **Hester, 2012**). Some drugs penetrate poorly into the brain, and this could lead to local proliferation of the virus. So far there is little cross-resistance among the three groups of drugs, but the virus has a high mutation rate – so this could be a problem in the future.

The choice of drugs to treat pregnant or breastfeeding women with HIV is difficult and depends upon whether the patient is already well controlled with HAART or not. The main aims are to avoid damage to the fetus and to prevent transmission of the disease to the neonate. Specialist advice is essential and while combination therapy is highly effective, it increases the chances of fetal toxicity.

Other applications that require special consideration are prophylaxis for individuals who may have been exposed to the virus accidently or who are likely to become infected. The former case is *post-exposure prophylaxis* and, the latter, *pre-exposure prophylaxis*. **Emtricitabine** with **tenofovir disoproxil** is often used in these cases but, once again, specialist advice is essential.

Treatment of HIV/AIDS

- Current treatment (supervised by experienced physicians) is not curative, but aims to optimise quantity and quality of life using HAART. This consists of combinations of drugs (e.g. of two nucleoside reverse transcriptase inhibitors with either a non-nucleoside reverse transcriptase inhibitor or with a boosted protease inhibitor or with an integrase inhibitor). Drugs with additive or synergistic therapeutic effects are selected to minimise the emergence of resistance, minimise toxicity and optimise adherence to lifelong therapy.
- Plasma viral load and $CD4^+$ cell count are monitored; viral sensitivity is determined before starting treatment and before changing drugs if the viral load increases.
- Treatment is started based on $CD4^+$ cell count and aims to reduce viral load as much as possible for as long as possible.
- Special situations (e.g. prophylaxis following accidental exposure via needle-stick injury, treatment of children and during pregnancy) are best managed by specialists.

COVID-19 Pharmacotherapy

The progress of the AIDS virus may have been arrested by modern medicines but has certainly not yet been vanquished and neither has the COVID-19 virus. The former is not eradicated by drug treatment but lies latent in the host genome of memory T cells, ready to reactivate if therapy is stopped. The COVID-19 virus still

ravages healthcare systems and economies around the world, with only a few countries now untouched. Vaccination has been shown to be a safe and effective strategy in controlling infection (but see **Ch. 58**). At the time of writing, there are some 120 vaccine candidates undergoing trial with 17 already approved in multiple countries (**Mohammed et al., 2022**), but until global coverage is achieved, new mutations with increased transmissibility will emerge. COVID-19 is likely to become endemic with different variants becoming dominant each winter (in the Northern hemisphere), and a need for repeat vaccination.

In contrast to HIV, the pharmacotherapy of COVID-19 is, as yet, relatively undeveloped. There have been several attempts to identify useful drugs to treat the acute infection and these fall into two main classes: 'repurposed' drugs – medicines originally designed to treat other disorders but for which presumptive evidence suggests some antiviral or other potentially beneficial action – and secondly, drugs with established antiviral properties which are usually already used to treat other types of viral infections.

The first group included as candidates the quinolone antimalarials, **chloroquine** and **hydroxychloroquine** (see **Ch. 55**), the antiparasitic drug **ivermectin** (see **Ch. 56**), the antibiotic **azithromycin** (see **Ch. 52**) and the glucocorticoid **dexamethasone** (see Chs **3** and **25**). [6] While some of these drugs exhibited some antiviral activity in vitro, subsequent clinical trials have ruled them out as ineffective and harmful. The exception is **dexamethasone** which has proved effective and safe in seriously ill patients potentially requiring ventilation. In this group, the administration of the drug reduces mortality by approximately a

third. However, this is not due to any antiviral action but likely because it prevents local pulmonary inflammation which exacerbates the severity of the viral pneumonia.

The second group of drugs trialled as anti-COVID therapies are existing antiviral drugs. This group includes **tribavirin** (**ribavirin**, an inhibitor of viral RNA synthesis), **remdesivir** and **favipiravir** (inhibitors of RNA-dependent RNA polymerase) and **umifenovir** (an inhibitor of viral entry). Newer orally active agents such as **molnupiravir**, which provides a modest protection (see **Fig. 53.6**), and **paxlovid** (a combination of **ritonavir** and **nirmatrelvir**) have been authorised in some countries including the UK.

This hugely important area has been reviewed by **Ahsan et al. (2020)**, **Ghasemiyeh and Mohammadi-Samani (2020)** and **Siddiqui et al. (2021)**.

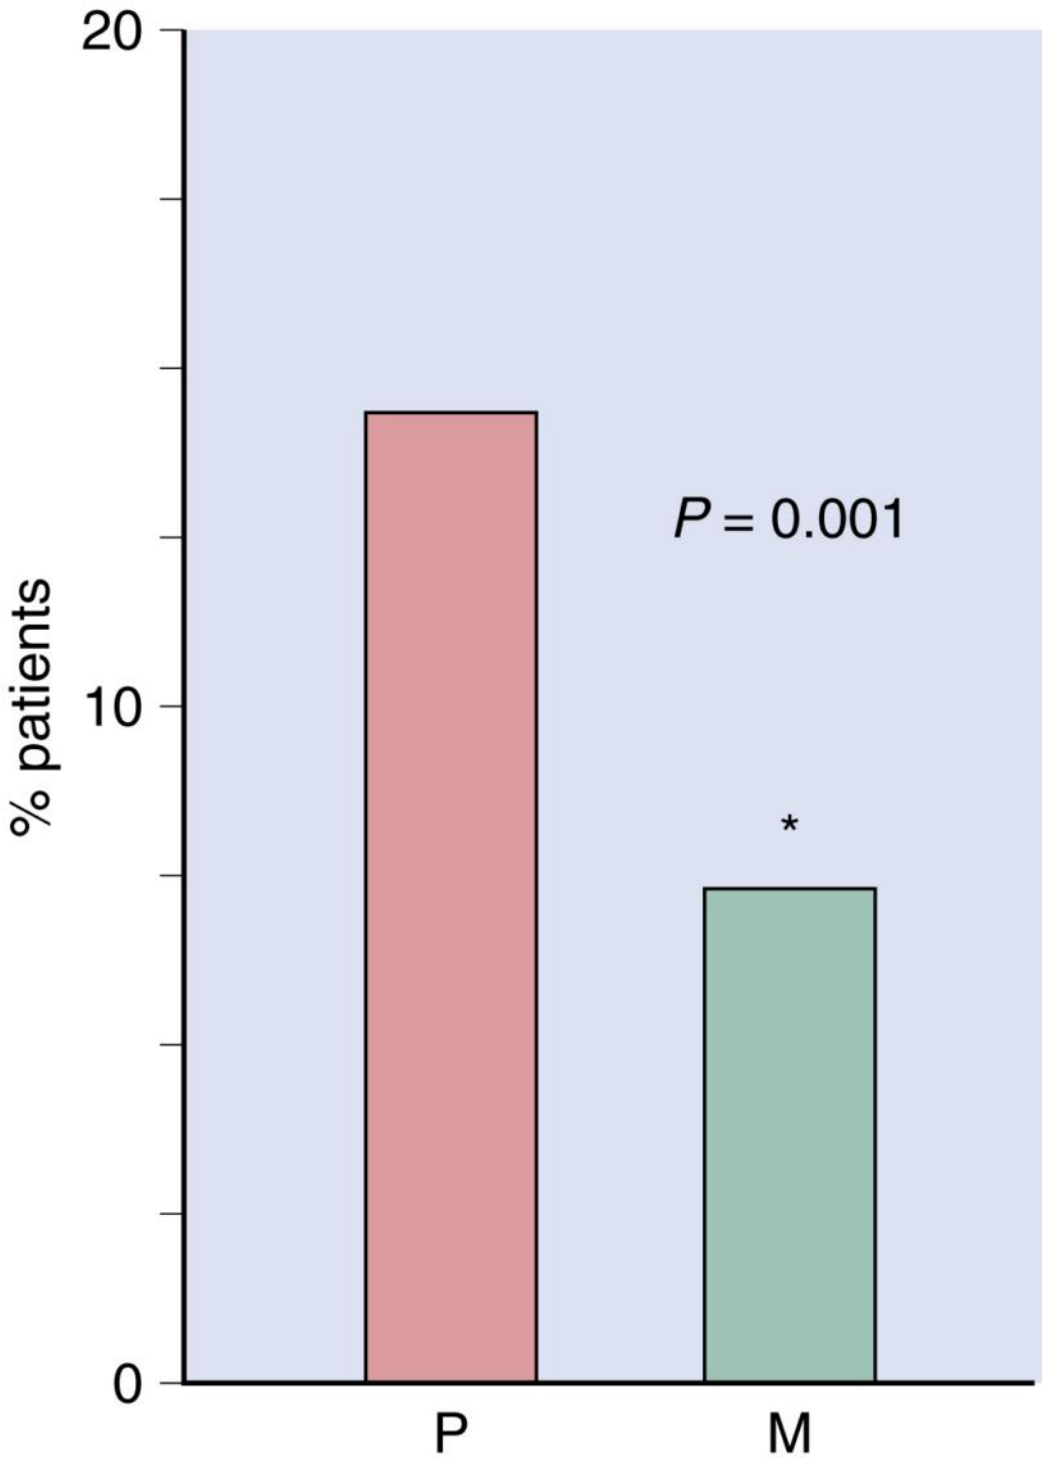

FIG. 53.6 The nucleoside analogue **molnupiravir**, which inhibits viral RNA synthesis, reduces the rate of hospitalisation or

death in unvaccinated patients with COVID-19.The bar graph summarises the data at 29 days: compared to placebo (P) treatment, **molnupiravir** (M) reduced the percentage of patients who were hospitalised or who died following COVID-19 infection from 14.1% to 7.3% in a randomised double-blind trial. Data from Jayk Bernal, A., Gomes da Silva, M.M., Musungaie, D.B., et al., 2022. Molnupiravir for oral treatment of Covid-19 in nonhospitalized patients. N. Engl. J. Med. 386, 509-520.

Prospects for New Antiviral Drugs

At the beginning of the 1990s, there were only five drugs available to treat viral infections, but this number has increased some 10-fold during the intervening years. Our understanding of the biology of pathogenic viruses and their actions in the host has grown enormously. This has led to the discovery and development of antiviral drugs and the formulation and implementation of HAART which has been a triumph in the fight against HIV, transforming the lives of millions of people in a dramatic manner. However, the ultimate weapon in the fight against HIV would be vaccination. This has proved to be highly effective in the past against diseases such as polio and smallpox, measles, mumps, rubella and more recently against influenza (both types), hepatitis B, COVID-19 and other pathogens. Such a development would have several advantages including the fact that it would be of great benefit to many people in

developing countries who are unable to afford expensive retroviral drugs and also, that while the latter are extremely effective when the dosing regime is strictly adhered to, their protection can falter when doses are missed.

Since the late 1980s, hundreds of vaccine candidates have been tested but unfortunately, and despite some encouraging results in animal models, clinical trials have proved disappointing There are various reasons for this relative lack of success: as well as the fact that patients may be infected with one or the other, or a mixture of, different viral subtypes, *antigenic drift* is a major problem. The HIV reverse transcriptase is highly prone to errors, resulting in changes to the viral coating hence different antigenic properties.

Despite these problems, there have recently been some partially successful attempts. A vaccine trial (RV144) which tested a combination of two vaccines that had proved ineffective when given separately had an efficacy of 60% a year after vaccination, declining to about 30% at 3.5 years. However, this trial was chiefly important because it confirmed that a vaccine-based approach to HIV was at least feasible, if difficult to achieve. Today, attempts to produce a long-lasting immunity to the disease with a vaccine are concentrating upon mRNA-based vaccines and improving understanding of mucosal immunity mechanisms in the female genital tract and the human rectal mucosa as these are the most common sites of infection. The whole area has been comprehensively reviewed (see **Hargrave et al., 2021**; **Sobia and Archary, 2021**, for recent assessments of the field).

Antigenic drift is also an issue with COVID-19 vaccines. Variant strains may arise following evolutionary pressure caused by

treatment with a vaccine minimising the chance of an effective and long-lasting immune response. Five variant COVID-19 strains have arisen at the time of writing all of which have different infective characteristics. A vaccine which induces *broad neutralising antibody* production by the host is today considered to be a key objective.

QUESTIONS

QUESTION 53.1

Following infection of host cells, viruses have to undergo a series of enzymatic steps involving host and viral proteins to both replicate their genetic material and produce viral proteins.

Which of the following enzymes is required to produce copies of double stranded RNA found in reoviruses?

OPTIONS:

A. DNA-dependent RNA polymerase

B. DNA-dependent DNA polymerase

C. RNA-dependent DNA polymerase

D. RNA-dependent RNA polymerase

E. Reverse transcriptase enzyme

QUESTION 53.2

The host utilises both innate and adaptive mechanisms to protect the body from viral infection.

Which of the following is not part of the host defence response to viral infection?

OPTIONS:

A. Increased Fas expression

B. Cytotoxic T-cell activation

C. Up-regulation of homologues of major histocompatibility complex (MHC) class I

D. Gene silencing

E. The ‘mother turkey’ strategy

QUESTION 53.3

In December 2019, a new strain of the SARS coronavirus was identified resulting in the COVID-19 pandemic.

Which of the following statements about SARS-CoV-2 is incorrect?

OPTIONS:

A. Viral entry is mediated by angiotensin-converting enzyme 2 (ACE2).

B. TMPRSS2 acts as co-receptor to mediate entry into upper respiratory tract cells.

C. The Omicron variant causes less damage to alveolar cells.

D. Variants occur due to mutations in the spike protein.

E. The coronavirus genome is comprised of (+) single-stranded RNA and utilises a reverse transcriptase to synthesise further viral particles.

QUESTION 53.4

As viruses utilise host mechanisms, it has been more challenging to find agents that target the virus specifically without harming host cells and functions.

Which of the following statements about antiviral therapeutics is correct?

OPTIONS:

A. Zidovudine inhibits the reverse transcriptase enzyme, resulting in inhibition of viral DNA.

B. Efavirenz causes chain termination by incorporation of non-functional nucleoside derivatives.

C. Ritonavir activates specific proteases to cause viral degradation.

D. Aciclovir blocks viral thymidine kinase so preventing chain elongation.

E. Oseltamivir prevents virion escape by inhibition of sialic acid binding.

ANSWERS

ANSWER 53.1

RATIONALE:

A. *DNA-dependent RNA polymerases are required to transcribe* double-stranded DNA of poxviruses or herpesviruses for example into mRNA which can then be translated by the host cell to make viral proteins in the usual way.

B. *DNA-dependent DNA polymerases are required to produce copies of viruses comprising double-stranded DNA.*

C. The dsDNA genome of hepadnaviruses contains stretches of single-stranded DNA. Enzymes in the host nucleus must first add additional bases to produce a replication-capable dsRNA copy. From this, a (+) ssRNA is synthesised so that a dsRNA species can be produced. A *reverse transcriptase* enzyme (an *RNA-dependent DNA polymerase* enzyme) uses this template to synthesise dsDNA which can then be utilised by the host to produce mRNA for subsequent translation.

D.

E. *Reverse transcriptase* enzymes such as *RNA-dependent DNA polymerases* use viral dsRNA as a template to synthesise dsDNA which can then be utilised by the host to produce mRNA for subsequent translation.

CORRECT ANSWER WITH EXPLANATION:

D. RNA-dependent RNA polymerase

Reoviruses, such as the rotaviruses, contain dsRNA which can be transcribed into a usable mRNA for the host cell to translate and also copied by an *RNA-dependent RNA polymerase* to replicate the viral genome.

ANSWER 53.2

RATIONALE:

A. Virally infected cells express Fas to mediate activation of the apoptotic pathways and sacrifice of the infected cell.

B. Cytotoxic T cells recognise viral particles presented in conjunction with MHC class I and are activated to kill the virally infected cell.

C.

D. The presence of viral double-stranded RNA causes the switching off or silencing of the gene coding for the RNA.

E. Alteration or down-regulation of MHC molecules leads to natural killer (NK)–mediated killing – known as the 'mother turkey' strategy of killing anything that is different.

CORRECT ANSWER WITH EXPLANATION:

C. Up-regulation of homologues of MHC class I

Some viruses induce the up-regulation of homologues of MHC class I on the host cells to bypass the NK-mediated mother turkey

strategy.

ANSWER 53.3

RATIONALE:

A. The virus gains access to cells by binding to the cell surface receptor ACE2.

B. A co-receptor, TMPRSS2, aids the binding to ACE2 by proteolytically modifying the spike protein such that the virus is more capable of fusing with the cell membrane. The enzyme is expressed at higher levels in the upper respiratory tract.

C. TMPRSS2 is much less abundant in the lower respiratory tract perhaps explaining why the omicron variant, which is unable to enter cells without this cofactor, is less damaging to alveolar cells.

D. Since the initial detection of the disease, several variant forms, generally with mutations in the characteristic coronavirus 'spike' protein, have been identified around the world.

E.

CORRECT ANSWER WITH EXPLANATION:

E. The coronavirus genome is comprised of (+) single-stranded RNA and utilises a reverse transcriptase to synthesise further viral particles.

(+) ssRNA viruses such as coronaviruses can be modified by the attachment of a poly A tail and a 5' cap to furnish a source of usable mRNA which is amplified by a viral *RNA-dependent RNA polymerase*, producing a (-) ssRNA copy as a template for producing more (+) ssRNA, which can then be used to furnish further proteins as well as replenishing the viral genome.

ANSWER 53.4

RATIONALE:

A. Zidovudine is a nucleoside analogue which is incorporated into the growing DNA chain but causes chain termination.

B. Efavirenz binds near the catalytic site of the reverse transcriptase enzyme and inhibits its function.

C. Ritonavir inhibits the action of proteases required for viral protein cleavage and activation.

D. Aciclovir is a guanosine derivative which, when converted to the trisphosphate form by viral thymidine kinase, then inhibits the viral DNA polymerase.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Oseltamivir prevents virion escape by inhibition of sialic acid binding.

Oseltamivir is a neuraminidase inhibitor that prevents the cleavage of the viral coat from host sialic acid residues in the cell membrane and therefore prevents the release of new virions.

[1] In 1960, the British immunologist Peter Medawar opined that: 'It has been well said that a virus is a piece of bad news wrapped up in protein.'

[2] The number of copies of viral genes on earth is "...beyond astronomical. There are hundreds of billions of stars in the Milky way and a couple of trillion galaxies in the observable universe. The virions in the surface waters of any smallish sea handily outnumber all the stars in all the skies that science could ever speak of." – '*The viral universe',* Economist, 22 August 2020.

[3] Named after David Baltimore, the American biologist and Nobel Laureate (1975) who devised this system.

[4] The technique is indeed cheap in the laboratory, but siRNA drugs certainly are not. Treatment with **givosiran**, the siRNA drug pictured on the front cover of this book, costs some $US0.5 million per annum.

[5] A tumor caused by infection with human herpesvirus 8 (HHV8), also known as Kaposi's sarcoma-associated herpesvirus (KSHV) or KS agent, was originally described by Moritz Kaposi, a Hungarian dermatologist practicing at the University of Vienna in 1872. It became more widely known as one of the AIDS-defining illnesses in the 1980s.

[6] At a press conference in April 2021, President Trump horrified his medical advisors by suggesting that bleach and disinfectants should be trialled used as intravenous anti-COVID treatments. Although he later dismissed this as a prank, the US Centre for Disease Control and Prevention noted a surge in calls to poison centres the following month and several suppliers of 'cleaning products' which claimed efficacy were subsequently prosecuted.

54: Antifungal drugs

OVERVIEW

Fungal infections (*mycoses*) are widespread in the population. In temperate climates, such as the United Kingdom, they are generally associated with the skin (e.g. 'athlete's foot') or mucous membranes (e.g. 'thrush'). [1] In otherwise healthy people, these infections are mainly minor, being more of a nuisance than a threat. However, they can pose a more serious (sometimes fatal) problem when the immune system is compromised or when the fungal organism gains access to the systemic circulation. In this chapter, we will briefly review the main types of fungal infections and discuss the drugs that can be used to treat them.

Fungi and Fungal Infections

Fungi are non-motile eukaryotic cells and thousands of species have been characterised. Unlike green plants, they cannot photosynthesise, and many are parasitic or saprophytic in nature. Many are of economic importance, either because they are edible (e.g. mushrooms), useful in manufacturing other products (e.g. yeast in brewing and in the production of antibiotics), or because of the damage they cause to other animals, crops or foodstuffs. Along with bacteria, fungi are the major *decomposers* in most terrestrial ecosystems.

Approximately 50 species are potentially pathogenic in humans. These organisms are present in the environment or may co-exist with humans as *commensals* (i.e. not pathogenic) without causing any overt risks to health. However, since the 1970s there has been a steady increase in the incidence of serious secondary systemic fungal infections, causing some 2 million deaths per year, usually in immunologically vulnerable individuals. One of the contributory factors has been the widespread use of broad-spectrum antibiotics, [2] which eradicate the non-pathogenic bacterial populations that normally compete with fungi for nutritional resources. Other causes include diseases in which the immune system is compromised, such as AIDS as well as the widespread use of immunosuppressant, and cancer chemotherapy agents. The result has been an increased prevalence of *opportunistic infections*, that is, infections that exploit vulnerabilities in host immune systems. Older people, people with diabetes, pregnant women and burn wound victims are particularly at risk of fungal infections such as *candidiasis*. Primary systemic fungal infections, once rare in the temperate world, are also now encountered more often because of increased international travel.

Clinically important fungi may be classified into four main types on the basis of morphological and other characteristics. Of particular taxonomic significance is the presence of *hyphae* – filamentous projections that can knit the fungal cells together to form a complex *mycelium*, a mat-like structure that is responsible for the characteristic appearance of moulds.

> Fungi are remarkably specific in their choice of preferred location. The main groups are:
> - yeasts (e.g. *Cryptococcus neoformans*)

- yeast-like fungi that produce a structure resembling a mycelium (e.g. *Candida albicans*)
- filamentous fungi with a true mycelium (e.g. *Aspergillus fumigatus*)
- 'dimorphic' fungi which, depending on nutritional constraints, may grow as either yeasts or filamentous fungi (e.g. *Histoplasma capsulatu* [3])

Most fungi only cause systemic infections in immunocompromised individuals, but the dimorphic fungi can infect healthy individuals. Another organism, *Pneumocystis jirovecii* (formerly known as *P. carinii*), described in **Chapter 55**, shares characteristics of both protozoa and fungi; it is an important opportunistic pathogen in patients with compromised immune systems, but is not susceptible to antifungal drugs.

Superficial fungal infections can be classified into the *dermatomycoses* and *candidiasis*. Dermatomycoses include infections of the skin, hair and nails (*onychomycosis*). They are most commonly caused by *Trichophyton*, *Microsporum* or *Epidermophyton*, giving rise to circular rashes known as 'ringworm' or, generically, *tinea* (not to be confused with genuine helminth infections; see **Ch. 56**). *Tinea capitis* affects the scalp; *Tinea cruris*, the groin ('dhobie itch', 'Jock itch'); *Tinea pedis*, the feet ('athlete's foot'); and *Tinea corporis*, the body. Superficial candidiasis, caused by the yeast-like organism *Candida*, may infect the mucous membranes of the mouth or vagina (thrush), or the skin in an area where two skin surfaces are in contact and can rub together ('intertriginous' areas), such as under the breast, in the groin or

between the toes. Secondary bacterial infections may complicate the course and treatment of these conditions.

Systemic (or 'disseminated') fungal diseases are much more serious than superficial infections. The commonest in the United Kingdom is *Candidiasis*. Other serious conditions include *cryptococcal meningitis*, endocarditis (particularly of artificial valves), *pulmonary aspergillosis* and *rhinocerebral mucormycosis*. Invasive *pulmonary aspergillosis* is now a leading cause of death in recipients of bone marrow transplants or those with neutropenia. Colonisation by *Aspergillus* of the lungs of patients with asthma or cystic fibrosis can lead to a condition termed allergic *bronchopulmonary aspergillosis* and growth of *Aspergillus* within a pathological cavity in lung tissue (usually caused by prior tuberculosis) can result in a fungus ball known as an *aspergilloma*. Aspergillomas may be asymptomatic but if they invade pulmonary vessels can cause death by massive haemoptysis.

Table 54.1

In other parts of the world, systemic fungal infections include *blastomycosis*, *histoplasmosis* (which produces characteristic calcifications on chest X-rays), *coccidiomycosis* and *paracoccidiomycosis*; these are often *primary* infections; that is, they are not secondary to reduced immunological function or altered commensal microorganisms.

In addition to a free-floating lifestyle, some fungi can develop and grow in *biofilms*, that is, fungal communities attached to the surface of inert (e.g. catheters) or living (e.g. implants) surfaces. Such

colonies are highly resistant to stress and to antifungal drugs, making them very difficult to treat.

Drugs Used to Treat Fungal Infections

Drugs vary in their efficacy between the different fungal groups. **Table 54.1** gives examples of each type of organism and lists some of the diseases they cause and the most common choice of drug used to treat them. Serious infections are often treated with combinations of these drugs.

The current therapeutic agents can be broadly classified into two groups: first, the naturally occurring antifungal antibiotics such as the *polyenes* and *echinocandins*, and second, synthetic drugs including *azoles* and *fluorinated pyrimidines*. Because many fungal infections are superficial, there are many topical preparations. Many antifungal agents are quite toxic, and when systemic therapy is required, this is generally undertaken under expert medical supervision.

Fig. 54.1 shows sites of action of common antifungal drugs.

Antifungal Antibiotics

Amphotericin

Amphotericin (also called **amphotericin B**) was originally a mixture of antifungal substances derived from cultures of *Streptomyces*. Structurally, the pure compound is a large ('macrolide') molecule belonging to the polyene group of antifungal agents.

Like other polyene antibiotics (see **Ch. 52**), the site of **amphotericin** action is the fungal cell membrane. The hydrophilic core of the doughnut-shaped amphotericin molecule creates a transmembrane ion channel, causing gross disturbances in ion balance with the loss of intracellular K+, altering cellular permeability and disrupting transport systems. **Amphotericin** has a selective action, binding avidly to the membranes of fungi and some protozoa, less avidly to mammalian cells and not at all to bacteria. The basis of this relative specificity is the drug's greater avidity for ergosterol, a fungal membrane sterol that is not found in animal cells (where cholesterol is the principal sterol). **Amphotericin** is active against most fungi and yeasts and is the gold standard for treating disseminated infections caused by organisms including *Aspergillus* and *Candida*. **Amphotericin** also enhances the antifungal effect of **flucytosine**, providing a useful synergistic combination.

Pharmacokinetic aspects

Amphotericin is very poorly absorbed when given orally, and this route is used only for treating fungal infections of the upper gastrointestinal (GI) tract. It can be used topically, but for systemic infections it is generally formulated in liposomes or other lipid-containing preparations and given by slow intravenous infusion. This improves the pharmacokinetics and reduces the (considerable) burden of harmful effects.

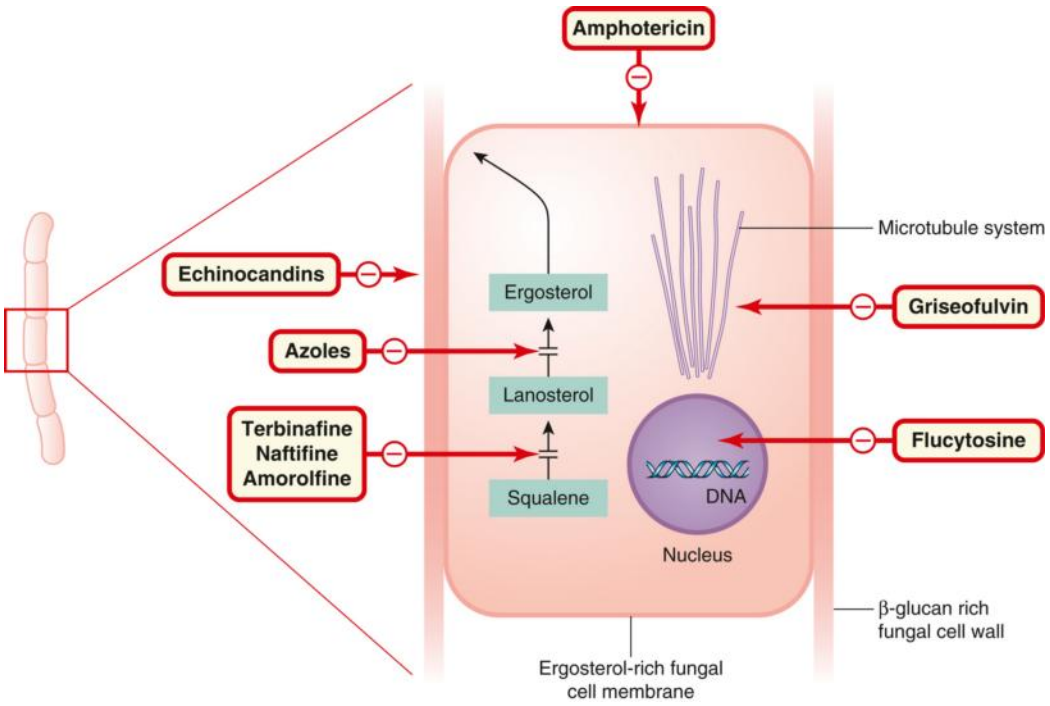

FIG. 54.1 Sites of action of common antifungal drugs. Fungi are morphologically very diverse organisms, and this schematic diagram of a 'typical' fungal cell is not intended to be structurally accurate. The principal sites of action of the main antifungal agents mentioned in this chapter are indicated as shown in *red-bordered boxes*.

Amphotericin is highly protein bound. It penetrates tissues and membranes poorly although it is found in fairly high concentrations in inflammatory exudates and may cross the blood–brain barrier quite readily when the meninges are inflamed. Intravenous **amphotericin** is essential in the treatment of cryptococcal meningitis, often with **flucytosine**. It is excreted very slowly via the kidney; traces being found in the urine for 2 months or more after administration has ceased.

Unwanted effects

The commonest (indeed almost invariable) adverse effects of **amphotericin** include rigors, fever, chills and headache during drug infusion; hypotension and anaphylactoid reactions occur in more severely affected individuals. The (considerably more expensive) liposome-encapsulated and lipid-complexed preparations have no greater efficacy than the native drug but cause much less frequent and less severe infusion reactions.

The most serious unwanted effect of **amphotericin** is renal toxicity. Some reduction of renal function occurs in more than 80% of patients receiving the drug; although this generally improves after treatment is stopped, some impairment of glomerular filtration may remain. Hypokalaemia occurs in 25% of patients, because of the action of the drug on renal tubular cells, and often requires potassium chloride supplementation. Hypomagnesaemia also occurs for the same reason. Acid–base disturbance and anaemia can be further problems. Other unwanted effects include impaired hepatic function and thrombocytopenia. The drug is irritant to the endothelium of the veins and can cause local thrombophlebitis. Intrathecal injections can cause neurotoxicity, and topical applications cause a rash.

Griseofulvin

Griseofulvin is a narrow-spectrum antifungal agent isolated from cultures of *Penicillium griseofulvum*. It interferes with mitosis by binding to fungal microtubules. It can be used to treat dermatophyte infections of skin or nails when local administration is ineffective, but treatment needs to be prolonged. It potently

induces cytochrome P450 enzymes and causes several clinically important drug interactions, and because of this is now seldom used.

Echinocandins

Echinocandins comprise a ring of six amino acids linked to a lipophilic sidechain. All drugs in this group are synthetic modifications of **echinocandin B**, which is found naturally in *Aspergillus nidulans*. As a group, the echinocandins are fungicidal for *Candida* and fungistatic for *Aspergillus*. The drugs inhibit the synthesis of 1,3-β-glucan, a glucose polymer that is necessary for maintaining the structure of fungal cell walls. In the absence of this polymer, fungal cells lose integrity and lyse. Resistance genes have been identified in *Candida* (**Chen et al., 2011**).

Caspofungin is active in vitro against a wide variety of fungi, and it has proved effective in the treatment of candidiasis and forms of invasive aspergillosis that are refractory to **amphotericin**. Oral absorption is poor, and it is given intravenously, once daily. **Anidulafungin** is used mainly for invasive candidiasis; again, it is given intravenously. The principal side effects of both drugs include nausea, vomiting and diarrhoea, and rash. The relatively new **micafungin** is also mainly used for treating invasive candidiasis. It shares many of the side effects of the group but may also cause serious hepatotoxicity.

Nystatin

Nystatin (also called **fungicidin**) is a polyene macrolide antibiotic similar in structure to **amphotericin** and with the same mechanism of action. Its use is mainly limited to *Candida*

infections of the oral mucosa; it is not absorbed through mucous membranes or skin and is administered as an oral suspension. ***Unwanted effects*** may include nausea, vomiting and diarrhoea.

Synthetic Antifungal Drugs

Azoles

The azoles are a group of synthetic fungistatic agents with a broad spectrum of antifungal activity. **Clotrimazole**, **econazole**, **fenticonazole**, **ketoconazole**, **miconazole**, **tioconazole** and **sulconazole** (not available in United Kingdom) are based on the imidazole nucleus and **isavuconazole**, **itraconazole**, **posaconazole**, **voriconazole** and **fluconazole** are triazole derivatives.

The azoles inhibit the fungal cytochrome P450 3A enzyme, *lanosine 14α-demethylase*, which converts lanosterol to ergosterol, the main sterol in fungal cell membranes. The resulting depletion of ergosterol alters the fluidity of the membrane, and this interferes with the action of membrane-associated enzymes. The net effect is an inhibition of replication. Azoles also inhibit the transformation of candidal yeast cells into hyphae – the invasive and pathogenic form of the organism. Depletion of membrane ergosterol reduces the binding of **amphotericin** but it is not known if this leads to a clinically important interaction.

Ketoconazole

Ketoconazole was the first azole that could be given orally to treat systemic fungal infections. It is effective against several different types of organism. It is, however, toxic, and relapse is common after

apparently successful treatment. It is well absorbed from the GI tract and is distributed widely throughout the tissues and tissue fluids although it does not reach therapeutic concentrations in the central nervous system unless high doses are given. It is inactivated in the liver and excreted in bile and in urine. Its half-life in the plasma is 8 h.

Unwanted effects

The main hazard of **ketoconazole** is liver toxicity, which is rare but can prove fatal. Liver function is therefore monitored before and during treatment. Other adverse effects include GI disturbances and pruritus. Inhibition of adrenocortical steroid and testosterone synthesis has been recorded with high doses, the latter resulting in gynaecomastia in some male patients. There may be adverse interactions with other drugs. **Ciclosporin** and **astemizole** compete with **ketoconazole** for cytochrome P450 mixed function oxidase enzymes, causing increased plasma concentrations of both parties. Drugs that reduce gastric acidity decrease the absorption of **ketoconazole**, and **rifampicin** reduces the plasma concentration by induction of metabolising enzymes.

Fluconazole

Fluconazole is well absorbed and can be given orally or intravenously. It reaches high concentrations in the cerebrospinal fluid and ocular fluids and is used as a second-line agent to treat most types of fungal meningitis. Fungicidal concentrations are also achieved in vaginal tissue, saliva, skin and nails. It has a half-life of ~25 h and is mainly excreted unchanged in the urine.

Unwanted effects

Unwanted effects, which are generally mild, include nausea, headache and abdominal pain. However, exfoliative skin lesions (including, on occasion, Stevens–Johnson syndrome [4]) have been seen in some individuals – primarily in AIDS patients who are being treated with multiple drugs. Hepatitis has been reported, although this is rare, and **fluconazole**, in usual doses, does not inhibit steroidogenesis and hepatic drug metabolism to the same extent as occurs with **ketoconazole**.

Itraconazole

Itraconazole is active against a range of dermatophytes. It may be given orally but, after absorption (which is variable), undergoes extensive hepatic metabolism. It is highly lipid-soluble (and water-insoluble), and a formulation in which the drug is retained within pockets of β-cyclodextrin is available. In this form, **itraconazole** can be administered intravenously, thereby overcoming the problem of variable absorption from the GI tract. It does not penetrate the cerebrospinal fluid. When administered orally, its half-life is about 36 h, and it is excreted in the urine.

Unwanted effects

The most serious are hepatoxicity and Stevens–Johnson syndrome. GI disturbances, headache and allergic skin reactions can occur. Inhibition of steroidogenesis has not been reported. Drug interactions as a result of inhibition of cytochrome P450 enzymes occur (similar to **ketoconazole**).

Miconazole

Miconazole is generally used topically (often as a gel) for oral and other infections of the GI tract or for skin or mucosal fungal infection. If significant systemic absorption occurs, drug interactions can present a problem.

Other azoles

Clotrimazole, **econazole**, **tioconazole** and **sulconazole** are used only for topical application. **Clotrimazole** interferes with amino acid transport into the fungus by an action on the cell membrane. It is active against a wide range of fungi, including *Candida*. These drugs are sometimes combined with anti-inflammatory glucocorticoids (see **Ch. 25**). **Isavuconazole, posacanazole** and **voriconazole** are used mainly for the treatment of invasive life-threatening infections such as aspergillosis.

Other Antifungal Drugs

Flucytosine is a synthetic, orally active antifungal agent that is effective against a limited range (mainly yeasts) of systemic fungal infections. In fungal, but not human, cells it is converted to the antimetabolite 5-fluorouracil which inhibits thymidylate synthetase and thus DNA synthesis (see Chs **6** and **57**). If given alone, drug resistance commonly arises during treatment, so it is usually combined with **amphotericin** for severe systemic infections such as systemic candidiasis and cryptococcal meningitis.

Flucytosine is usually given by intravenous infusion (because such patients are often too ill to take medicine by mouth) but can also be given orally. It is widely distributed throughout the body fluids, including the cerebrospinal fluid. About 90% is excreted

unchanged via the kidneys, and the plasma half-life is 3–5 h. The dosage should be reduced if renal function is impaired.

Unwanted effects

include GI disturbances, anaemia, neutropenia, thrombocytopenia and alopecia (possibly due to formation of fluorouracil [see **Ch. 57**] from **flucytosine** by gut bacteria), but these are usually manageable. Uracil is reported to decrease the toxic effects on the bone marrow without impairing the antimycotic action. Hepatitis has been reported but is rare.

Terbinafine is a highly lipophilic, keratinophilic fungicidal compound active against a wide range of skin pathogens. It is particularly useful against nail infections. It acts by selectively inhibiting the enzyme *squalene epoxidase*, which catalyses a key step in the synthesis of ergosterol from squalene in the fungal cell wall. The accumulation of squalene within the cell is toxic to the organism.

When used to treat ringworm or fungal infections of the nails, it is given orally. The drug is rapidly absorbed and is taken up by skin, nails and adipose tissue. Given topically, it penetrates skin and mucous membranes. It is metabolised in the liver by the cytochrome P450 system, and the metabolites are excreted in the urine.

Unwanted effects

occur in about 10% of individuals and are usually mild and self-limiting. They include GI disturbances, rashes, pruritus, headache and dizziness. Joint and muscle pains have been reported and, more rarely, hepatitis.

Naftifine is similar in action to **terbinafine**. Among other developments, a morpholine derivative, **amorolfine**, which interferes with fungal sterol synthesis, is available as a nail lacquer, being effective against onychomycoses.

Future Developments

Fungal infections are on the rise no doubt encouraged by the prevalence of cancer chemotherapy, the increase in type 2 diabetes and transplant-associated immunosuppression. Many existing drugs have low efficacy, and problems with toxicity and new strains of commensal-turned-pathogenic fungi are emerging. Furthermore, increasing numbers of fungal strains are becoming resistant to the current antifungal drugs (see **Ch. 51**) as they develop resistance genes or acquire naturally occurring protective mutations. The capacity of some species to develop biofilms exacerbates this problem (although also offering other opportunities for drug design; see **de Mello et al., 2017**). It is fortunate that drug resistance is not transferable between fungi as it is in bacteria.

There is therefore a pressing need for more antifungals. Encouragingly, several new synthetic compounds are in development (see **Gintjee et al, 2020**), including novel azole drugs and new **amphotericin** derivatives as well as some with novel mechanisms of action such as **ibrexafungerp** (approved in the United States for vulvo-vaginal candidiasis), an oral inhibitor of glucan synthase, and **olorofim** (the first of a new class of antifungals), which is highly active against *Aspergillus* species. **Rezafungin** is a novel echinocandin antifungal derived by chemical modification of **anidulafungin** which has been approved

in the United States and EU (but not yet in the UK). It is characterised by high potency against a range of fungal pathogens and a long-lasting effect requiring only a once weekly administration.

New therapeutic strategies are being developed too, including novel drug formulations (**Asadi et al., 2021**; **Nagaraj et al., 2021**) and the deployment of naturally occurring substances including microbial peptides (**Li et al., 2021**) and herbal extracts (**Hsu et al., 2021**). An ideal solution would be an antifungal vaccine(s). The idea was first mooted in the 1960s but so far success has proved elusive and there is no clinically approved antifungal vaccine available at the time of writing. Several approaches are being trialled (see **Taborda and Nosanchuk, 2017**). One promising development has been the use of 'hybrid' molecules bearing peptide and carbohydrate antigens. This strategy has already been shown to provoke robust immune responses in animals (**Liao et al., 2019**) but one fundamental problem with any vaccine-based solution is that it is dependent upon an appropriate function of the patient's immune system and it is precisely immunocompromised patients who often require treatment.

QUESTIONS

QUESTION 54.1

Fungal infections (*mycoses*) are widespread in the population and can be classified as primary or secondary infections.

Which of the following patients would be most likely to contract a primary fungal infection?

OPTIONS:

A. A patient with AIDS

B. A cancer patient being treated with chemotherapy

C. A patient on antibiotics

D. Burns wound victims

E. A healthy individual

QUESTION 54.2

The efficacy of treatment of fungal infections depends largely on the type of organism and the spread of the infection.

Which of the following would be the most difficult to treat?

OPTIONS:

A. Athlete's foot

B. Fungal growths on catheters

C. *Onychomycosis*

D. Thrush

E. Ringworm

ANSWERS

ANSWER 54.1

RATIONALE:

A. Serious secondary systemic fungal infections, causing some 2 million deaths per year, occur in immunologically vulnerable individuals.

B. Patients being treated with chemotherapy are immunocompromised and at risk of secondary fungal

infections.

C. One of the contributory factors to secondary fungal infections has been the widespread use of broad-spectrum antibiotics, which eradicate the non-pathogenic bacterial populations that normally compete with fungi for nutritional resources.

D. Burn wound victims are particularly at risk of secondary fungal infections such as *candidiasis*.

E.

CORRECT ANSWER WITH EXPLANATION:

E. A healthy individual

Primary infections are not secondary to reduced immunological function or altered commensal microorganisms. Once rare in the temperate world, they are also now encountered more often because of increased international travel.

ANSWER 54.2

RATIONALE:

A. Athlete's foot is a superficial dermatomycoses infection that can be treated with clotrimazole or miconazole.

B.

C. *Onychomycosis* is a dermatomycoses infection of the skin, hair and nails and is treated topically with miconazole or systemically with griseofulvin when local administration is ineffective.

D. Thrush is a superficial candidiasis fungal infection. Oral thrush can be treated with nystatin or clotrimazole.

E. Ringworm infections are caused by superficial dermatomycoses and can be treated ketoconazole, clotrimazole or miconazole.

CORRECT ANSWER WITH EXPLANATION:

B. Fungal growths on catheters

Some fungi can develop and grow in *biofilms*, that is, fungal communities attached to the surface of inert (e.g. catheters) or living (e.g. implants) surfaces. Such colonies are highly resistant to stress and to antifungal drugs, making them very difficult to treat.

[1] However, they may also 'infect' buildings and contribute to 'sick building syndrome'.

[2] In the days when tetracycline use was widespread, a common physical sign in chronic users was a black tongue – caused by overgrowth of commensal *Aspergillus niger*: dramatic and potentially alarming but harmless in that situation.

[3] Histoplasma is endemic in the mid-West United States. The organism is taken up intracellularly by histiocytes where they can survive and provoke a granulomatous reaction like tuberculosis (TB). Individuals are often asymptomatic, and past infection is picked up on X-rays as calcifications in various organs such as lung, spleen, etc., due to calcified granulomata like old TB but more densely calcified. As with TB the adrenal glands can be infected and, like TB, it is a cause of Addison's disease.

[4] This is a severe and sometimes fatal condition involving blistering of the skin, mouth, GI tract, eyes and genitalia, often accompanied by fever, polyarthritis and kidney failure.

55: Antiprotozoal drugs

OVERVIEW

Protozoa are motile, unicellular eukaryotic organisms that have colonised virtually every habitat and ecological niche are collectively responsible for an enormous burden of illness in humans as well as domestic and wild animal populations. Historically, malaria has been one of mankind's greatest afflictions. Even today there are over 200 million cases of malaria each year and some half a million deaths, with pregnant women and children constituting the bulk of the victims. In this chapter, we will first review some general features of protozoa, discuss the interactions of these parasites with their hosts and then consider the therapy of each group of diseases in turn. In view of its continuing global importance, malaria is the main topic.

Background

Protozoa may be conveniently classified into four main groups on the basis of their mode of locomotion: *amoebas*, *flagellates* and *sporozoa* are easily characterised, but the final group which includes *ciliates* also contain other organisms of uncertain affiliation, such as the *Pneumocystis jirovecii* mentioned in the last chapter. Protozoa have diverse feeding behaviour, with some being parasitic. Many have extremely complex life cycles, sometimes

involving several hosts, reminiscent of the helminths discussed in **Chapter 56**. **Table 55.1** lists some of the clinically important organisms, together with the diseases that they cause and an overview of current anti-infective drugs.

Host–Parasite Interactions

While mammals have developed very efficient mechanisms for defending themselves against invading parasites, many species have, in turn, evolved sophisticated evasion tactics. One common parasite ploy is to take refuge within the cells of the host, where antibodies cannot reach them. Most protozoa do this; for example, *Plasmodium* species take up residence in red cells, *Leishmania* species infect macrophages exclusively, while *Trypanosoma* species invade many other cell types. The host deals with these intracellular fugitives by deploying cytotoxic $CD8^+$ T cells and T helper (Th) 1 pathway cytokines, such as interleukin (IL)-2, tumour necrosis factor (TNF)-α and interferon-γ. These cytokines (see **Ch. 17**) activate macrophages, which can then kill the infected cells along with the intracellular parasites.

As we explained in **Chapter 7**, the Th1 pathway responses can be down-regulated by Th2 pathway cytokines (e.g. transforming growth factor-β, IL-4 and IL-10) and some intracellular parasites have exploited this by stimulating the production of Th2 cytokines thus reducing their vulnerability to Th1-driven activated macrophages. For example, the invasion of macrophages by *Leishmania* species induces transforming growth factor-β and IL-10, inactivates complement pathways and down-regulates many other intracellular defence mechanisms (**Singh et al., 2012**). Similar parasite

countermeasures operate during worm (helminth) infestations (see **Ch. 56**).

Toxoplasma gondii has evolved a different, counterintuitive, gambit – *up-regulation* of host defence responses. The definitive host (i.e. in which sexual recombination occurs) of this protozoon is the cat, but humans can inadvertently become intermediate hosts, harbouring the asexual form of the parasite. In humans, *T. gondii* infects numerous cell types and has a highly virulent replicative stage. To ensure that its host survives, it stimulates production of interferon-γ, modulating the host's cell-mediated responses to promote encystment (and thus persistence) of the parasite in the tissues.

Malaria and Antimalarial Drugs

Malaria [1] is caused by parasites belonging to the genus *Plasmodium*. Four main species infect humans: *Plasmodium falciparum, Plasmodium vivax, Plasmodium ovale* and *Plasmodium malariae*. A related parasite that infects monkeys, *Plasmodium knowlesi*, can also infect humans and is causing increasing concern in some regions, such as South-East Asia. The insect vector in all cases is the female *Anopheles* mosquito. This breeds in stagnant water and the disease it spreads is estimated to have killed half the human beings who have ever existed. Despite substantial therapeutic advances, it shows little sign of abandoning its murderous rampage.

Malaria was eradicated from most temperate countries in the 20th century, and the WHO attempted to eradicate malaria elsewhere using the powerful 'residual' insecticides and highly

effective antimalarial drugs, such as **chloroquine**, which had, by then, become available. By the end of the 1950s, the incidence of malaria had dropped dramatically. However, it was clear by the 1970s that this attempt at eradication had failed, mainly because of the increasing resistance of the mosquito to the insecticides, and of the parasite to antimalarial drugs.

Massive increases in spending on public health campaigns, sponsored by a partnership of private, national governments and transnational organisations such as the WHO and the World Bank, have yielded significant successes and the global death toll has fallen by 60% over the last 20 years. In the latest World Malaria Report, the WHO has estimated that 1.5 million infections had been averted and 7.6 million lives saved. Progress in Sub-Saharan Africa which bears the greatest burden of disease has been particularly impressive, with the mortality rate falling by over 40% in the last decade. In Southeast Asia, the fall in infections was 75% and in the Indian subcontinent, 70%.

Table 55.1

[a] See also **Table 55.2**.

[b] This organism is of uncertain classification. See text for details and **Chapter 54** for further comments.

Despite these successes, the overall global statistics are still deeply concerning. According to the latest reported (2019) figures there were almost 230 million cases and 409,000 deaths, not much different from the previous year. Half the world's population is still at risk from the disease with Sub-Saharan Africa reporting some

94% of all cases. Even those who survive may suffer lasting impairment, with pregnant women, refugees and labourers entering endemic regions being at particularly high risk. Malaria also imposes a huge economic burden on countries where the disease is rife.

Also of concern is the fact that malaria has gained a foothold in other countries where it is not normally endemic. In Europe (declared 'Malaria free' in 2015), for example, virtually all reported cases (>8641 in 2019) of the disease are imported malaria [2] and this figure has remained fairly constant, unlike the global fall in cases. This phenomenon is partly due to increasing international travel, partly due to immigration from countries where the disease is endemic and (possibly) partly caused by global warming.

Malaria

Malaria is caused by various species of plasmodia, which are carried by the infected female *Anopheles* mosquito. Sporozoites (the asexual form of the parasite) are introduced into the host following insect bite and these develop in the liver into:

- schizonts (the pre-erythrocytic stage), which liberate merozoites – these infect red blood cells, forming motile trophozoites, which, after development, release another batch of erythrocyte-infecting merozoites, causing fever; this constitutes the *erythrocytic cycle*;
- dormant hypnozoites, which may liberate merozoites later (the exoerythrocytic stage).

The main malarial parasites causing tertian ('every third day') malaria are:

- *P. vivax*, which causes benign tertian malaria;
- *P. falciparum*, which causes malignant tertian malaria; unlike *P. vivax*, this plasmodium has no exoerythrocytic stage.

Some merozoites develop into gametocytes, the sexual forms of the parasite. When ingested by the mosquito, these give rise to further stages of the parasite's life cycle within the insect.

The Life Cycle of the Malaria Parasite

The symptoms of malaria include fever, shivering, pain in the joints, headache, repeated vomiting, generalised convulsions and coma. Symptoms, which appear during the erythrocytic phase of infection, only become apparent 7–9 days after being bitten by an infected mosquito. By far the most dangerous parasite is *P. falciparum* (predominant in Africa) followed by *P. vivax* (the dominant form of the parasite in other countries).

The life cycle of the parasite consists of a *sexual cycle*, which takes place in the female *Anopheles* mosquito, and an *asexual cycle*, which occurs in humans (**Fig. 55.1** and the 'Malaria' box). Therefore, it is the mosquito, not the human, that is the *definitive* host for plasmodia. Indeed, it has been said that the only function of humans is to enable the parasite to infect more mosquitoes so that further sexual recombination can occur.

The sexual cycle in the mosquito involves fertilisation of the female *gametocyte* by the male gametocyte, with the formation of a *zygote*, which develops into an *oocyst (sporocyst)*. A further stage

of division and multiplication takes place, leading to rupture of the sporocyst with release of *sporozoites*, which then migrate to the mosquito's salivary glands and thus enter the human host following mosquito bites.

When sporozoites enter the human host, they disappear from the bloodstream within 30 min and enter the parenchymal cells of the liver where, during the next 10–14 days, they undergo a *pre-erythrocytic* stage of development and multiplication. The parasitised liver cells then rupture, and a host of fresh *merozoites* are released. These bind to and enter erythrocytes and develop into motile intracellular parasites termed *trophozoites*. During the *erythrocytic stage*, the parasite remodels the host cell, inserting parasite proteins and phospholipids into the red cell membrane. The host's haemoglobin is transported to the parasite's food vacuole, where it is digested, providing a source of amino acids. Free haem, which would be toxic to the plasmodium, is rendered harmless by polymerisation to *haemozoin*. Some antimalarial drugs act by inhibiting the haem polymerase enzyme responsible for this step.

Following mitotic replication, the parasite in the red cell is termed a *schizont*, and its rapid growth and division, *schizogony*. Another phase of multiplication results in the production of further *merozoites*, which are released when the red cell ruptures. These merozoites then bind to and enter fresh red cells, and the erythrocytic cycle begins again. In certain forms of malaria, some sporozoites entering the liver cells form *hypnozoites*, or 'sleeping' forms of the parasite, which can be reactivated months or years later to continue an *exoerythrocytic* cycle of multiplication.

Malaria parasites can multiply in the body at a phenomenal rate – a single parasite of *P. vivax* can give rise to 250 million merozoites in 14 days. To appreciate the therapeutic challenges this entails, note that destruction of 94% of the parasites every 48 h will serve only to maintain equilibrium and will not further reduce their number or their propensity for proliferation. Some merozoites, on entering red cells, differentiate into male and female gametocytes. These can complete their life cycle only when taken up again by the mosquito, when it sucks the blood from the infected host.

The periodic episodes of fever that characterise malaria result from the synchronised rupture of red cells with release of merozoites and cell debris. The rise in temperature is associated with a rise in the concentration of TNF-α in the plasma. Relapses of malaria are likely to occur with those forms of malaria that have an exoerythrocytic cycle, because the dormant hypnozoite form in the liver may emerge after an interval of weeks or months to start the infection again.

The characteristic clinical presentations of the different forms of human malaria are as follows:

- *P. falciparum*, which has an erythrocytic cycle of 48 h in humans, produces *malignant tertian malaria* – 'tertian' because the fever was believed to recur every third day (actually it varies) and 'malignant' because it is the most severe form of malaria and is responsible for most malaria deaths. The plasmodium induces adhesion molecules on the infected cells, which then stick to uninfected red cells forming clusters (rosettes). These adhere to, and obstruct the vessels of the microcirculation, interfering with tissue

blood flow and causing organ dysfunction including renal failure and encephalopathy (cerebral malaria). *P. falciparum* does not have an exoerythrocytic stage, so if the erythrocytic stage is eradicated, relapses do not occur.

- *P. vivax* produces *benign tertian malaria*, less severe than falciparum malaria and rarely fatal. However, exoerythrocytic forms may persist for years and cause relapses.
- *P. ovale*, which has a 48-h cycle and an exoerythrocytic stage, is the cause of a rare form of malaria.
- *P. malariae*, which is said to cause *quartan malaria*, has a 72-h cycle. It has no exoerythrocytic cycle.

Individuals living in areas where malaria is endemic may acquire a natural immunity, but this may be lost if the individual is absent from the area for more than 6 months. *Sickle cell disease*, which is also common in Africa, may have persisted in the population because those carrying the single copy of the mutated haemoglobin gene (and who do not therefore develop the disease) have about 30% less incidence of malaria. The best way to prevent malaria is to prevent mosquito bites by suitable clothing, insect repellents and bed nets. Bed nets sprayed with insecticides such as permethrin are very effective and form the cornerstone of many public health campaigns.

Sometimes mistaken for malaria is *babesiosis* which is caused by tickborne parasites of the *Babesia* sp. (five examples known). The main vector seems to be the arthropod, *Ixodes ricinus* . The disease is endemic in many countries including Europe but cases are rare and may be asymptomatic. Like malaria, the life cycle of the parasite

also includes an erythrocytic stage. Treatment, if required, is usually with **clindamycin**, **quinine** or **atovaquone**.

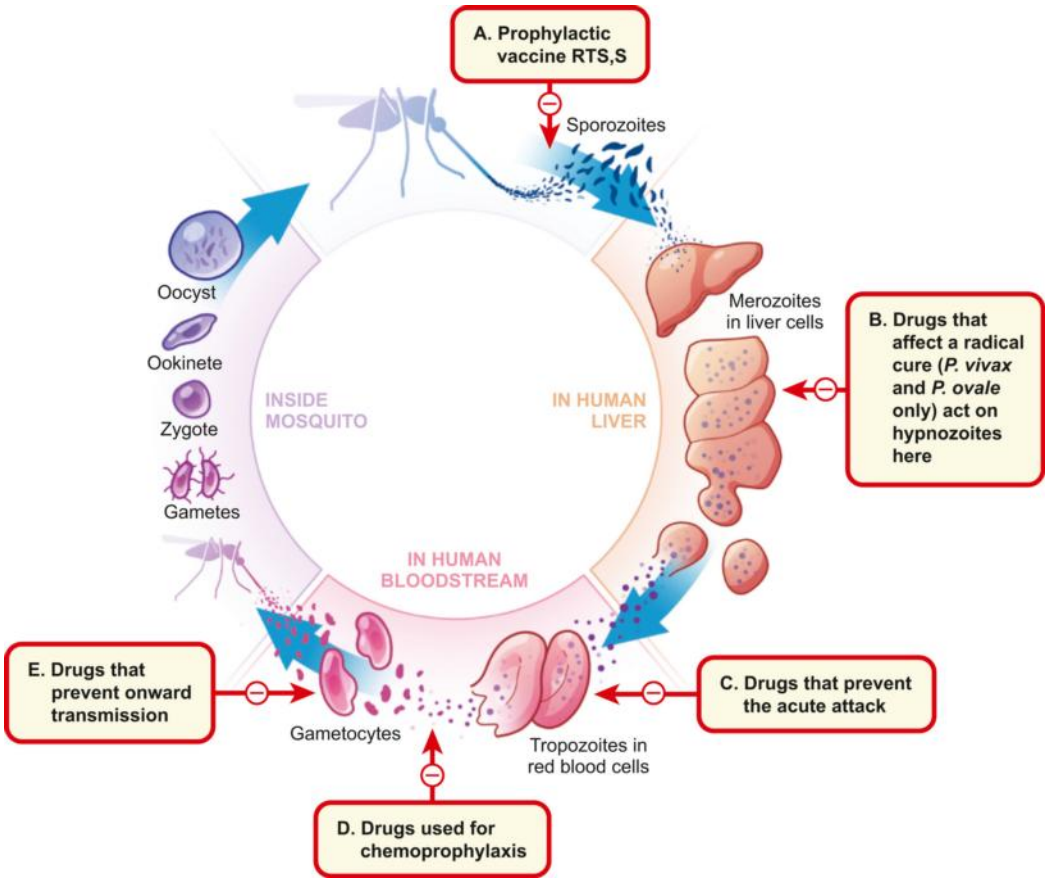

FIG. 55.1 The life cycle of the malarial parasite and the site of action of some current antimalarial drugs.Infection is initiated by the bite of a parasite-bearing female *Anopheles* mosquito, which introduces the asexual sporozoite form of the parasite into the victim's blood. These are susceptible to immune-mediated clearance by the RTS,S vaccine *(yellow box A)*. The sporozoites then enter a *pre-* or *exoerythrocytic cycle* in the liver infecting the liver cells entering the merozoite stage. Here, the merozoites multiply, eventually rupturing the liver cells and releasing vesicles containing large

numbers of the parasite. Some may re-enter other liver cells to become hypnozoites, dormant forms of the parasite. In the case of *Plasmodium vivax* and *Plasmodium ovale* these may reactivate years later causing relapses in the disease. Drugs that affect a radical cure act here *(yellow box B)*. Once released into the blood the merozoites begin the erythrocytic phase of their life cycle, entering red blood cells, dividing and multiplying (schizogony). Drugs which prevent acute attacks of malaria can act at this point *(yellow box C)*. Eventually the infected erythrocytes rupture, releasing large numbers of motile trophozoites into the blood; it is at this point that the characteristic clinical symptoms of the disease appear. Drugs which block the link between the exoerythrocytic stage and the erythrocytic stage that are used for chemoprophylaxis act here *(yellow box D)*. Some merozoites develop into male and female gametocytes in red cells. If consumed by another mosquito, these gametocytes can mature in the insect's gut to form oocysts. These pass into the mosquito salivary glands where they give rise to further sporozoites which may enter the next victim to begin the cycle again. Drugs which block onward transmission of the infection act at this step *(yellow box E)*. Adapted and modified

Antimalarial Drugs

In general, antimalarial drugs are classified in terms of their action against the different stages of the life cycle of the parasite (see **Fig. 55.1**). **Fig. 55.2** shows chemical structures of some significant agents and **Fig. 55.3** summarises what is known about their molecular targets. Most current drugs are only effective against the erythrocytic phase of the parasitic life cycle (**primaquine** is an exception). Some are used prophylactically to prevent malaria (**Table 55.2**), while others are used to treat acute attacks.

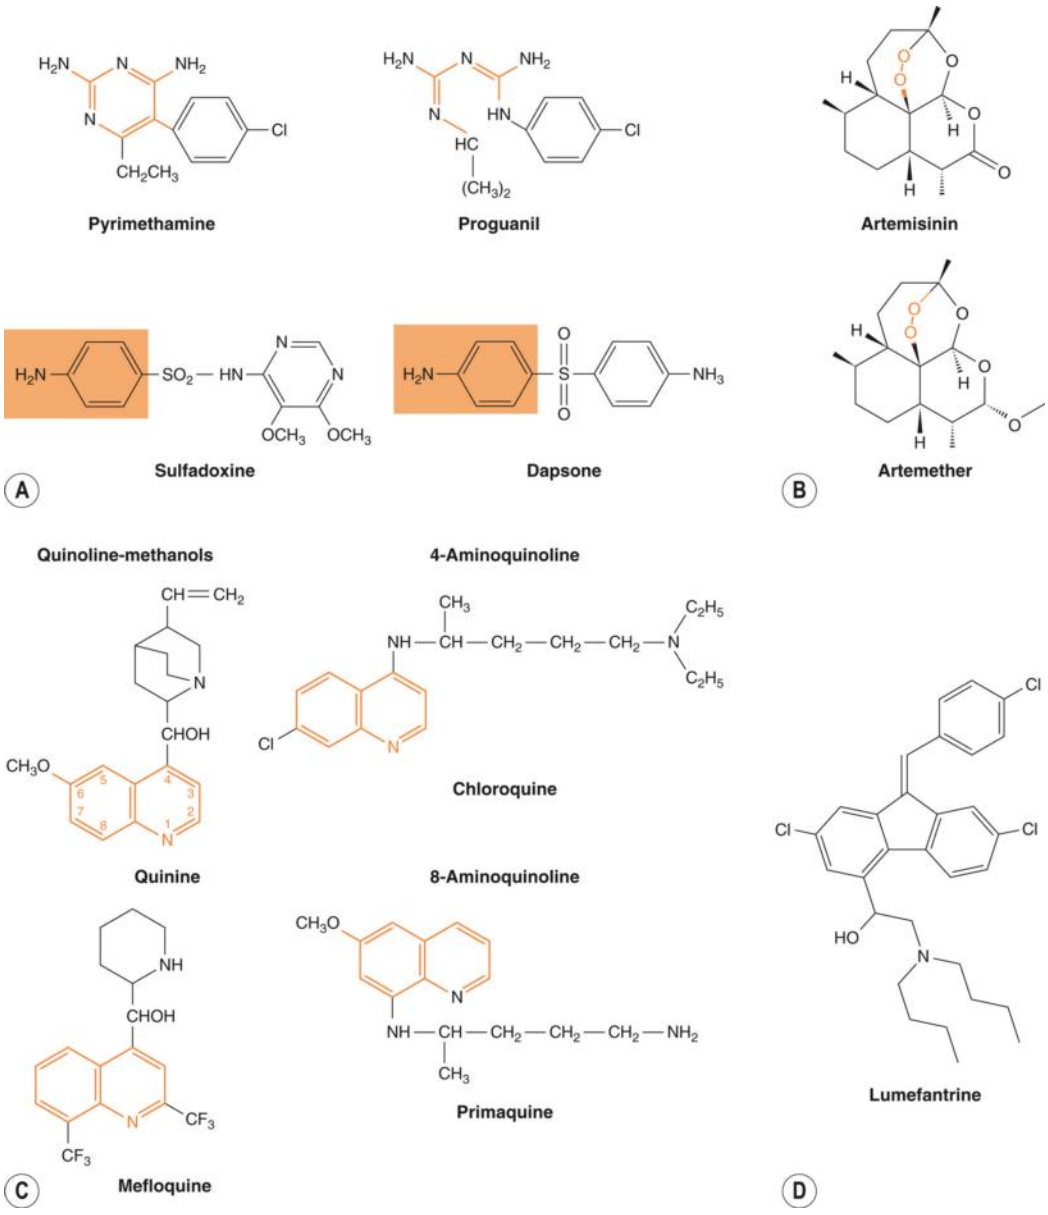

FIG. 55.2 Structures of some significant antimalarial drugs.(A) Drugs that act on the folic acid pathway of the plasmodia. Folate antagonists (**pyrimethamine**, **proguanil**) inhibit dihydrofolate reductase; the relationship between these drugs and the pteridine moiety is shown in *orange*. Sulfones (e.g. **dapsone**) and sulfonamides (e.g. **sulfadoxine**) compete with

p-aminobenzoic acid for dihydropteroate synthetase (relationship shown in *orange box*; see also Chs **51** and **52**). (B) **Artemisinin** and a derivative artemether. Note the endoperoxide bridge structure *(in orange)* that is crucial to their action. (C) Some quinolone antimalarials. The quinoline moiety is shown in *orange*. (D) The aryl amino alcohol **lumefantrine**.

The use of antimalarials has changed considerably during the last half-century, mainly because resistance developed to **chloroquine** and other successful early drug combinations (see **Butler et al., 2010**). Where this has occurred, monotherapy has largely been abandoned in favour of **artemisinin**-based combination therapy (ACT) regimes. The WHO 'malaria' page (see Further Reading list) provides links to their latest recommendations covering all areas in the world and the 'Antimalarial drugs' box and **Table 55.2** provide a brief summary of currently recommended treatment regimens. Only antimalarial drugs in common use are described in this chapter.

Antimalarial therapy and the parasite life cycle

Drugs used in the treatment of malaria are directed at several sites of action and no single agent is able to target all phases of the parasite life cycle.

The main agents used are:

- Drugs which treat the acute attack of malaria by acting on the parasites in the blood; these can cure infections with parasites (e.g. *P. falciparum*) that have no exoerythrocytic stage.
- Drugs which provide prophylactic protection act on merozoites emerging from liver cells.
- Drugs which effect a 'radical cure' are active against parasites in the liver.
- Some drugs act on gametocytes and prevent transmission by the mosquito.

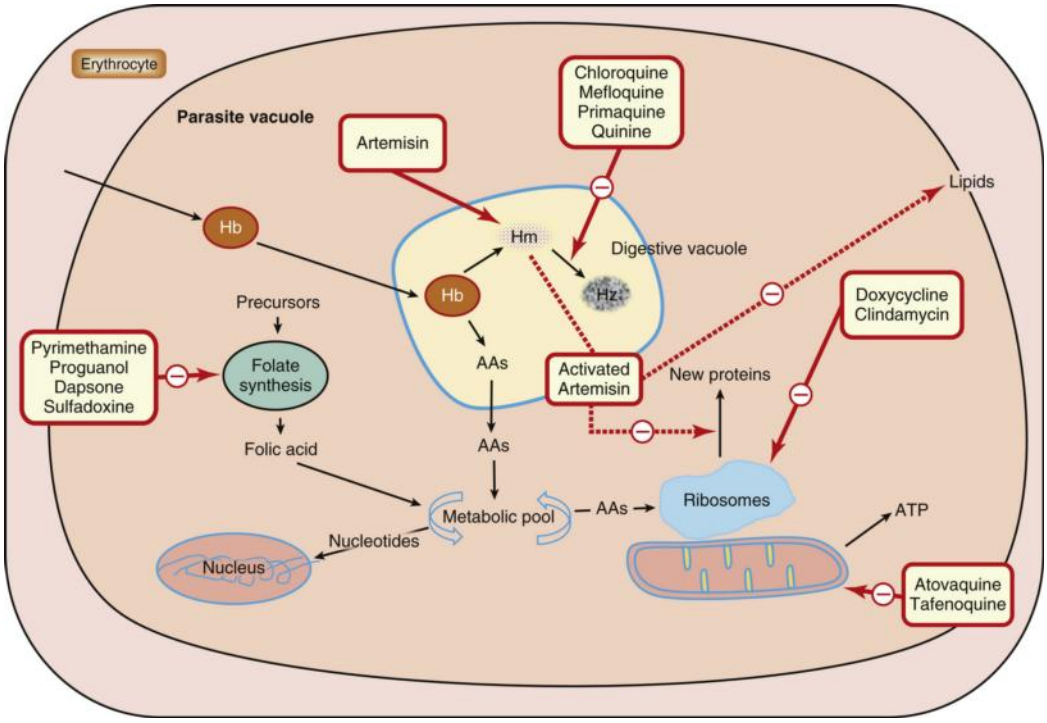

FIG. 55.3 Schematic diagram showing the sites of action of antimalarial drug targets in plasmodia.During the *erythrocytic stage* of infection the parasite lives within erythrocytes in a *parasitophorus vacuole* and feeds on haemoglobin (Hb) which is imported into the *digestive vacuole* where it is metabolised to amino acids (AAs) for use by the parasite. The haem (Hm) residue remaining is toxic to the parasite, so this is metabolised to haemozoin (Hz). Some quinolone antimalarials (e.g. **chloroquine**) prevent the detoxification of haem, thus poisoning the parasite. Other drugs (e.g. **pyrimethamine**) prevent the synthesis of folic acid, which is essential for nucleotide synthesis, target the synthesis of nascent

proteins by ribosomes (e.g. antibiotics such as **clindamycin**) or inhibit mitochondrial function (e.g. **atovaquone**). **Artemisinin** and its derivatives enter the digestive vacuole where they are 'activated' by haem to form compounds that react with, and thus damage, proteins and lipids. After Blasco, B., Leroy, D., Fidock, D.A., 2017. Antimalarial drug resistance: linking *Plasmodium falciparum* parasite biology to the clinic. Nat. Med. 23, 917–928.

Drugs used to treat acute malaria

Blood schizonticidal agents which act on the erythrocytic forms of the plasmodium (see **Fig. 55.1**, site A) can suppress the acute manifestations of the disease. In the case of *P. falciparum* or *P. malariae*, which have no exoerythrocytic stage, these drugs effect a 'suppressive' or 'clinical' cure; however, in the case of *P. vivax* or *P. ovale*, which have exoerythrocytic forms, the parasite can re-emerge later to cause relapses.

This group of drugs includes:

- **artemisinin** and related compounds derived from the Chinese herb *qinghao*, which are usually used in combination with other drugs;
- the quinoline–methanols (e.g. **quinine** and **mefloquine**) and various 4-aminoquinolines (e.g. **chloroquine**);
- agents that interfere either with the synthesis of folate (e.g. **dapsone**) or with its action (e.g. **pyrimethamine** and

proguanil);

- **atovaquone**, which affects mitochondrial function.

Combinations of these agents are frequently used. Some antibiotics, such as the tetracycline **doxycycline** (see **Ch. 52**), have proved useful when combined with the above agents. They have an antiparasitic effect in their own right, but also control other concomitant infections.

Drugs that effect a radical cure

Tissue schizonticidal agents effect a 'radical' cure by eradicating *P. vivax* and *P. ovale* parasites in the liver (see **Fig. 55.1**, site B). Only the 8-aminoquinolines (e.g. **primaquine** and **tafenoquine**) have this action. These drugs also destroy gametocytes and thus reduce the spread of infection.

Drugs used for chemoprophylaxis

Drugs used for chemoprophylaxis (also known as *causal prophylactic drugs*) block the link between the exoerythrocytic stage and the erythrocytic stage, and thus prevent the development of malarial attacks. True causal prophylaxis – the prevention of infection by the killing of the sporozoites on entry into the host – is not feasible with present drugs, although it may be possible with vaccines (see later). Clinical attacks can be prevented by chemoprophylactic drugs that kill the parasites when they emerge from the liver after the pre-erythrocytic stage (see **Fig. 55.1**, site C). The drugs used for this purpose are mainly **artemisinin** derivatives, **chloroquine**, **piperaquine**, **lumefantrine**, **mefloquine**, **proguanil**, **pyrimethamine**, **dapsone** and

doxycycline. They are often used in combinations with other drugs.

Table 55.2

[a] This information is based on current UK recommendations including the *British National Formulary* 2022. It must be appreciated that this is only a summary, not a definitive guide to prescription, as the recommended drug combinations vary depending on the patient, the area visited, the overall risk of infection, the presence of resistant forms of the disease and specialised help should be sought. Also, these regimes must be used with other preventive measures.

[b] **Malarone** is a proprietary fixed-dose combination of **atovaquone** and **proguanil hydrochloride**.

[c] **Riamet** is a proprietary fixed-dose combination of **artemether** and **lumefantrine**

Chemoprophylactic agents are given to individuals who intend travelling to an area where malaria is endemic. Administration should start at least 1 week before entering the area and should be continued throughout the stay and for at least a month afterwards. No chemoprophylactic regimen is 100% effective, and unwanted effects may occur. A further problem is the complexity of some regimens, which require different drugs to be taken at different times, and the fact that different agents may be required for different travel destinations. For a brief summary of currently commonly recommended regimens of chemoprophylaxis, see **Table 55.2**.

Drugs used to prevent transmission

Some drugs (e.g. **primaquine**, **proguanil** and **pyrimethamine**) can also destroy gametocytes (see **Fig. 55.1**, site D), preventing transmission by the mosquito and thus diminishing the human reservoir of the disease, although they are rarely used for this action alone.

Drug resistance

Parasite resistance is a serious and ongoing problem with almost all antimalarial drugs, with the possible exception of **lumefantrine**. In many cases, resistant strains of the parasite appear within a decade, or even less, of the introduction of a novel drug. Most of the resistance is due to the appearance of spontaneously arising point mutations in (for example) target proteins such as dihydrofolate reductase (which confers resistance to antifolate drugs such as **proguanil**) or in the mitochondrial cytochrome B subunit (which confers resistance to **atovaquone**). Mutations in parasite transporters that facilitate entry, or control the exit of, quinolone drugs into the digestive vacuoles can also confer resistance and mutations in other enzymes are also thought to be important (see **Blasco et al., 2017**).

A rather alarming development is the increase in *multidrug resistance* in certain parts of the world. This may be linked to poor compliance, poor therapy or local variations in host immune responses to infection

Chloroquine

The 4-aminoquinoline **chloroquine** dates from the 1940s but is still widely used as a blood schizonticidal agent (see **Fig. 55.1**, site A), effective against the erythrocytic forms of all four plasmodial species (in areas where resistance is not an issue), but it does not have any effect on sporozoites, hypnozoites or gametocytes. It is uncharged at neutral pH and can therefore diffuse freely into the parasite lysosome. At the acid pH of the lysosome, it is converted to a protonated, membrane-impermeable form and is 'trapped' inside the parasite. Its chief antimalarial action derives from an inhibition of *haem polymerase*, the enzyme that polymerises toxic free haem to harmless *haemozoin*. This poisons the parasite and prevents it from utilising the amino acids from haemoglobin proteolysis. **Chloroquine** has also been used as a disease-modifying antirheumatoid drug (see **Ch. 25**) and also has some **quinidine**-like actions on the heart (see **Ch. 20**).

Resistance

P. falciparum is now resistant to **chloroquine** in most parts of the world. Resistance appears to result from enhanced efflux of the drug from parasitic vesicles as a result of mutations in plasmodia transporter genes (**Baird, 2005**). Resistance of *P. vivax* to **chloroquine** is also a growing problem.

Administration and pharmacokinetic aspects

Chloroquine is generally administered orally, but severe falciparum malaria may be treated by frequent intramuscular or subcutaneous injection of small doses, or by slow continuous intravenous infusion. Following oral dosing, it is completely absorbed, extensively distributed throughout the tissues and

concentrated in parasitised red cells. Release from tissues and infected erythrocytes is slow. The drug is metabolised in the liver and excreted in the urine, 70% as unchanged drug and 30% as metabolites. Elimination is slow, the major phase having a half-life of 50 h, and a residue persists for weeks or months.

Unwanted effects

Chloroquine has few adverse effects when given for chemoprophylaxis. However, unwanted effects, including nausea and vomiting, dizziness and blurring of vision, headache and urticarial symptoms, can occur when larger doses are administered to treat acute attacks of malaria. Large doses have also sometimes resulted in retinopathies and hearing loss. Bolus intravenous injections of **chloroquine** may cause hypotension and, if high doses are used, fatal dysrhythmias. **Chloroquine** is considered to be safe for use by pregnant women.

Amodiaquine has very similar action to chloroquine. It was withdrawn several years ago because of the risk of agranulocytosis but has now been reintroduced in several areas of the world where **chloroquine** resistance is endemic. **Piperaquine** is also structurally related to **chloroquine** and shares a similar pharmacology. It is often used in combination with **artenimol**.

Quinine

Quinine, derived from cinchona bark, has been used for the treatment of 'fevers' since the 16th century, when Jesuit missionaries brought the bark, and the knowledge of its action, to Europe from Peru. It is a blood schizonticidal drug effective against the erythrocytic forms of all four species of *Plasmodium* (see **Fig.**

55.1, site A), but it has no effect on exoerythrocytic forms or on the gametocytes of *P. falciparum*. Its mechanism of action is the same as that of **chloroquine**, but **quinine** is not so extensively concentrated in the plasmodium as **chloroquine**, so other mechanisms could also be involved. With the emergence and spread of **chloroquine** resistance, **quinine** is now the main chemotherapeutic agent for *P. falciparum* in certain parts of the world. Pharmacological actions on host tissue include a depressant action on the heart, a mild oxytocic effect on the uterus in pregnancy, a marginal blocking action on the neuromuscular junction and a weak antipyretic effect.

Resistance

Some degree of resistance to **quinine** has developed because of increased expression of plasmodial drug efflux transporters.

Pharmacokinetic aspects

Quinine is well absorbed and is usually administered orally as a 7-day course, but it can also be given by slow intravenous infusion for severe *P. falciparum* infections and in patients who are vomiting. A loading dose may be required, but bolus intravenous administration is contraindicated because of the risk of cardiac dysrhythmias. The half-life of the drug is 10 h; it is metabolised in the liver and the metabolites are excreted in the urine within about 24 h.

Unwanted effects

Quinine has a bitter taste, and oral compliance is often poor. [3] It is irritant to the gastric mucosa and can cause nausea and vomiting. 'Cinchonism' – characterised by nausea, dizziness, tinnitus,

headache and blurring of vision – is likely to occur if the plasma concentration exceeds 30–60 μmol/L. Excessive plasma levels may also cause hypotension, cardiac dysrhythmias and severe central nervous system (CNS) disturbances such as delirium and coma.

Other, infrequent, unwanted reactions that have been reported are bone marrow depression (mainly thrombocytopenia) and hypersensitivity reactions. **Quinine** can stimulate insulin release. Patients with marked falciparum parasitaemia may develop hypoglycaemia for this reason and also because of glucose consumption by the parasite. This can make a differential diagnosis between a coma caused by cerebral malaria and low blood sugar difficult. A rare result of treating malaria with **quinine**, or of erratic and inappropriate use of the drug, is *Blackwater fever*, a severe and often fatal condition in which acute haemolytic anaemia is associated with renal failure.

Mefloquine

Mefloquine (see **Fig. 55.2**) is a blood schizonticidal compound active against *P. falciparum* and *P. vivax* (see **Fig. 55.1**, site A); however, it has no effect on hepatic forms of the parasites, so treatment of *P. vivax* infections is usually followed by a course of **primaquine** to eradicate the hypnozoites. **Mefloquine** acts in the same way as quinine and is frequently combined with **pyrimethamine**.

Resistance

P. falciparum is resistant to **mefloquine** in some areas – particularly in South-East Asia – and is thought to be caused, as

with **quinine**, by increased expression in the parasite of drug efflux transporters.

Pharmacokinetic aspects and unwanted effects

Mefloquine is given orally and is rapidly absorbed. It has a slow onset of action and a very long plasma half-life (up to 30 days), which may be the result of enterohepatic cycling or tissue storage.

When **mefloquine** is used for treatment of the acute attack, about 50% of subjects complain of GI disturbances. Transient CNS side effects – giddiness, confusion, dysphoria and insomnia – can occur, and there have been a few reports of aberrant atrioventricular conduction and, rarely, serious skin diseases or severe neuropsychiatric reactions. It is contraindicated in pregnant women or in those liable to become pregnant within 3 months of stopping the drug, because of its long half-life and uncertainty about its teratogenic potential. When used for chemoprophylaxis, the unwanted actions are usually milder, but the drug should not be used in this way unless there is a high risk of acquiring **chloroquine**-resistant malaria.

Lumefantrine

This aryl amino alcohol drug is related to an older compound, **halofantrine**, which is now seldom used. **Lumefantrine** is never used alone but is combined with **artemether**. Its mode of action is probably to prevent parasite detoxification of haem. The pharmacokinetics of the combination are complex (see **Ezzet et al., 1998**). Unwanted effects of the combination may include GI and CNS symptoms.

Drugs Affecting Folate Metabolism

Whilst known as antibacterial drugs, agents which affect folate metabolism also have antiprotozoal activity. **Pyrimethamine** and **proguanil** inhibit dihydrofolate reductase, which prevents the utilisation of folate in DNA synthesis. Used together, they block the folate pathway at different points, thus acting synergistically.

Pyrimethamine is similar in structure to the antibacterial drug **trimethoprim** (see **Ch. 52**). **Proguanil** has a slightly different structure but its (active) metabolite can assume a similar configuration. Both drugs have a greater affinity for the plasmodium enzyme than for the human enzyme. They have a slow action against the erythrocytic forms of the parasite (see **Fig. 55.1**, site A), and **proguanil** is believed to have an additional effect on the initial hepatic stage (see **Fig. 55.1**) but not on the hypnozoites of *P. vivax* (see **Fig. 55.1**, site B). **Pyrimethamine** is used only in combination with either a sulfone or a sulfonamide.

Sulfonamides and sulfones inhibit the synthesis of folate in plasmodia by competing with p-aminobenzoic acid (see **Ch. 52**). The main sulfonamide used in malaria treatment is **sulfadoxine**, and the only sulfone used is **dapsone**. Details of these drugs are given in **Chapter 52**. The sulfonamides and sulfones are active against the erythrocytic forms of *P. falciparum* but are less active against those of *P. vivax*; they have no activity against the sporozoite or hypnozoite forms of the plasmodia. **Pyrimethamine–sulfadoxine** has been extensively used for chloroquine-resistant malaria, but unfortunately resistance to this combination has developed in many areas.

Resistance

Point mutations in the enzymes of the folate synthesis pathway can confer resistance to these drugs.

Pharmacokinetic aspects

Both **pyrimethamine** and **proguanil** are given orally and are well, although slowly, absorbed. **Pyrimethamine** has a plasma half-life of 4 days, and effective 'suppressive' plasma concentrations may last for 14 days; it is taken once a week. The half-life of **proguanil** is 16 h. It is a prodrug and is metabolised in the liver to its active form, *cycloguanil*, which is excreted mainly in the urine. It must be taken daily.

Unwanted effects

These drugs have few untoward effects in therapeutic doses. Larger doses of the **pyrimethamine–dapsone** combination can however cause serious reactions such as haemolytic anaemia, agranulocytosis and lung inflammation. The **pyrimethamine–sulfadoxine** combination can cause serious skin reactions, blood dyscrasias and allergic alveolitis and it is no longer recommended for chemoprophylaxis. In high doses, **pyrimethamine** may inhibit mammalian dihydrofolate reductase and cause a *megaloblastic anaemia* (see **Ch. 24**) and folic acid supplements should be given if this drug is used during pregnancy. Resistance to antifolate drugs may arise from single-point mutations in the genes encoding parasite dihydrofolate reductase.

Primaquine

Primaquine is an 8-aminoquinoline drug, which is (almost uniquely among clinically available antimalarial drugs) active against liver hypnozoites (see **Fig. 55.2**). **Etaquine** and **tafenoquine** are more active and slowly metabolised analogues of **primaquine**. These drugs can effect a radical cure of *P. vivax* and *P. ovale* malaria in which the parasites have a dormant stage in the liver. **Primaquine** does not affect sporozoites and has little if any action against the erythrocytic stage of the parasite. However, it has a gametocidal action and is the most effective antimalarial drug for preventing transmission of all four species of plasmodia. It is almost invariably used in combination with another drug, usually **chloroquine**. The pharmacology of **primaquine** and similar drugs has been reviewed by **Shanks et al. (2001)**.

Resistance

Resistance to primaquine is (happily) scarce, although evidence of a decreased sensitivity of some *P. vivax* strains has been reported.

Pharmacokinetic aspects

Primaquine is given orally and is well absorbed. Its metabolism is rapid, and very little drug is present in the body after 10–12 h. The half-life is 3–6 h. **Tafenoquine** is metabolised much more slowly and therefore has the advantage that it can be given on a weekly basis.

Unwanted effects

Primaquine has few unwanted effects in most patients when used in normal therapeutic dosage. Dose-related GI symptoms may occur

however, and large doses may cause methaemoglobinaemia with cyanosis.

Primaquine can also cause haemolysis in individuals with the X chromosome-linked genetic metabolic condition, *glucose 6-phosphate dehydrogenase deficiency*, in red cells (see **Ch. 12**). When this deficiency is present, the red cells are not able to regenerate nicotinamide adenine dinucleotide phosphate (NADPH), which is depleted by the oxidant metabolic derivatives of **primaquine**. As a consequence, the metabolic functions of the red cells are impaired, and haemolysis occurs. The deficiency of the enzyme occurs in up to 15% of black males and is also fairly common in some other ethnic groups. Glucose 6-phosphate dehydrogenase activity should be estimated before giving **primaquine**.

Artemisinin and Related Compounds

The importance of this group cannot be overstated as they are often the only effective treatment for drug-resistant *P. falciparum*. These sesquiterpene lactones are derived from *sweet wormwood*, *qinghao*, a traditional Chinese remedy for fevers. The scientific name, conferred on the herb by Linnaeus, is *Artemisia*.[4] **Artemisinin**, a poorly soluble chemical extract from *Artemisia*, is a fast-acting blood schizonticide effective in treating acute attacks of malaria (including **chloroquine**-resistant and cerebral malaria). In randomised trials, artemisinins have cured attacks of malaria, including cerebral malaria, more rapidly and with fewer unwanted effects than any other antimalarial agents. **Artemisinin** and derivatives are effective against multidrug-resistant *P. falciparum* in

sub-Saharan Africa and, combined with **mefloquine**, against multidrug-resistant *P. falciparum* in South-East Asia.

Pharmacokinetic aspects

Derivatives of artemisinin, which include **artenimol (**dihydroartemisinin, the active metabolite of **artemisinin**), **artesunate** (a water-soluble derivative available in some countries) and **artemether,** are more potent and better absorbed than the parent compound. All artemisinins are concentrated in parasitised red cells. Upon entering the digestive vacuoles, haem iron activates their unusual 'endoperoxide bridge' giving rise to highly reactive oxygen-containing compounds. These cause irreversible damage to parasite proteins, lipid membranes and other targets. These drugs are without effect on liver hypnozoites.

Artemisinin can be given orally, intramuscularly or by suppository; **artemether** orally or intramuscularly; and artesunate intramuscularly or intravenously. They are rapidly absorbed and widely distributed and are converted in the liver to the active metabolite *dihydroartemisinin*. The half-life of **artemisinin** is about 4 h, of **artesunate** is 45 min and of **artemether** is 4–11 h.

Unwanted effects

are few. Transient heart block, decrease in blood neutrophil count and brief episodes of fever have been reported. In animal studies, **artemisinin** causes an unusual injury to some brain stem nuclei, particularly those involved in auditory function; however, there have been no reported incidences of neurotoxicity in humans.

In rodent studies, **artemisinin** potentiated the effects of **mefloquine**, **primaquine** and **tetracycline**, was additive with

chloroquine and antagonised the sulfonamides and the folate antagonists. For this reason, **artemisinin** derivatives are frequently used in combination with other antimalarial drugs as part of ACT regimes; for example, **artemether** is often given in combination with **lumefantrine**.

Resistance

Initially resistance was not a major problem but, alarmingly, reports that the parasite in some areas of the world (e.g. South-East Asia) was becoming less sensitive to these drugs – either alone or in ACT combinations – began to appear about a decade ago (**Blasco et al., 2017**). The situation is being monitored very carefully.

Atovaquone

Atovaquone is a hydroxynaphthoquinone drug used prophylactically to prevent malaria, and to treat cases resistant to other drugs. It acts primarily to inhibit the parasite's mitochondrial electron transport chain, possibly by mimicking the natural substrate ubiquinone. **Atovaquone** is usually used in combination with the antifolate drug **proguanil**, because they act synergistically. The mechanism underlying this synergism is not known, but it is specific for this particular pair of drugs, because other antifolate drugs or electron transport inhibitors have no such synergistic effect. When combined with **proguanil**, **atovaquone** is highly effective and well tolerated. Few unwanted effects of such combination treatment have been reported, but abdominal pain, nausea and vomiting can occur. Pregnant or breastfeeding women should not take **atovaquone**.

Resistance

Resistance to **atovaquone** alone is rapid and results from a single-point mutation in the gene for cytochrome B. Resistance to combined treatment with **atovaquone** and **proguanil** is less common.

Potential New Antimalarial Drugs

Malaria has been dubbed a 're-emerging disease', largely because of the increasing appearance of drug-resistant strains of the parasite. No new *synthetic* drug has been discovered for over 40 years and so progress has become a matter of some urgency.

In this context, **Ceravolo et al. (2021)** have reviewed the quest for naturally occurring substances with antimalarial actions (recall that the first antimalarial was **quinine**) and reported some success, while **Nweze et al. (2021)** have focused on products derived from marine organisms with antiprotozoal properties. **Miller et al. (2019)** discuss progress in the quest for novel drugs that inhibit of parasite digestive vacuole proteases. Coupled with a better understanding of the pharmacokinetic aspects of current drugs (**Elewa and Wilby, 2017**), these advances may enable novel, more selective treatment regimes in the future.

A significant development in existing antimalarial drugs has arisen through the application of synthetic biology to solve the problem of **artemisinin** production. **Artemisinin** is notoriously difficult to synthesise by conventional chemical techniques and awkward to harvest in large amounts. Using genetically modified yeast transfected with genes from *Artemisia* it has been possible to produce substantial amounts of the precursor *artemisinic acid*,

which can be easily converted into **artemisinin** (**Paddon et al., 2013**), thus relieving the desperate shortage of the drug.

Historically, the creation of an antimalarial vaccine has proved technically problematic because of the different forms the parasite assumes during its life cycle, but after decades of frustration, 2021 finally saw a major breakthrough (see **Laurens, 2020**). The launch of the *RTS,S* vaccine (**Mosquirix**), the first antimalarial vaccine (and the first antiprotozoal vaccine ever) to be approved for clinical use, was the result of over 30 years of development funded by a private–public initiative which included substantial funding arising from the philanthropic Bill and Melinda Gates Foundation.

The vaccine was launched in 2020 and endorsed by the WHO as a treatment for vulnerable children (who constitute the majority of the victims) in Sub-Saharan Africa, a continent where the deadliest form of the parasite, *P. falciparum*, predominates. Its target is the *circumsporozoite antigen* which, as the name implies, is present in the earliest forms of the parasite introduced into the bloodstream by the infecting mosquito. It therefore prevents the spread of the parasite into the liver and therefore subsequent stages of its development. Studies have shown that the vaccine provides a 30% protection against *P. falciparum* infection. This may not sound much but is highly significant especially when considered together with other concomitant preventive measures such as insecticide impregnated mosquito nets, treatment of stagnant water, etc.

But perhaps the main lesson from the development of this vaccine is that it is technically feasible. Indeed, several other vaccines are in preparation (**Almeida et al., 2021**; **Bonam et al., 2021**) but whilst vaccine prophylaxis is indeed a breakthrough in

public health treatment, it still important to remember that it cannot treat the acute disease and that antimalarial drugs will still be important even following the widespread adoption of the vaccine.

Antimalarial drugs

- **Chloroquine** is a blood schizonticide that is concentrated in the parasite and inhibits the haem polymerase. Resistance is now common. **Piperaquine** is a long-lasting derivative of **chloroquine.**
- **Quinine** is a blood schizonticide. It is usually given in combination therapy with:
  - **pyrimethamine**, a folate antagonist that acts as a slow blood schizonticide, and either
  - **dapsone**, a sulfone, or
  - **sulfadoxine**, a long-acting sulfonamide (orally active; half-life 7–9 days).
- **Proguanil**, a folate antagonist, is a slow blood schizonticide with some action on the primary liver forms of *P. vivax*.
- **Mefloquine** is a blood schizonticidal agent active against *P. falciparum* and *P. vivax* and which acts by inhibiting the parasite haem polymerase.
- **Primaquine** is effective against the liver hypnozoites and also gametocytes.
- **Artemisinin** derivatives are now widely used particularly in combination with other drugs such as **lumefantrine** and

artenimol. They are fast-acting blood schizonticidal agents that are effective against both *P. falciparum* and *P. vivax*.

- **Artenimol** (dihydroxyartemisinin) is the active metabolite of **artemisinin.**
- **Artesunate** is water-soluble and can be given orally or by intravenous, intramuscular or rectal administration. Resistance is so far uncommon.
- **Atovaquone** (in combination with **proguanil**) is used for prevention, and for the treatment of, acute uncomplicated *P. falciparum* malaria. Resistance to **atovaquone** develops rapidly if it is given alone.

Amoebiasis and Amoebicidal Drugs

Amoebiasis is caused by infection with one or more strains of *Entamoeba* organisms. Infection may be asymptomatic or provoke a range of GI symptoms, some of which may be serious. The main organism of concern is *Entamoeba histolytica*, the causative agent of amoebiasic dysentery, which can produce a severe colitis (dysentery) and, sometimes, liver abscesses.

The infection is encountered around the world, but more often in warmer climates, and is associated with poor sanitation. Approximately 50 million people are currently (2020) thought to harbour the disease, with some 100,000 deaths occurring each year as a result. It is considered to be the second-leading cause of death from parasitic diseases worldwide.

The organism has a simple life cycle, and humans are the chief hosts. Infection, generally spread by poor hygiene, follows the

ingestion of the mature cysts in water or food that is contaminated with human faeces. The infectious cysts pass into the colon, where they develop into *trophozoites*. These motile organisms adhere to colonic epithelial cells, utilising a galactose-containing lectin on the host cell membrane. Here, the trophozoites feed, multiply, encyst and eventually pass out in the faeces, thus completing their life cycle. Some individuals are symptomless 'carriers' and harbour the parasite without developing overt disease, but cysts are present in their faeces, and they can infect other individuals. The cysts can survive outside the body for at least a week in a moist and cool environment.

Drugs used in amoebiasis

Amoebiasis is caused by infection with *E. histolytica*, which causes dysentery and liver abscesses. The organism may be present in motile invasive form or as a cyst. The main drugs are:

- **Metronidazole** given orally (half-life 7 h). Active against the invasive form in gut and liver but not the cysts. Unwanted effects (rare): gastrointestinal (GI) disturbances and CNS symptoms. **Tinidazole** is similar. Follow-on treatment directed at the GI lumen is needed to ensure eradication.
- **Diloxanide** is a luminal agent given orally with no serious unwanted effects. It is active, while unabsorbed, against the non-invasive form in the GI tract.

The trophozoite lyses the colonic mucosal cells (hence 'histolytica') using proteases, *amoebapores* (peptides that form pores in cell membranes) or by inducing host cell apoptosis. The organism then invades the submucosa, where it secretes factors to modify the host response which would otherwise prove lethal to the parasite. It is this process that produces the characteristic bloody diarrhoea and abdominal pain, although a chronic intestinal infection may be present in the absence of dysentery. In some patients, an *amoebic granuloma (amoeboma)* may be present in the intestinal wall. The trophozoites may also migrate through the damaged intestinal tissue into the portal blood and hence the liver, giving rise to the most common extra-intestinal symptom of the disease – amoebic liver abscesses.

The use of drugs to treat this condition depends largely on the site and type of infection. The drugs of choice, which are often used in combination for the various forms of amoebiasis, are:

- **metronidazole** (or **tinidazole**) followed by **diloxanide** for acute invasive intestinal amoebiasis resulting in acute severe amoebic dysentery;
- **diloxanide** for chronic intestinal amoebiasis;
- **metronidazole** followed by **diloxanide** for hepatic amoebiasis;
- **diloxanide** for the asymptomatic 'carrier' state.

Metronidazole

Metronidazole kills the trophozoites of *E. histolytica* but has no effect on the cysts. It is the drug of choice for invasive amoebiasis of the intestine or the liver, but it is less effective against organisms in

the lumen of the gut. The drug is activated by anaerobic organisms to a compound that damages DNA, leading to parasite apoptosis.

Metronidazole is usually given orally and is rapidly and completely absorbed. Rectal and intravenous preparations are also available. It is distributed rapidly throughout the tissues, reaching high concentrations in the body fluids, including the cerebrospinal fluid. Some is metabolised, but most is excreted in urine.

Unwanted effects

are mild. The drug produces a metallic, bitter taste in the mouth but causes few unwanted effects in therapeutic doses. Minor GI disturbances have been reported, as have CNS symptoms (dizziness, headache, sensory neuropathies). **Metronidazole** causes a **disulfiram**-like reaction to alcohol (see **Ch. 50**), which should be strictly avoided. It should not be used in pregnancy.

Tinidazole is similar to **metronidazole** in its mechanism of action and unwanted effects, but is eliminated more slowly, having a half-life of 12–14 h.

Diloxanide

Diloxanide and, more commonly, an insoluble ester, **diloxanide furoate**, are the drugs of choice for the asymptomatic infected patient and are often given as a follow-up after the disease has been reversed with metronidazole. Both drugs have a direct amoebicidal action, affecting the parasites before encystment. **Diloxanide furoate** is given orally and acts without being absorbed. Unwanted GI or other effects may be seen but it has an excellent safety profile.

Other drugs that are sometimes used include the antibiotic **paromomycin** (see Further Reading list for information). Some

promising new candidate drugs have been identified by **Shrivastav et al. (2020)**.

Trypanosomiasis and Trypanocidal Drugs

Trypanosomes belong to the group of pathogenic flagellate protozoa. Two subtypes of *Trypanosoma brucei* (*rhodesiense* and *gambiense*) cause sleeping sickness in Africa (also known as *HAT* – human African trypanosomiasis). In South America, another species, *Trypanosoma cruzi*, causes *Chagas disease* (also known as American trypanosomiasis).

Almost eliminated by 1960, HAT re-emerged but, because of concerted public health campaigns, the number of cases is now falling again. Thanks to improved awareness, treatment and preventive measures, WHO reported in 2019 less than 1000 cases detected (25,000 in 1995) out of some 60 million people at risk of contracting sleeping sickness. The disease is caused by *T. brucei gambiense* (TbG) and *T. brucei rhodesiense* (TbR) with TbR being the more aggressive form albeit less widespread. Civil unrest, famine, AIDS and pandemic diseases such as COVID-19 encourage the spread of the disease by reducing the chances of distributing medication or because patients are immunocompromised. Related trypanosome infections also pose a major risk to livestock and thus have a secondary impact on human health and well-being. In the case of Chagas disease, some 6–7 million people are believed to harbour the infection according to the latest WHO survey.

The vector of HAT is the tsetse fly. In both types of the disease, there is an initial local lesion at the site of entry, which may (in the case of TbR) develop into a painful *chancre* (ulcer or sore). This is

followed by bouts of parasitaemia and fever as the parasite enters the haemolymphatic system. The parasites, and the toxins they release during the second phase of the disease, cause organ damage. This manifests as ‘sleeping sickness’ when parasites reach the CNS causing somnolence and progressive neurological breakdown. Left untreated, such infections are fatal.

T. cruzi is spread through other blood-sucking insects, including the ‘kissing bugs’. The initial phases of the infection are similar, but the parasites damage the heart, muscles and sometimes liver, spleen, bone and intestine. Many people harbour chronic infections. The cure rate is good if treatment begins immediately after infection but is less successful if delayed. An accessible account of trypanosomiasis is given by **Buscher et al. (2017)**.

The main drugs used for HAT are **suramin**, with **pentamidine** as an alternative, in the haemolymphatic stage of the disease, and the arsenical **melarsoprol** for the late stage with CNS involvement and/or **eflornithine** (see **Burchmore et al., 2002**; **Burri and Brun, 2003**). All have toxic side effects. **Nifurtimox**, **eflornithine** and **benznidazole** are used in Chagas disease: however, there is no totally effective treatment for this form of trypanosomiasis.

Suramin

Suramin was introduced into the therapy of trypanosomiasis in 1920. The drug binds firmly to host plasma proteins, and the complex enters the trypanosome by endocytosis, and is then liberated by lysosomal proteases. It inhibits key parasite enzymes

inducing gradual destruction of organelles, such that the organisms are cleared from the circulation after a short interval.

Administration is by slow intravenous injection. The blood concentration drops rapidly during the first few hours and then more slowly over the succeeding days. A residual concentration remains for 3–4 months. **Suramin** tends to accumulate in mononuclear phagocytes, and in the cells of the proximal tubule in the kidney.

Unwanted effects are common. **Suramin** is relatively toxic, particularly in malnourished patients, the main organ affected being the kidney. Many other slowly developing adverse effects have been reported, including optic atrophy, adrenal insufficiency, skin rashes, haemolytic anaemia and agranulocytosis. A small proportion of individuals have an immediate idiosyncratic reaction to **suramin** injections, which may include nausea, vomiting, shock, seizures and loss of consciousness.

Pentamidine

Pentamidine has a direct trypanocidal action in vitro. It is rapidly taken up into parasites by a high-affinity energy-dependent carrier and is thought to interact with their DNA. The drug is administered intravenously or by deep intramuscular injection, usually daily for 10–15 days. After absorption from the injection site, it binds strongly to tissues (especially in the kidney) and is eliminated slowly, only 50% of a dose being excreted over 5 days. Fairly high concentrations of the drug persist in the kidney, the liver and the spleen for several months, but it does not penetrate the blood–brain barrier. It is also active in *Pneumocystis* pneumonia (see **Ch. 52**).

Its usefulness is limited by its unwanted effects – an immediate decrease in blood pressure, with tachycardia, breathlessness and vomiting, and later serious toxicity, such as kidney damage, hepatic impairment, blood dyscrasias and hypoglycaemia.

Melarsoprol

This is an organic arsenical compound that is used mainly when the CNS is involved. It is given intravenously and enters the CNS in high concentrations, where it kills the parasite. It is a highly toxic drug that produces many unwanted effects including encephalopathy and, sometimes, immediate fatality. As such, it is only administered under strict supervision.

Eflornithine

Eflornithine inhibits the parasite *ornithine decarboxylase* enzyme. It shows good activity against *TbG* and is used as a back-up for **melarsoprol**, although unfortunately it has limited activity against *TbR*. Side effects are common and may be severe but are readily reversed when treatment is discontinued. Combined therapy with **nifurtimox** and **eflornithine** has yielded promising results in patients with late-stage disease.

Until the recent introduction of **fexinidazole** (only approved in 2021 and not covered here), **eflornithine** was the only novel drug adopted in the last 30 years. There is therefore an urgent need for new agents to treat trypanosome infections, partly because of the toxicity of existing drugs and partly because of developing drug resistance. Several reviews detail recent progress in the area both in natural (**Simoben et al., 2018**) and other synthetic therapeutic agents (**Altamura et al., 2022**; **Kourbeli et al., 2021**).

Other Protozoal Infections and Drugs Used to Treat Them

Leishmaniasis

Leishmania organisms are flagellate protozoa, and the infection that they cause is spread by the female sandfly. According to the latest (2020) WHO figures, more than 1 billion people are at risk from the disease and some 30,000 cases of visceral *leishmaniasis* and 1 million cases of the cutaneous disease are currently seen worldwide. Many cases are asymptomatic so the disease is not found in all those infected. With increasing international travel, leishmaniasis is being imported into new areas and opportunistic infections are now being reported (particularly in AIDS patients).

The parasite exists in a flagellated form (*promastigote*) in the gut of the infected insect and a nonflagellated intracellular form (*amastigote*) in the mononuclear phagocytes of the infected mammalian host. Within these cells, the parasites thrive in modified phagolysosomes. By deploying an array of countermeasures (**Singh et al., 2012**), they promote the generation of Th2 cytokines and subvert the macrophage's microbiocidal systems to ensure their survival. The amastigotes multiply, and eventually the infected cell releases a new crop of parasites into the haemolymphatic system, where they can infect further macrophages and possibly other cells.

Different species of *Leishmania* exist in different geographical areas and cause distinctive clinical manifestations (see **Table 55.1**). Typical presentations include:

- a *cutaneous form*, which presents as an unpleasant chancre ('oriental sore', 'Chiclero's ulcer' and other names), which may heal spontaneously, but can leave scarring. This is the most common form and is found in the Americas, some Mediterranean countries and parts of central Asia;
- a *mucocutaneous form* ('espundia' and other names), which presents as large ulcers of the mucous membranes of the mouth, nose and throat; most cases are seen in South America;
- a serious *visceral form* ('kala-azar' and other names), where the parasite spreads through the bloodstream causing hepatomegaly, splenomegaly, anaemia and intermittent fever. This manifestation is encountered mainly in the Indian subcontinent and West Africa.

The main drugs used in visceral leishmaniasis are pentavalent antimony compounds such as **sodium stibogluconate** and **pentamidine** as well as **amphotericin** (see **Ch. 54**), which is sometimes used as a follow-up treatment. **Miltefosine**, an antitumour drug, is also used in some countries (not United Kingdom), as is **meglumine antimoniate**.

Sodium stibogluconate is given intramuscularly or by slow intravenous injection in a 10-day course. It is rapidly eliminated in the urine, 70% being excreted within 6 h. More than one course of treatment may be required. The mechanism of its action is not clear, but the drug may increase production of toxic oxygen free radicals in the parasite.

Unwanted effects

include anorexia, vomiting, bradycardia and hypotension. Coughing and substernal pain may occur during intravenous infusion. Reversible hepatitis and pancreatitis are common.

Miltefosine (hexadecylphosphocholine) is also effective in the treatment of both cutaneous and visceral leishmaniasis. The drug may be given orally and is well tolerated. Side effects are mild and include nausea and vomiting. In vitro, the drug induces DNA fragmentation and apoptosis in the parasites.

Other drugs, such as antibiotics and antifungals, may be given concomitantly with the earlier agents. They may have some action on the parasite in their own right, but their main utility is to control the spread of secondary infections.

Resistance to current drugs, particularly the pentavalent antimonials (possibly caused by increased expression of an antimonial efflux pump), is a serious problem and there is no immediate prospect of a vaccine. The pharmacology of current drugs and prospects for new agents have been reviewed by **Singh et al. (2012)**, **Altamura et al. (2022)** and **Santana et al. (2020)**.

Trichomoniasis

The principal *Trichomonas* organism that produces disease in humans is *Trichomonas vaginalis*. Virulent strains cause inflammation of the vagina and sometimes of the urethra in males. The main drug used in therapy is **metronidazole** (see **Ch. 52**), although resistance to this drug is on the increase. High doses of **tinidazole** are also effective, with few side effects.

Giardiasis

Giardia lamblia colonises the upper GI tract in its trophozoite form, and the cysts pass out in the faeces. Infection is then spread by ingestion of food or water contaminated with faecal matter containing the cysts. It is encountered worldwide, and epidemics caused by bad sanitation are not uncommon. **Metronidazole** is the drug of choice, and treatment is usually very effective. **Tinidazole** or **mepacrine** may be used as an alternative.

Toxoplasmosis

The cat is the definitive host of *T. gondii*, a pathogenic member of this group of organisms (i.e. it is the only host in which the sexual cycle can occur). It expels the infectious cysts in its faeces; humans can inadvertently become intermediate hosts, harbouring the asexual form of the parasite. Ingested oocysts develop into sporozoites, then to trophozoites, and finally encyst in the tissues. In most individuals, the disease is asymptomatic or self-limiting, although intrauterine infections can severely damage the developing foetus and it may cause fatal generalised infection in immunosuppressed patients or those with AIDS, in whom *toxoplasmic encephalitis* may occur. In humans, *T. gondii* infects numerous cell types and has a highly virulent replicative stage.

The treatment of choice is **pyrimethamine–sulfadiazine** (to be avoided in pregnant patients); trimethoprim–**sulfamethoxazole** (**co-trimoxazole**, see **Ch. 52**); or combinations of **pyrimethamine** with **clindamycin**, **clarithromycin** or **azithromycin** (see **Ch. 52**).

Pneumocystis

First recognised in 1909, *Pneumocystis carinii* (now known as *P. jirovecii*; see also **Ch. 54**) shares structural features with both protozoa and fungi, leaving its precise taxonomy uncertain. Previously considered to be a widely distributed but largely innocuous microorganism, it is now recognised as an important cause of opportunistic infections in immunocompromised patients. It is common in AIDS, where *P. carinii* pneumonia is often the presenting symptom as well as a leading cause of death.

High-dose **co-trimoxazole** (see Chs **51** and **52**) is the drug of choice in serious cases, with parenteral **pentamidine** as an alternative. Treatment of milder forms of the disease (or prophylaxis) can be effected with **atovaquone**, **trimethoprim–dapsone** or **clindamycin–primaquine** combinations.

Future Developments

Antiprotozoal pharmacology is a huge global challenge, with each species posing its own distinct problems to the would-be designer of new antiprotozoal drugs. But it is not simply a lack of new drugs that is the problem: for political and economic reasons, the countries and populations most affected often lack an efficient infrastructure for the distribution and safe administration of the drugs that we already possess. Cultural attitudes, civil wars, famine, pandemics, the circulation of counterfeit or defective drugs, drought and natural disasters also exacerbate this problem.

QUESTIONS

QUESTION 55.1

The life cycle of the malarial parasite consists of a *sexual cycle*, which takes place in the female *Anopheles* mosquito, and an *asexual cycle*, which occurs in humans.

Which form of the malarial parasite binds and enters human erythrocytes?

OPTIONS:

A. Sporozoites

B. Hypnozoites

C. Merozoites

D. Trophozoites

E. Schizont

QUESTION 55.2

Protozoa are motile, unicellular eukaryotic organisms that have colonised virtually every habitat and ecological niche are collectively responsible for an enormous burden of illness in humans.

Which of the following statements about protozoal-transmitted diseases is correct?

OPTIONS:

A. Amoebiasic dysentery is caused by ingestion of *trophozoites from contaminated water*.

B. *Trypanosoma cruzi causes sleeping sickness when the* parasites reach the CNS causing somnolence and progressive neurological breakdown.

C. *Leishmania* infection is spread by the tsetse fly.

D. *Leishmania invades macrophages and stimulates the release of pro-inflammatory Th1 cytokines*.

E. Humans harbour the asexual form of the toxoplasmosis parasites.

ANSWERS

ANSWER 55.1

RATIONALE:

A. Sporozoites are the form of the parasite injected into the human host where they enter the parenchymal cells of the liver.

B. Hypnozoites are the dormant forms of the parasite in the liver.

C.

D. Trophozoites are motile intracellular parasites in the erythrocytes.

E. Schizont is the form of the parasite once inside the red blood cell.

CORRECT ANSWER WITH EXPLANATION:

C. Merozoites are released from ruptured parasitised liver cells and then bind to and enter erythrocytes.

ANSWER 55.2

RATIONALE:

A. Amoebiasic dysentery infection *follows the ingestion of the mature cysts in water or food that is contaminated with human faeces. The infectious cysts pass into the colon, where they develop into trophozoites*.

B. *Trypanosoma cruzi* causes *Chagas disease affecting the heart, muscles and sometimes liver, spleen, bone and intestine.*

C. *Leishmania* organisms are flagellate protozoa and the infection that they cause is spread by the female sandfly.

D. The invasion of macrophages by *Leishmania* species induces Th2 cytokines, e.g. transforming growth factor-β and interleukin (IL)-10, inactivates complement pathways and down-regulates many other intracellular defence mechanisms.

E.

CORRECT ANSWER WITH EXPLANATION:

E. The cat is the definitive host of *Toxoplasma gondii* (i.e. it is the only host in which the sexual cycle can occur). It expels the infectious cysts in its faeces; humans can inadvertently become intermediate hosts, harbouring the asexual form of the parasite.

---

[1] The disease was once considered to arise from marshy land and be somehow airborne, hence the Latin name '*mal aria*', meaning bad or poisonous air.

[2] More terminology: 'Airport malaria' is caused by infected mosquitoes in aircraft arriving from areas where the disease is endemic; 'baggage malaria' is caused by their presence in luggage arriving from such areas; and 'runway malaria' has been contracted by some rather unlucky passengers who have stopped in endemic areas even though they have not actually left the aircraft.

[3] Quinine may be the first documented anti-infective agent. The Scottish doctor George Leghorn is credited with re-introducing it as a remedy for 'fevers' (often malarial in origin) in the 18th century.

British soldiers stationed in India in the 1870s were encouraged to take the drug to counteract the risk of this disease. The bitter taste of the quinine was masked by incorporating it into palatable drinks, which included fruit, gin, vodka and other beverages. Originally named ‘Indian Tonic Water’ it is still popular today, although less quinine is used in its preparation.

4 *Artemisia* extracts have been used for thousands of years in China for treating ‘fevers’. *Artemisia* was the wife and sister of the 4th-century king of Halicarnassus. Upon his death, she was so distraught that she mixed his ashes with whatever she drank to make it bitter. Since ‘sweet’ wormwood is noted for its extreme bitterness, it was named in her honour. The biologically active compound artemisinin was isolated by Chinese chemists in 1972. This was ignored in the West for more than 10 years, until the WHO recognised its importance and, in 2002, placed it on their list of ‘essential drugs’ for malaria treatment. In 2015, the Chinese pharmacologist Youyou Tu was awarded the Nobel Prize for her role in developing this drug.

56: Antihelminthic drugs

OVERVIEW

Some 1.5 billion people around the world suffer from *helminthiasis* – infection with various species of parasitic *helminths* (worms). Inhabitants of tropical or subtropical low-income countries are most at risk; children often become infected at birth (polyparasitaemia is common) and may remain so throughout their lives. The clinical consequences of helminthiasis vary: for example, threadworm infections mainly cause discomfort but infection with *schistosomiasis* (*bilharzia*) or hookworm is associated with serious morbidity. Anaemia, nutritional problems and cognitive impairment are common in helminth-infected children. Helminthiasis is often co-endemic with malaria, tuberculosis and HIV/AIDS, adding to the disease burden as well as interfering with vaccination campaigns. Helminth infections are an even greater concern in veterinary medicine, affecting both domestic pets and farm animals leading to significant welfare and economic challenges. Because of its prevalence and economic significance, the pharmacological treatment of helminthiasis with antihelminthics (or anthelmintics) is therefore of great practical therapeutic importance.

Helminth Infections

The helminths comprise two major groups: the *nemathelminths* (nematodes, roundworms) and the *platyhelminths* (flatworms). The latter group is subdivided into the *trematodes* (flukes) and the *cestodes* (tapeworms). Almost 350 species of helminths have been found in humans, and most colonise the gastrointestinal (GI) tract. The global range and occurrence of helminthiasis have been reviewed by **Lustigman et al. (2012)**.

Helminths have a complex life cycle, often involving several host species. Infection may occur in many ways, with poor hygiene a major contributory factor. Humans are generally the *primary* (or *definitive*) host for relevant helminth infections, in the sense that they harbour the sexually mature reproductive form. Direct ingestion is common: eggs or larvae in the faeces of infected humans enter the soil then drinking water and subsequently are ingested and infect the *secondary* (*intermediate*) host. In some cases, the eggs or larvae may persist in the human host and become *encysted*, covered with granulation tissue, giving rise to *cysticercosis*. Encysted larvae may lodge in the muscles and viscera or, more seriously, in the eye or the brain.

Approximately 20 helminth species are considered to be clinically significant (see **Figs 56.1** and **56.2**) and these fall into two main categories – those in which the worm lives in the host's alimentary canal and those in which the worm lives in other tissues of the host's body.

The main examples of intestinal worms are:

- *Tapeworms*: *Taenia saginata*, *Taenia solium*, *Hymenolepis nana* and *Diphyllobothrium latum*. Some 85 million people in Asia, Africa and parts of America commonly harbour one

or other of these tapeworm species. Only the first two are likely to be seen in the United Kingdom. Cattle and pigs are the usual intermediate hosts of the most common tapeworms (*T. saginata* and *T. solium*). Humans become infected by eating raw or undercooked meat containing the larvae, which have encysted in the animals' muscle tissue. *H. nana* may exist as both the adult (the intestinal worm) and the larval stage in the same host, which may be human or rodent, although some insects (fleas, grain beetles) can also serve as intermediate hosts. The infection is usually asymptomatic. [1] *D. latum* has two sequential intermediate hosts: a freshwater crustacean and a freshwater fish. Humans become infected by eating raw or incompletely cooked fish containing the larvae.

- *Intestinal roundworms*: *Ascaris lumbricoides* (common roundworm), *Enterobius vermicularis* (threadworm, called pinworm in the United States), *Trichuris trichiura* (whipworm), *Strongyloides stercoralis* (threadworm in the United States), *Necator americanus* and *Ancylostoma duodenale* (hookworms). Again, undercooked meat or contaminated food is an important cause of infection by roundworm, threadworm and whipworm, whereas hookworm is generally acquired when their larvae penetrate the skin. Intestinal blood loss is a common cause of anaemia in regions where hookworm is endemic.

The main examples of worms that live elsewhere in host tissues are:

- *Flukes*: *Schistosoma haematobium*, *Schistosoma mansoni* and *Schistosoma japonicum*. These cause schistosomiasis (bilharzia). The adult worms of both sexes live and mate in the veins or venules of the bladder or the gut wall. The female lays eggs that pass into the bladder or gut, triggering inflammation in these organs. This results in haematuria in the former case and, occasionally, loss of blood in the faeces in the latter. The eggs hatch in water after discharge from the body and thus enter the secondary host – in this case a particular species of snail. After a period of development in this host, free-swimming *cercariae* emerge. These are capable of infecting humans by penetration of the skin. About 200 million people are infected with schistosomes in this manner.

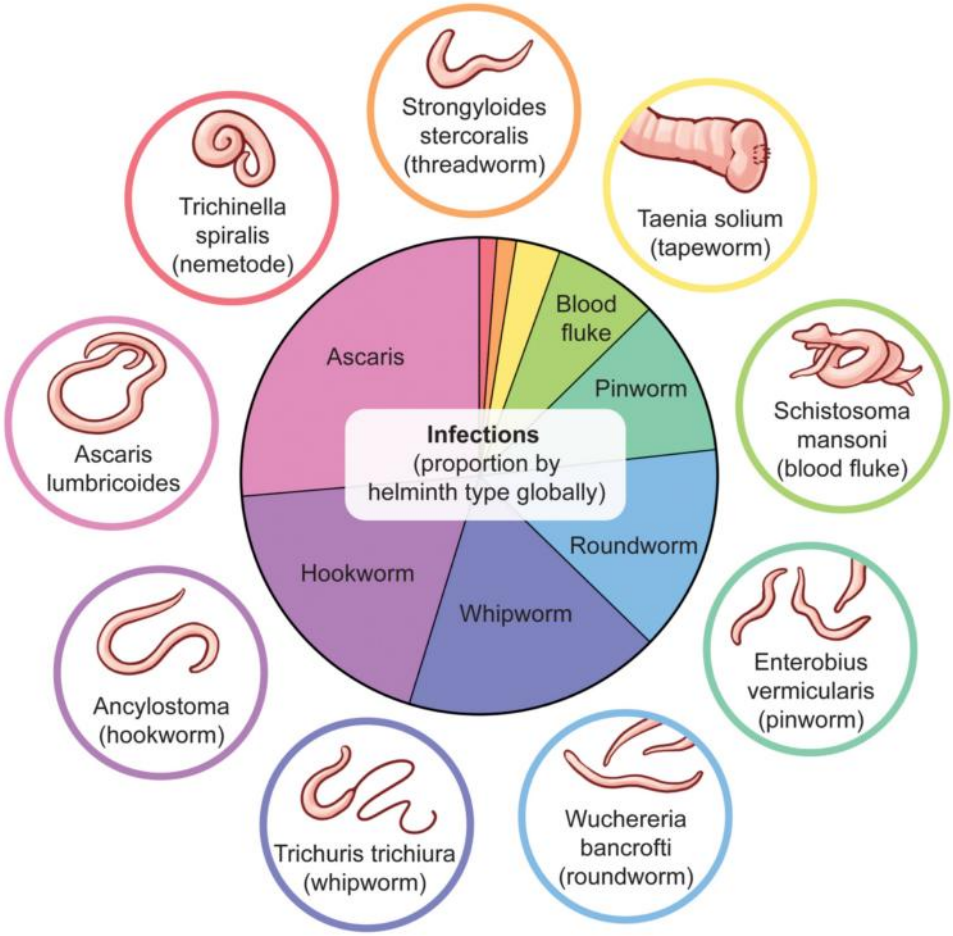

FIG. 56.1 Incidence of different helminth infections as a proportion of the world population and by type of infection.Surrounding illustrations show examples of species associated with each of the main genus.

- *Tissue roundworms: Trichinella spiralis*, *Dracunculus medinensis* (*guinea worm*) and the *filariae*, which include *Wuchereria bancrofti*, *Loa loa*, *Onchocerca volvulus* and *Brugia malayi*. The adult filariae live in the lymphatics, connective tissues or mesentery of the host and produce live

embryos or *microfilariae*, which find their way into the bloodstream and may be ingested by mosquitoes or other biting insects. After a period of development within this secondary host, the larvae pass into the mouth parts of the insect and thus infect the next victim. Major filarial diseases are caused by *Wuchereria* or *Brugia*, which cause obstruction of lymphatic vessels, producing *elephantiasis* – hugely swollen legs. Other related diseases are *onchocerciasis* (in which the presence of microfilariae in the eye causes 'river blindness' – a leading preventable cause of blindness in Africa and Latin America) and *loiasis* (in which the microfilariae cause inflammation in the skin and other tissues). *T. spiralis* causes trichinosis; the larvae from the viviparous female worms in the intestine migrate to skeletal muscle, where they become encysted. In *guinea worm disease*, [2] larvae of *D. medinensis* released from crustaceans in wells and waterholes are ingested and migrate from the intestinal tract to mature and mate in the tissues; the gravid female then migrates to the subcutaneous tissues of the leg or the foot, and may protrude through an ulcer in the skin. The worm may be up to a metre in length and must be removed surgically or by slow mechanical winding of the worm on to a stick over a period of days, to ensure that the worm does not break, because the remains would putrefy.

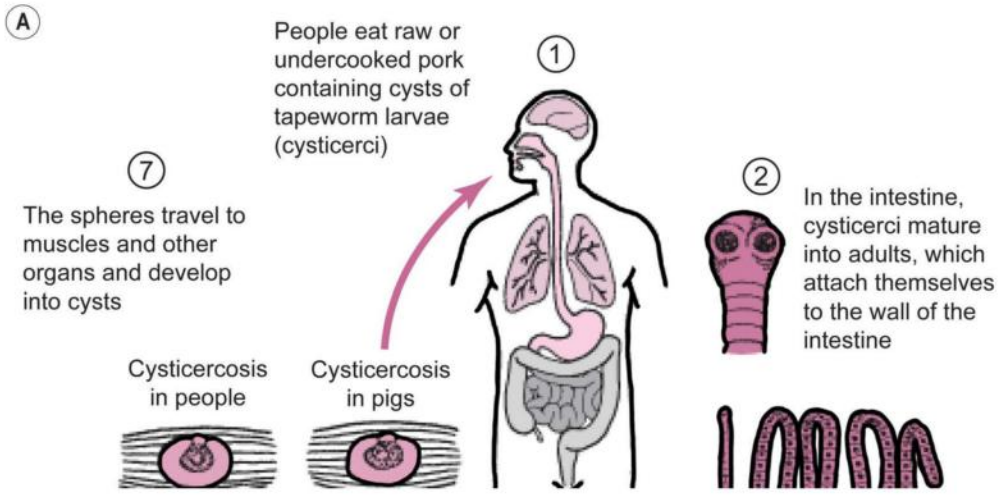
- *Hydatid tapeworm*. These are cestodes of the *Echinococcus* species for which dogs are the primary hosts, and sheep the intermediate hosts. The primary, intestinal stage does not occur in humans, but under certain circumstances humans

can function as the intermediate host, in which case the larvae develop into *hydatid cysts* within the tissues, sometimes with fatal consequences.

Some nematodes that generally live in the GI tract of animals may infect humans and penetrate tissues. A skin infestation, termed *creeping eruption* or *cutaneous larva migrans*, is caused by the larvae of dog and cat hookworms which often enter through the foot. Visceral larva migrans is caused by larvae of cat and dog roundworms of the *Toxocara* genus.

Antihelminthic Drugs

The aim of treatment is to eliminate the parasite but without adversely affecting the biology of the host. Helminths being distinct species has the advantage of different biology, e.g. motor function, metabolism offer a route to achieving selective toxicity, a similar concept to antibiotics for example (**Ch. 51**). These same principles rely on the selective toxicity of a drug, whereby the drug is more toxic to a parasite or cancer cell, than the host itself.



A
People eat raw or undercooked pork containing cysts of tapeworm larvae (cysticerci)
1
2
In the intestine, cysticerci mature into adults, which attach themselves to the wall of the intestine
7
The spheres travel to muscles and other organs and develop into cysts
Cysticercosis in people
Cysticercosis in pigs

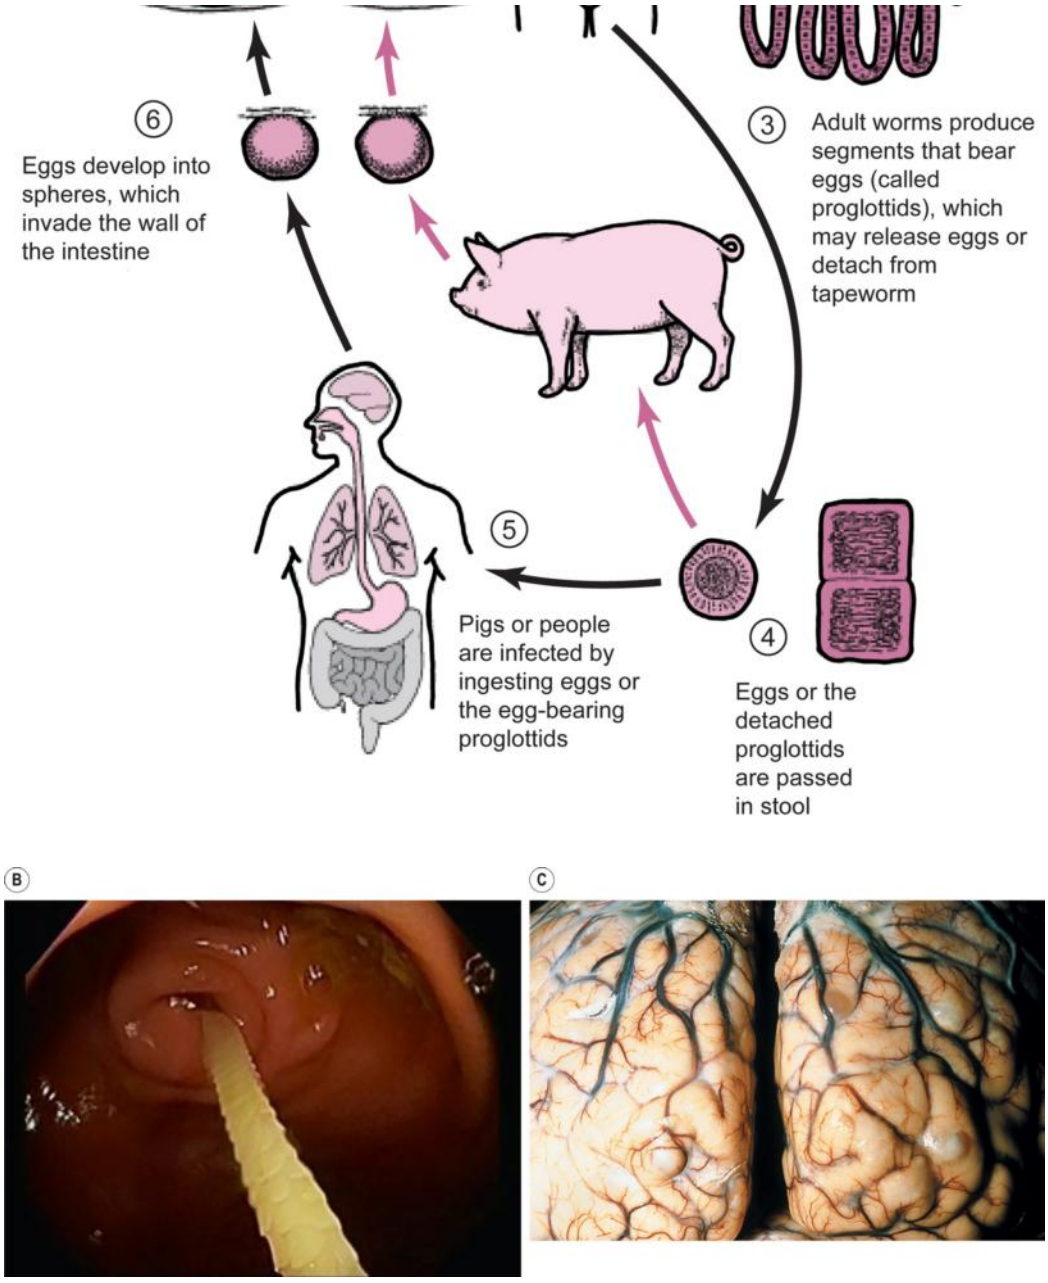


FIG. 56.2 Life cycle of *Taenia solium*. (A) *T. solium*, the pork tapeworm, is found throughout the world and has humans as its definitive host and pigs as the intermediate or secondary hosts. Humans can be infected by either eating undercooked pork meat that contains the intermediate cysts or eating food or drinking

water contaminated with faeces which contain tapeworm eggs. (B) The former, known as taeniasis, results in adult tapeworm in the intestines which usually has no symptoms and is easily treated with anthelmintic medications. The later, known as cysticercosis, results in cysts forming in different organs of the body. This is usually muscle and has minimal symptoms but (C) the cysts can form in the brain with more serious symptoms.

Table 56.1

The first effective antihelminthic drugs (also known as anthelmintics) were discovered in the 20th century and incorporated toxic metals such as arsenic (*atoxyl*) or antimony (*tartar emetic*). They were used to treat trypanosome and schistosome infestations.

Current antihelminthic drugs generally act by paralysing the parasite (e.g. by preventing muscular contraction), by damaging the worm such that the host immune system can eliminate it or by altering parasite metabolism (e.g. by affecting microtubule function). Because the metabolic requirements of these parasites vary greatly from one species to another, drugs that are highly effective against one type of worm may be ineffective against others.

To bring about its action, the drug must penetrate the tough exterior cuticle of the worm or gain access to its alimentary tract. This may present difficulties, because helminths have different

lifestyles with some worms being exclusively *haemophagous* ('blood-eating'), while others are best described as 'tissue grazers'. A further complication is that many helminths possess active drug efflux pumps that reduce the concentration of the drug in the parasite. The route of administration and dose of antihelminthic drugs are therefore important. In a reversal of the normal order of things, several antihelminthic drugs used in human medicine were originally developed for veterinary use.

Some individual antihelminthic drugs are described briefly here and indications for their use are given in **Table 56.1**. Many of these drugs are unlicensed in the United Kingdom but are used on a 'named patient' basis [3] : in some cases (e.g. mebendazole) restricted dosage forms are available from pharmacies.

Benzimidazoles

This group includes **mebendazole**, **tiabendazole** and **albendazole,** which are widely used broad-spectrum antihelminthics. They are thought to act by inhibiting the polymerisation of helminth β-tubulin, thus interfering with microtubule-dependent functions such as glucose uptake. They have a selective inhibitory action, being 250–400 times more effective in producing this effect in helminth, than in mammalian, tissue. However, the effect takes time to develop and the worms may not be expelled for several days. Cure rates are generally between 60% and 100% with most parasites.

Only 10% of mebendazole is absorbed after oral administration, but a fatty meal increases absorption. It is rapidly metabolised; the products being excreted in the urine and the bile within 24–48 h. It

is generally given as a single dose for threadworm, and twice daily for 3 days for hookworm and roundworm infestations. Tiabendazole is rapidly absorbed from the GI tract, and very rapidly metabolised and excreted in the urine in conjugated form. It may be given twice daily for 3 days for guinea worm and *Strongyloides* infestations, and for up to 5 days for hookworm and roundworm infestations. Albendazole is also poorly absorbed but, as with mebendazole, absorption is increased by food, especially fats. It is metabolised extensively by presystemic metabolism to sulfoxide and sulfone metabolites. The former is likely to be the pharmacologically active species.

Unwanted effects

are few with albendazole or mebendazole, although GI disturbances can occasionally occur. Unwanted effects with tiabendazole are more frequent but usually transient, the commonest being GI disturbances, although headache, dizziness and drowsiness have been reported and allergic reactions (fever, rashes) may also occur. Mebendazole is considered unsuitable for pregnant women or children less than 2 years old, although more recent WHO guidance suggests albendazole or mebendazole could be suitable in pregnant women after their first trimester.

Praziquantel

Praziquantel is a highly effective broad-spectrum antihelminthic drug that was introduced over 20 years ago. It is the drug of choice for all forms of schistosomiasis and is the agent generally used in large-scale schistosome eradication programmes. It is also effective in cysticercosis. The drug affects not only the adult schistosomes

but also the immature forms and the cercariae – the form of the parasite that infects humans by penetrating the skin.

Praziquantel disrupts Ca^{2+} homeostasis in the parasite by binding to consensus protein kinase C-binding sites in a β subunit of schistosome voltage-gated calcium channels (**Greenberg, 2005**). This induces an influx of Ca^{2+}, a rapid and prolonged contraction of the musculature and eventual paralysis and death of the worm. Praziquantel also disrupts the tegument of the parasite, unmasking novel antigens, and may thus make the worm more susceptible to the host's normal immune responses.

Given orally, praziquantel is well absorbed; much of the drug is rapidly metabolised to inactive metabolites on first passage through the liver, and the metabolites are excreted in the urine. The plasma half-life of the parent compound is 60–90 min.

Praziquantel has minimal side effects in therapeutic dosage. Such unwanted effects as do occur are usually transitory and rarely of clinical importance. Effects may be more marked in patients with a heavy worm load because of products released from the dead worms. Praziquantel is considered safe for pregnant and lactating women, an important property for a drug that is commonly used in national disease control programmes. Some resistance has developed to the drug.

Piperazine

Piperazine (discontinued in United Kingdom due to issues sourcing the raw ingredients) can be used to treat infections with the common roundworm (*A. lumbricoides*) and the threadworm (*E. vermicularis*). It reversibly inhibits neuromuscular transmission in

the worm, probably by mimicking GABA (see **Ch. 38**), at GABA-gated chloride channels in nematode muscle. The paralysed worms are expelled alive by normal intestinal peristaltic movements. It is administered with a stimulant laxative such as **senna** (see **Ch. 30**) to facilitate expulsion of the worms.

Piperazine is given orally and some, but not all, is absorbed. It is partly metabolised, and the remainder is eliminated, unchanged, via the kidney. The drug has little pharmacological action in the host. When used to treat roundworm, piperazine is effective in a single dose. For threadworm, a longer course (7 days) at lower dosage is necessary.

Unwanted effects

may include GI disturbances, urticaria and bronchospasm. Some patients experience dizziness, paraesthesia, vertigo and incoordination. The drug should not be given to pregnant patients or to those with compromised renal or hepatic function.

Diethylcarbamazine

Diethylcarbamazine is a piperazine derivative that is active in filarial infections caused by *B. malayi*, *W. bancrofti* and *L. loa*. Diethylcarbamazine rapidly removes the microfilariae from the blood circulation and has a limited effect on the adult worms in the lymphatics, but it has little action on microfilariae in vitro. It may act by changing the parasite such that it becomes susceptible to the host's normal immune responses or by interfering with helminth arachidonate metabolism.

The drug is absorbed following oral administration and is distributed throughout the cells and tissues of the body, excepting

adipose tissue. It is partly metabolised, and both the parent drug and its metabolites are excreted in the urine, being cleared from the body within about 48 h.

Unwanted effects

are common but transient, subsiding within a day or so even if the drug is continued. Side effects from the drug itself include GI disturbances, joint pain, headache and a general feeling of weakness. Allergic side effects referable to the products of the dying filariae are common and vary with the species of worm. In general, these start during the first day's treatment and last 3–7 days; they include skin reactions, enlargement of lymph glands, dizziness, tachycardia and GI and respiratory disturbances. When these symptoms disappear, larger doses of the drug can be given without further problem. The drug is not used in patients with onchocerciasis, in whom it can have serious unwanted effects.

Niclosamide

Niclosamide is widely used for the treatment of tapeworm infections together with praziquantel. The *scolex* (the head of the worm that attaches to the host intestine) and a proximal segment are irreversibly damaged by the drug, such that the worm separates from the intestinal wall and is expelled. For *T. solium*, the drug is given in a single dose after a light meal, usually followed by a purgative 2 h later in case the damaged tapeworm segments release ova, which are not affected by the drug. For other tapeworm infections, this precaution is not necessary. There is negligible absorption of the drug from the GI tract.

Unwanted effects

nausea, vomiting, pruritus and light-headedness may occur but generally such effects are few, infrequent and transient.

Levamisole

Levamisole is effective in infections with the common roundworm (*A. lumbricoides*). It has a nicotine-like action (see **Ch. 14**), stimulating and subsequently blocking the neuromuscular junctions. The paralysed worms are then expelled in the faeces. Ova are not killed. Given orally the drug is rapidly absorbed and is widely distributed crossing the blood–brain barrier. It is metabolised in the liver to inactive metabolites, which are excreted via the kidney. Its plasma half-life is 4 h. It has immunomodulatory effects and has in the past been used to treat various solid tumours.

It can cause central nervous system (CNS) and GI disturbances as well as several other unwanted effects, including agranulocytosis. The drug has been withdrawn from North American markets.

Ivermectin

First introduced in 1981 as a veterinary drug, **ivermectin** is a safe and highly effective broad-spectrum antiparasitic in humans. [4] It is frequently used in global public health campaigns, [5] and is the first choice of drug for the treatment of many filarial infections. It yields good results against *W. bancrofti*, which causes elephantiasis. A single dose kills the immature microfilariae of *O. volvulus* but not the adult worms. Ivermectin is also the drug of choice for onchocerciasis, which causes river blindness and reduces the incidence of this disease by up to 80%. It is also active against some

roundworms: common roundworms, whipworms and threadworms of both the UK (*E. vermicularis*) and US (*S. stercoralis*) variety, but not hookworms.

Chemically, ivermectin is a semisynthetic agent derived from a group of natural substances, the *avermectins*, obtained from an actinomycete organism. The drug is given orally and has a half-life of 11 h. It is thought to kill the worm either by opening glutamate-gated chloride channels (found only in invertebrates) and increasing Cl^- conductance; by binding to GABA receptors; or by binding to a novel allosteric site on the acetylcholine nicotinic receptor to cause an increase in transmission, leading to motor paralysis.

Unwanted effects

include skin rashes and itching but in general the drug is very well tolerated. One interesting exception in veterinary medicine is the CNS toxicity seen in Collie dogs. [6]

Resistance to Antihelminthic Drugs

Resistance to antihelminthic drugs is a widespread and growing problem affecting not only humans but also the animal health market. Understanding of the mechanisms of helminth mutations in drug-resistant forms is not as well understood or researched, as with other microbes. During the 1990s, helminth infections in sheep (and, to a lesser extent, cattle) developed varying degrees of resistance to a number of different drugs. Parasites that develop such resistance pass this ability on to their offspring, leading to treatment failure. The widespread use of antihelminthic agents in farming has been blamed for the spread of resistant species.

There are probably several molecular mechanisms that contribute to drug resistance. The presence of the P-glycoprotein transporter (see **Ch. 10**) in some species of nematode has already been mentioned, and agents such as **verapamil** that block the transporter in trypanosomes can partially reverse resistance to the benzimidazoles. However, some aspects of benzimidazole resistance may be attributed to alterations in their high-affinity binding to parasite β-tubulin. Likewise, resistance to levamisole is associated with changes in the structure of the target acetylcholine nicotinic receptor.

Of great significance is the way in which helminths evade the host's immune system. Even though they may reside in immunologically exposed sites such as the lymphatics or the bloodstream, many are long-lived and may co-exist with their hosts for many years without seriously affecting their health, or in some cases without even being noticed. It is striking that the two major families of helminths, while evolving separately, deploy similar strategies to evade destruction by the immune system. Clearly, this must be of major survival value for the species.

In addition to rapidly changing external antigens, which hamper immune recognition, it appears that many helminths secrete immunomodulatory products that steer the host's immune system away from a local Th1 response (see **Ch. 7**), which would damage the parasite, and instead promote a modified systemic Th2 type of response. This is associated with the production by the host of 'anti-inflammatory' cytokines such as interleukin-10 and is favourable to, or at least better tolerated by, the parasites. The immunology

underlying this is fascinating but complex (see e.g. **Harris, 2011**; **Harnett, 2014**; **McNeilly and Nisbet, 2014**).

Ironically, the ability of helminths to modify the host immune response in this way may confer some survival value on the hosts themselves. For example, in addition to the local anti-inflammatory effect exerted by helminth infections, rapid wound healing is also seen. Clearly, this is of advantage to parasites that must penetrate tissues without killing the host, but may also be beneficial to the host as well. It has been proposed that helminth infections may mitigate some forms of malaria and other diseases, possibly conferring survival advantages in populations where these diseases are endemic. The deliberate, 'therapeutic' ingestion of helminths by patients has been evaluated as an (admittedly unappealing) strategy to induce remission of inflammatory diseases such as Crohn's disease, ulcerative colitis and even multiple sclerosis (see **Ch. 30**; **Benzel et al., 2012**; **Heylen et al., 2014**; **Peon and Terrazas, 2016**; **Summers et al., 2005a**, **2005b**), although their effectiveness in clinical trials is mixed.

On the basis that Th2 responses reciprocally inhibit the development of Th1 diseases, it has also been hypothesised that the comparative absence of Crohn's disease, as well as some other autoimmune diseases, in the developing world may be associated with the high incidence of parasite infection, and that the rise of these disorders in the West is associated with superior sanitation and reduced helminth infection! This type of argument is generally known as the 'hygiene hypothesis'.

On the negative side however, helminth infections may undermine the efficacy of tuberculosis and other vaccination

programmes that depend upon a vigorous Th1 response (see, for example, **Elias et al., 2006**, and **Apiwattanakul et al., 2014**).

Vaccines and Other Novel Approaches

Despite the enormity of the clinical (and economic) problems associated with helminth infection, there are few novel antihelminthic drugs in development, possibly because the similarity between helminth and mammalian targets makes achieving selective toxicity difficult. New candidates such as **tribendimidine** are being assessed in a range of human infections and have shown promise in liver fluke infection (**Duthaler et al., 2016**) and some new veterinary drugs (e.g. **derquantel**) also tested in humans (see **Prichard et al., 2012**). The identification of new parasite metabolic enzymes as targets may help with future drug design (**Timson, 2016**).

Public health measures to eliminate helminth infections depend upon promoting better sanitation and mass drug administration programmes (e.g. **McCarty et al., 2014**). The development of effective anti-helminth vaccines would be a major step forward in this endeavour. Using surface protein and glycoprotein antigens as immunogens, some success has been achieved with veterinary vaccines (e.g. **Sciutto et al., 2013**; **Bassetto and Amarante, 2015**). The use of sophisticated tools such as genomics, transcriptomics, proteomics, metabolomics, lipidomics (collectively known as 'OMICS') to identify novel antigens may facilitate progress (**Loukas et al., 2011**).

QUESTIONS

QUESTION 56.1

Some 1.5 billion people around the world suffer from *helminthiasis* which is often co-endemic with several other infectious diseases, adding to the disease burden as well as interfering with vaccination campaigns.

Which of the following statements about helminth infections is incorrect?

OPTIONS:

A. Helminth infections that spread quickly are more detrimental to the host.

B. Humans are generally the *primary* host for helminth infections as they harbour the sexually mature reproductive form.

C. Infection with *schistosomiasis* is associated with serious morbidity.

D. Cognitive impairment is commonly seen in children infected by helminths.

E. *Cysticercosis* can occur when eggs or larvae persist in the human host and become *encysted*.

QUESTION 56.2

Many helminths secrete immunomodulatory products that steer the host's immune system away from a local Th1 response which would damage the parasite, and instead promote a modified systemic Th2 type of response.

Due to this immunomodulatory effect, which of the following conditions may be exacerbated by a helminth infection?

OPTIONS:

A. Crohn's disease

B. Malaria

C. Tuberculosis

D. Multiple sclerosis

E. Wound healing

ANSWERS

ANSWER 56.1

RATIONALE:

A.

B. Humans are generally the *primary* (or *definitive*) host for relevant helminth infections, in the sense that they harbour the sexually mature reproductive form.

C. The clinical consequences of helminthiasis vary: threadworm infections mainly cause discomfort but infection with *schistosomiasis* (*bilharzia*) or hookworm is associated with serious morbidity.

D. Anaemia, nutritional problems and cognitive impairment are common in children infected by helminths.

E. In some cases, the eggs or larvae may persist in the human host and become *encysted*, covered with granulation tissue, giving rise to *cysticercosis*. Encysted larvae may lodge in the muscles and viscera or, more seriously, in the eye or the brain.

CORRECT ANSWER WITH EXPLANATION:

A. Helminth infections that spread quickly are more detrimental to the host.

A general principle is that the infecting helminths spread more efficiently if they are less detrimental to the hosts. The least effective vector would kill its secondary host quickly and thus not be very good at spreading among its population.

ANSWER 56.2

RATIONALE:

A. The deliberate, 'therapeutic' ingestion of helminths by patients has been evaluated as an (admittedly unappealing) strategy to induce remission of inflammatory diseases such as Crohn's disease.

B. It has been proposed that helminth infections may mitigate some forms of malaria and other diseases, possibly conferring survival advantages in populations where these diseases are endemic.

C.

D. The deliberate, ‘therapeutic’ ingestion of helminths by patients has been evaluated as an (admittedly unappealing) strategy to induce remission of inflammatory diseases such as multiple sclerosis.

E. In addition to the local anti-inflammatory effect exerted by helminth infections, rapid wound healing is also seen.

CORRECT ANSWER WITH EXPLANATION:

C. Tuberculosis

Helminth infections may undermine the efficacy of tuberculosis and other vaccination programmes that depend upon a vigorous Th1 response.

---

[1] A general principle is that the infecting vector (in this case helminths) spreads more efficiently if they are less detrimental to the hosts. The least effective vector would kill its secondary host quickly and thus not be very good at spreading among its population. Survival of the sneakiest.

[2] Now, happily, eliminated from many parts of the world. There are no effective drug treatments for *guinea worm disease*, but clean drinking water and filtering larval-contaminated water through nylon mesh tights have helped reduce global infection from 3.5 million to 5 in only 30 years – the first globally eradicated parasitic disease.

[3] A situation in which the physician seeks access to an unlicensed drug from a pharmaceutical company to use in a named individual. The drug is either a ‘newcomer’ that has shown promise in clinical trials but has not yet been licensed or, as in these instances, an

established drug that has not been licensed because the company has not applied for a product license for this indication (possibly for commercial reasons).

[4] The Western World has collectively lost its mind over the potential use and repurposing of ivermectin as a possible treatment for COVID-19, surprising for a drug which won its inventors the Nobel Prize in 2015.

[5] Ivermectin is supplied by the manufacturers free of charge in countries where river blindness is endemic. Because the worms develop slowly, a single annual dose of ivermectin is sufficient to prevent the disease.

[6] A multidrug-resistance (MDR) gene (see Ch. 3) coding for a transporter that expels ivermectins from the CNS is mutated to an inactive form in Collie dogs.

57: Anticancer drugs

OVERVIEW

Cancer is one of the great challenges for pharmacology. There have been great strides in the overall treatment of cancer, with some cancer types seeing marked improvement in survival thanks to drug advances – many cancer types remaining stubbornly intractable, for now. A wealth of new drugs have been brought onto the market, due in part to the often terminal nature of the disease and the willingness of a sufferer to try a novel treatment in the hope of extending their life. Many of the toxicities associated with cancer treatments are tolerated in the hope of a cure. Companies continually strive to improve cancer drug effectiveness without increasing toxicity, resulting in a range of new anticancer therapies that have evolved and improved over recent decades. In this chapter, we consider cancer in general and anticancer drug therapy. We discuss first the pathogenesis of cancer and then describe the drugs that can be used to treat malignant disease. Finally, we consider the extent to which our new knowledge of cancer biology is leading to new therapies.

Introduction

'Cancer' is characterised by uncontrolled multiplication and spread of abnormal forms of the body's own cells. It is second only to

cardiovascular disease as cause of death in developed nations, and one in every two people born in the United Kingdom after 1960 will be diagnosed with some form of cancer during their lifetime. According to Cancer Research UK (2018), over 375,000 new cases were reported per annum in the United Kingdom and mortality was in excess of 166,000 (global figures respectively are 17 and 9.6 million). Cancer is responsible for approximately 30% of all deaths in the United Kingdom. Lung and bowel cancers are the commonest malignancies, closely followed by breast and prostate cancer. Statistics from most other countries in the developed world tell much the same story.

A comparison of the incidence of cancer over the past 100 years or so gives the impression that the disease is increasing in developed countries, but this is not so. Cancer occurs mainly in later life and, with advances in public health and medical science, many more people now live to an age where malignancy is common. [1]

The terms *cancer*, *malignancy* and *malignant tumour* are often used synonymously. [2] Both benign and malignant tumours manifest uncontrolled proliferation, but the latter are distinguished by their capacity for *de-differentiation*, their *invasiveness* and their ability to *metastasise* (spread to other parts of the body). The appearance of these abnormal characteristics reflects altered patterns of gene expression in the cancer cells, resulting from inherited or acquired mutations.

There are three main approaches to treating established cancer – *surgical excision*, *irradiation* and *drug therapy* (previously often called *chemotherapy*, but now often including hormonal and biological agents as described later and in Chs **5** and **35**) – and the

relative value of each of these approaches depends on the disease and the stage of its development. Drug therapy may be used on its own or as an adjunct to other forms of therapy.

Compared with that of bacterial diseases, cancer chemotherapy presents a difficult conceptual problem. Microorganisms differ qualitatively from human cells (see **Ch. 51**), but cancer cells and normal cells are so similar in most respects that it is more difficult to find general, exploitable, biochemical differences between these differing cell types. Conventional *cytotoxic drugs* act on all cells and rely on a small margin of selectivity to be useful as anticancer agents, but the scope of cancer therapy has now broadened to include drugs that affect either the hormonal regulation of tumour growth or the defective cell cycle controls that underlie malignancy (see **Ch. 6** and **Croce, 2008**; **Weinberg, 1996**). Numerous biopharmaceuticals including monoclonal antibodies (see **Ch. 5**), as well as other novel immunomodulators, have transformed the chemotherapeutic landscape.

The Pathogenesis of Cancer

It is important to consider the pathobiology in more detail to understand how anticancer drugs work and may be improved on in future.

Cancer cells manifest, to varying degrees, four characteristics that distinguish them from normal cells. These are

- *Uncontrolled proliferation*
- *De-differentiation and loss of function*
- *Invasiveness*

- *Metastasis*

The Genesis of A Cancer Cell

A normal cell turns into a cancer cell because of one or, more often, several mutations in its DNA. These can be inherited or acquired, usually through exposure to viruses or *carcinogens* (e.g. tobacco products, ultraviolet radiation, asbestos). A good example is breast cancer; women who inherit a single defective copy of either of the tumour suppressor genes *BRCA1* and *BRCA2* have a significantly increased *risk* of developing breast cancer. However, carcinogenesis is a complex multistage process, usually involving more than one genetic change as well as other, *epigenetic* factors (hormonal, co-carcinogen and tumour promoter effects – see later) that do not themselves produce cancer but which increase the *likelihood* that the genetic mutation(s) will eventually result in cancer. These mutations accumulate and lead to '*genomic instability*', which is a hallmark of carcinogenesis.

There are two main categories of relevant genetic change:

- The activation of *proto-oncogenes* to *oncogenes*. Proto-oncogenes are genes that normally control cell division, apoptosis and differentiation (see **Ch. 6**), but which can be converted by viruses or carcinogens to oncogenes that induce malignant change.
- The inactivation of *tumour suppressor genes*. Normal cells contain genes that suppress malignant change – termed *tumour suppressor genes* (*anti-oncogenes*) – and mutations of these genes are commonly involved in many different

cancers. The loss of function of tumour suppressor genes can be the critical event in carcinogenesis.

The Cancer Gene Census has catalogued more than 500 genes with mutations that have a causal role in cancer (**https://cancer.sanger.ac.uk/cosmic/census**). Among the changes that lead to malignancy are mutations (e.g. inactivating mutations in tumour suppressor genes and missense mutations for dominant oncogenes), gene amplification or chromosomal translocation (see **Hanahan and Weinberg, 2011**).

The Special Characteristics of Cancer Cells

Uncontrolled Proliferation

It is not generally true that cancer cells proliferate faster than normal cells. Many healthy cells, in the bone marrow and the epithelium of the gastrointestinal (GI) tract (for example), undergo continuous rapid division. Some cancer cells multiply slowly (e.g. those in plasma cell tumours) and some much more rapidly (e.g. the cells of *Burkitt's lymphoma*). The significant issue is that cancer cells *have escaped from the mechanisms that normally regulate cell division and tissue growth; the normal brakes on cell division, present in a healthy cell, have been cut*. It is this, rather than their rate of proliferation, that distinguishes them from normal cells.

What are the changes that lead to the uncontrolled proliferation of tumour cells? Inactivation of tumour suppressor genes or transformation of proto-oncogenes into oncogenes can confer autonomy of growth on a cell and thus result in uncontrolled proliferation by producing changes in cellular systems (**Fig. 57.1**), including:

- *growth factors*, their receptors and signalling pathways;
- the *cell cycle transducers*, for example, cyclins, cyclin-dependent kinases (cdks) or the cdk inhibitors;
- the *apoptotic machinery* that normally disposes of abnormal cells;
- *telomerase expression;*
- *local blood supply*, resulting from tumour-directed angiogenesis.

Potentially all the genes coding for the earlier components could be regarded as oncogenes or tumour suppressor genes (**Fig. 57.2**), although not all are equally prone to malignant transformation and malignant transformation of several components is needed for the development of cancer.

Resistance to apoptosis

Apoptosis is programmed cell death (see **Ch. 6**), and mutations in antiapoptotic genes are usually a prerequisite for cancer; indeed, resistance to apoptosis is a hallmark of malignant disease. It can be brought about by inactivation of proapoptotic factors or by activation of antiapoptotic factors.

Telomerase expression

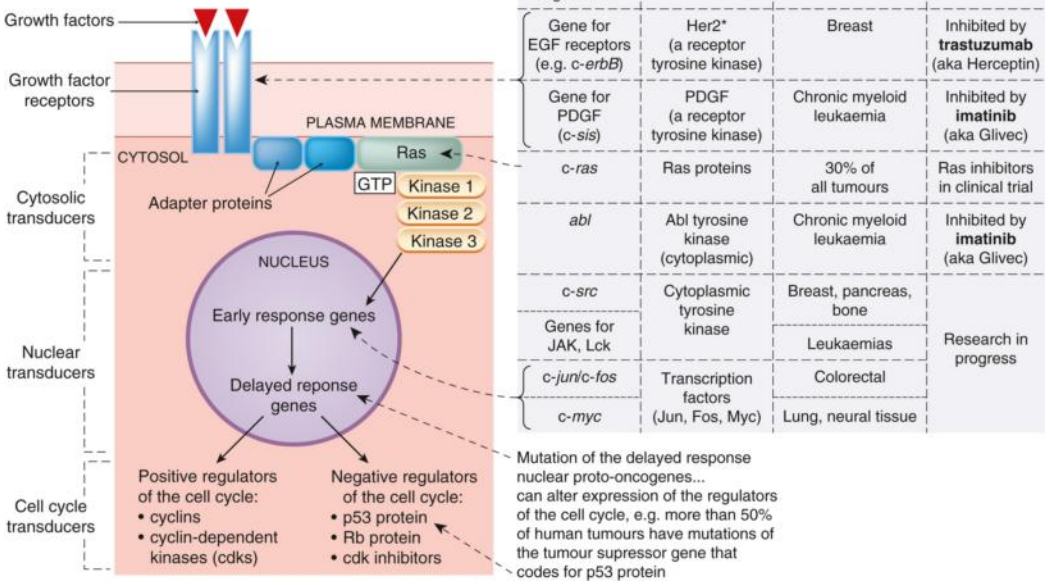
Telomeres are specialised structures that cap the ends of chromosomes – like the small metal tubes on the end of shoelaces – protecting them from degradation, rearrangement and fusion with other chromosomes. Furthermore, DNA polymerase cannot easily duplicate the last few nucleotides at the ends of DNA, and telomeres prevent loss of these ‘end’ genes. With each round of cell division, a

portion of the telomere is eroded, so that eventually it becomes non-functional. At this point, DNA replication ceases and the cell becomes senescent. [3]

Healthy stem cells express *telomerase*, a *terminal transferase* enzyme that maintains and elongates telomere ends. While it is absent from most fully differentiated somatic cells, about 95% of late-stage malignant tumours express telomerase enzymes to continuously rebuild the telomere end and extend the cell's replicative ability, thus elongating the telomere ends and effectively conferring 'immortality' on cancer cells (see **Buys, 2000**; **Keith et al., 2004**).

The control of tumour-related blood vessels

The factors described earlier lead to the uncontrolled proliferation of individual cancer cells, but other factors, particularly blood supply, determine the actual growth of a solid tumour. Tumours 1–2 mm in diameter can obtain nutrients by diffusion through their exterior wall boundary, but their further expansion requires *angiogenesis* to feed this propagating tumour with nutrients, the development of new blood vessels in response to growth factors produced by the growing tumour itself (see **Griffioen and Molema, 2000**).



Proto-oncogene	Proto-oncogene products	Cancer	Anticancer drugs
Genes for growth factors e.g. for IGF	Growth factors e.g. IGF	Prostate, breast colorectal, etc.	Research in progress
Gene for EGF receptors (e.g. *c-erbB*)	Her2* (a receptor tyrosine kinase)	Breast	Inhibited by **trastuzumab** (aka Herceptin)
Gene for PDGF (*c-sis*)	PDGF (a receptor tyrosine kinase)	Chronic myeloid leukaemia	Inhibited by **imatinib** (aka Glivec)
c-ras	Ras proteins	30% of all tumours	Ras inhibitors in clinical trial
abl	Abl tyrosine kinase (cytoplasmic)	Chronic myeloid leukaemia	Inhibited by **imatinib** (aka Glivec)
c-src	Cytoplasmic tyrosine kinase	Breast, pancreas, bone	Research in progress
Genes for JAK, Lck		Leukaemias	
c-jun/c-fos	Transcription factors (Jun, Fos, Myc)	Colorectal	
c-myc		Lung, neural tissue	

FIG. 57.1 Signal transduction pathways initiated by growth factors and their relationship to cancer development.A few examples of proto-oncogenes and the products they code for are given in the table, with examples of the cancers that are associated with their conversion to oncogenes. Many growth factor receptors are receptor tyrosine kinases, the cytosolic transducers including adapter proteins that bind to phosphorylated tyrosine residues in the receptors. Ras proteins are guanine nucleotide-binding proteins and have GTPase action; decreased GTPase action means that Ras remains activated. ∗*Her2* is also termed *her2/neu*. *EGF,* Epidermal growth factor; *IGF,*

insulin-like growth factor; *PDGF,* platelet-derived growth factor.

De-Differentiation and Loss of Function

The multiplication of normal cells in a tissue begins with division of the undifferentiated stem cells, giving rise to two *daughter cells*, one of which differentiates to become a mature non-dividing cell, ready to perform functions appropriate to that differentiated tissue. One of the main characteristics of cancer cells is that they de-differentiate to varying degrees. In general, poorly differentiated cancers carry a worse prognosis than well-differentiated cancers.

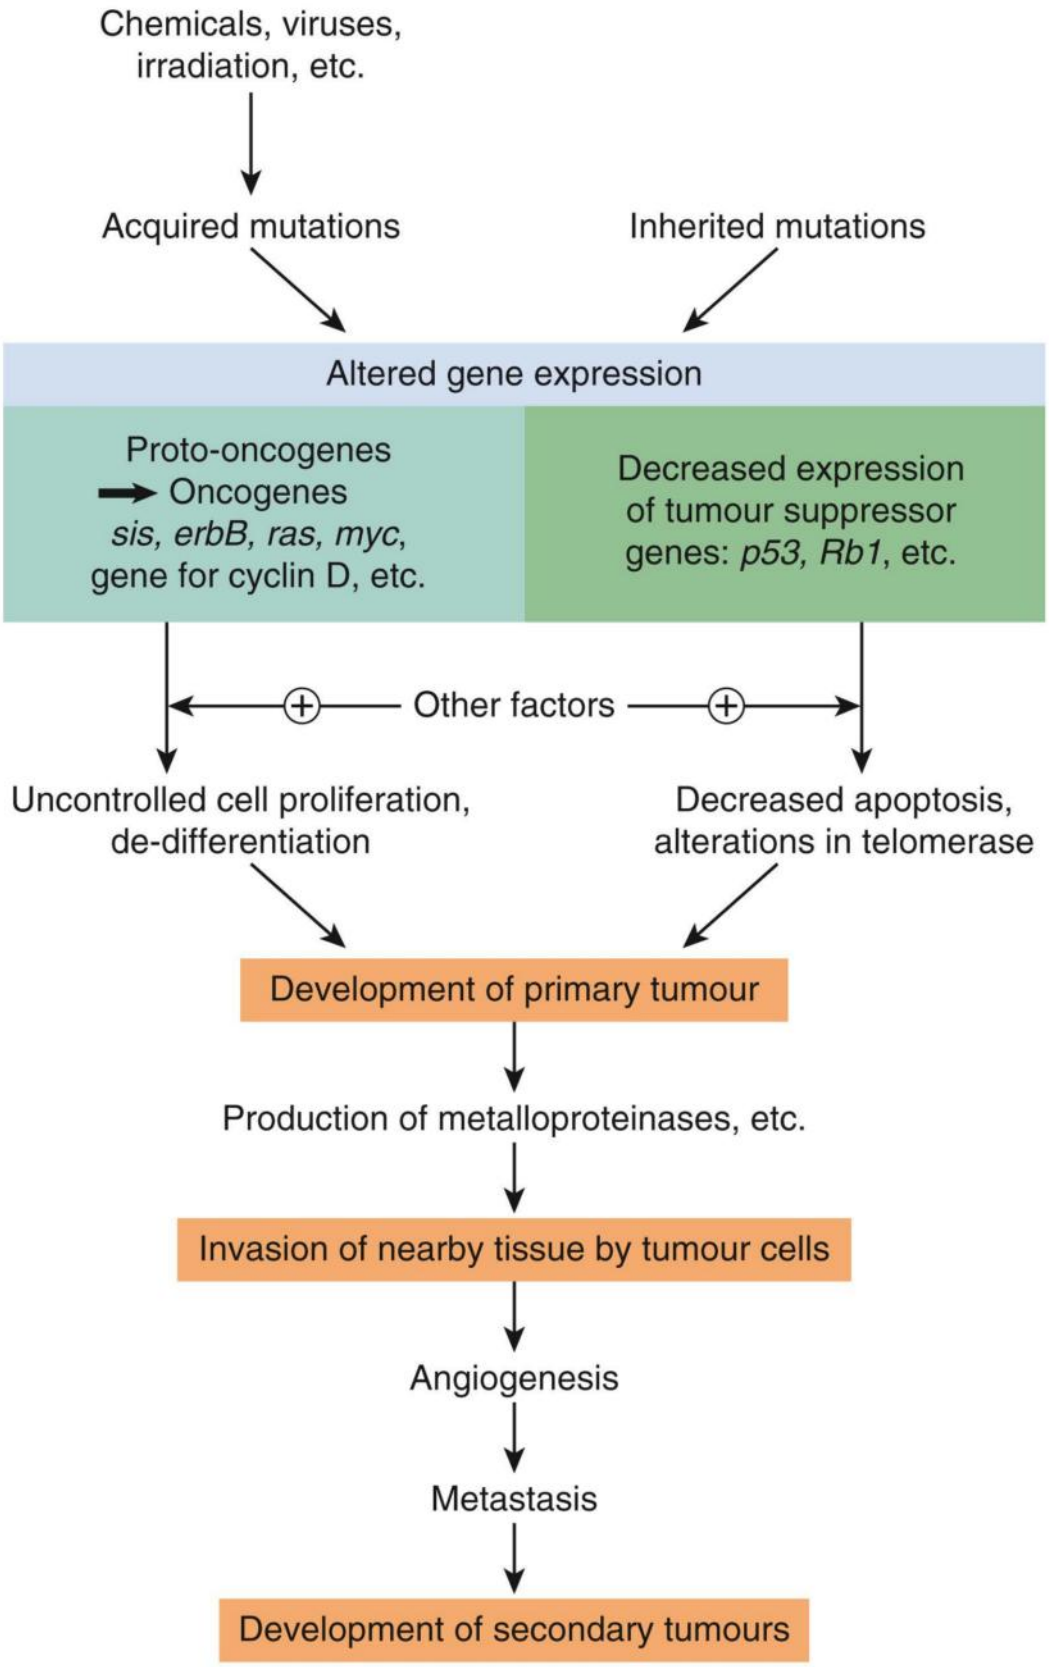
Invasiveness

Normal cells, other than those of the blood and lymphoid tissues, are not generally found outside their 'designated' tissue of origin. This is because, during differentiation and tissue or organ growth, they develop certain spatial relationships with respect to each other. These relationships are maintained by various tissue-specific survival factors that prevent apoptosis (see **Ch. 6**). In this way, any cells that escape accidently lose these survival signals and die.

For example, while the cells of the normal mucosal epithelium of the rectum proliferate continuously as the lining is shed, they remain as a lining epithelium. A cancer of the rectal mucosa, in contrast, invades other surrounding tissues. Cancer cells have not only lost, through mutation, the restraints that act on normal cells but also secrete enzymes (e.g. metalloproteinases; see **Ch. 6**) that break down the extracellular matrix, enabling them to move around.

Metastasis

Metastases are *secondary tumours* ('secondaries') formed by cells that have been released from the initial or *primary tumour* and which have reached other sites through blood vessels or lymphatics, by transportation on other cells or as a result of being shed into body cavities. Often, the primary tumour is asymptomatic and it is not until the cancer spreads that the secondary tumours cause symptoms leading to diagnosis of illness. As such, metastases are the principal cause of mortality and morbidity in most solid tumours and constitute a major problem for cancer therapy [4] (see **Chambers et al., 2002**).



Chemicals, viruses, irradiation, etc.
Acquired mutations
Inherited mutations
Altered gene expression
Proto-oncogenes
Oncogenes
sis, erbB, ras, myc, gene for cyclin D, etc.
Decreased expression of tumour suppressor genes: p53, Rb1, etc.
Other factors
Uncontrolled cell proliferation, de-differentiation
Decreased apoptosis, alterations in telomerase
Development of primary tumour
Production of metalloproteinases, etc.
Invasion of nearby tissue by tumour cells
Angiogenesis
Metastasis
Development of secondary tumours

FIG. 57.2 Simplified outline of the genesis of cancer.The diagram summarises the information given in the text. The genesis of cancer is usually multifactorial, involving more than one genetic change. 'Other factors', as specified above, may involve the actions of promoters, co-carcinogens, hormones, etc., which, while not themselves carcinogenic, increase the likelihood that genetic mutation(s) will result in cancer.

As discussed earlier, displacement or aberrant migration of normal cells would lead to programmed cell death as a result of withdrawal of the necessary antiapoptotic factors. Cancer cells that metastasise have undergone a series of genetic changes that alter their responses to the regulatory factors that control the cellular architecture of normal tissues, enabling them to establish themselves 'extraterritorially'. Tumour-induced angiogenic growth of new blood vessels locally favours metastasis.

Secondary tumours occur more frequently in some tissues than in others. For example, metastases of mammary cancers are often found in brain, lung, bone and liver. The reason for this is that breast cancer cells express chemokine receptors such as CXCR4 (see **Ch. 7** and **Hughes and Nibbs, 2018**) on their surfaces, and chemokines that recognise these receptors are expressed at high level in these tissues but not in others (e.g. kidney), facilitating the selective accumulation of cells at these sites, providing a microenvironmental niche for them to reside and thrive. Similarly, lung cancer most commonly spreads to brain, bone and adrenal gland; malignant melanoma to brain; colorectal and ovarian

tumours most commonly spread to liver and pancreatic cancer typically to liver and lung.

General Principles of Cytotoxic Anticancer Drugs

In experiments with rapidly growing transplantable leukaemias in mice, it has been found that a given therapeutic dose of a cytotoxic drug [5] destroys a constant fraction of the malignant cells. If used to treat a tumour with 10^{11} cells, a dose of drug that kills 99.99% of cells will still leave 10 million (10^7) viable malignant cells. As the same principle holds for fast-growing tumours in humans, schedules for chemotherapy are aimed at producing as near a total cell kill as possible because, in contrast to the situation that occurs in microorganisms, little reliance can be placed on the host's immunological defence mechanisms against the remaining cancer cells. If a tumour is removed (or at least *de-bulked*) surgically, any remaining *micro-metastases* are now more accessible to chemotherapy, hence its use as adjuvant therapy in these circumstances.

One of the major difficulties in treating cancer is that tumour growth is usually far advanced before cancer is diagnosed. Let us suppose that a tumour arises from a single cell and that the growth is exponential, as it may well be during the initial stages. 'Doubling' times vary, being, for example, approximately 24 h with Burkitt's lymphoma, 2 weeks in the case of some leukaemias, and 3 months with mammary cancers. Approximately 30 doublings would be required to produce a cell mass with a diameter of 2 cm, containing 10^9 cells. Such a tumour is within the limits of diagnostic

procedures, although it could easily go unnoticed. A further 10 doublings would produce 10^{12} cells, a tumour mass that is likely to be lethal, and which would measure about 20 cm in diameter if it were one solid mass.

However, continuous exponential growth of this sort does not usually occur. In the case of most solid tumours, as opposed to *leukaemias* (tumours of white blood cells), the growth rate falls as the neoplasm grows. This is partly because the tumour outgrows its blood supply, and partly because not all the cells proliferate continuously. The cells of a solid tumour can be considered as belonging to three compartments:

1. *Compartment A* consists of dividing cells, possibly being continuously in the cell cycle.
2. *Compartment B* consists of resting cells (G_0 phase) which, although not dividing, are potentially able to do so.
3. *Compartment C* consists of cells that are no longer able to divide but which contribute to the tumour volume.

Essentially, only cells in *compartment A*, which may form as little as 5% of some solid tumours, are susceptible to the main current cytotoxic drugs. The cells in *compartment C* do not constitute a problem, but the existence of *compartment B* makes cancer chemotherapy difficult, because these cells are not very sensitive to cytotoxic drugs and are liable to re-enter *compartment A* following chemotherapy.

Benign tumours can still grow (often more slowly) but are characteristically unable to metastasise and spread, and are thus considered much less dangerous to the individual. One example of

such is basal cell carcinoma (BCC) skin cancer which continues to expand but will not metastasise, unlike malignant melanoma skin cancer, which readily metastasises to threaten critical organs, such as the brain. BCC still has the potential to transform from its benign form into a malignant form, and kill. Some benign tumours such as colonic polyps have the potential to become malignant, and therefore need close monitoring and removal. Conversely, other benign tumours (such as uterine fibroids) have low risk of turning malignant, and do not need surgical removal unless there are symptoms of bleeding or local compression of other organs.

Most current anticancer drugs, particularly cytotoxic agents, affect only one characteristic aspect of cancer cell biology – cell division – but have no specific inhibitory effect on invasiveness, the loss of a differentiated phenotype or the tendency to metastasise. In many cases, the antiproliferative action results from an action during S phase of the cell cycle (see **Ch. 6**), and the resultant damage to DNA initiates apoptosis. Furthermore, because their main target is cell division, they will affect all rapidly dividing normal tissues, and therefore are likely to produce, to a greater or lesser extent, the following general toxic effects:

- *bone marrow toxicity* (myelosuppression) with decreased leukocyte production and thus decreased resistance to infection;
- *impaired wound healing*;
- *loss of hair* (alopecia);
- damage to GI *epithelium* (including oral mucous membranes);
- *depression of growth* in children;

- *sterility*;
- *teratogenicity*;
- *carcinogenicity* – because many cytotoxic drugs are mutagenic themselves.

Rapid cell destruction also entails extensive purine catabolism, and urates may precipitate in the renal tubules and cause kidney damage. Finally, in addition to specific toxic effects associated with individual drugs, virtually all cytotoxic drugs produce severe nausea and vomiting, an 'inbuilt deterrent' now thankfully largely overcome by modern antiemetic drug prophylaxis (see **Ch. 30**).

Cytotoxic drugs, along with surgery and radiotherapy, remain the mainstay of cancer treatment, but newer treatments based on targeting the specific malfunctions of cell cycle control that characterise cancer cells, and on increasing their susceptibility to immunological attack, are becoming increasingly important. These include hormone antagonists, kinase inhibitors and monoclonal antibodies – drugs that are not cytotoxic in the conventional sense, and have a different range of side effects. Described later, they herald a significant shift in pharmacological approaches to cancer treatment. Often these newer types of therapy are guided by the genomic profile of the cancer they target – a principle that is coming more and more into reality for most drugs aimed at treating cancer (see also **Ch. 12**).

Cancer pathogenesis and cancer chemotherapy: general principles

- Cancer arises as a result of a series of genetic and epigenetic changes, the main genetic lesions being:
  - inactivation of tumour suppressor genes;
  - the activation of oncogenes (mutation of the normal genes controlling cell division and other processes).
- Cancer cells have four characteristics that distinguish them from normal cells:
  - uncontrolled proliferation;
  - loss of function because of lack of capacity to differentiate;
  - local invasiveness;
  - the ability to metastasise.
- Cancer cells have uncontrolled proliferation often because of changes in:
  - growth factors and/or their receptors;
  - intracellular signalling pathways, particularly those controlling the cell cycle and apoptosis;
  - telomerase expression.
- Proliferation may be supported by tumour-related angiogenesis.
- Most anticancer drugs are antiproliferative – most damage DNA and thereby initiate apoptosis. They also affect rapidly dividing normal cells and are thus likely to depress bone marrow, impair healing and depress growth. Most cause nausea, vomiting, sterility, hair loss and teratogenicity.

Anticancer Drugs

The main anticancer drugs can be divided into the following general categories:

- *Cytotoxic drugs*. These include:
  - *alkylating agents* and related compounds, which act by forming covalent bonds with DNA and thus impeding its replication;
  - *antimetabolites*, which block or subvert one or more of the catabolic pathways involved in DNA synthesis;
  - *cytotoxic antibiotics*, i.e. substances of microbial origin that prevent mammalian cell division;
  - *plant derivatives* (e.g. vinca alkaloids, taxanes, camptothecins): most of these specifically affect microtubule function and hence the formation of the mitotic spindle.
- *Hormones*, especially steroids and their antagonists (see Chs **33** and **35**).
- *Protein kinase inhibitors* which inhibit growth factor receptor signal transduction (see **Krause and Van Etten, 2005**) and other non-proliferative effects of tyrosine kinases, such as cell adhesion.
- Monoclonal antibodies.
- Miscellaneous agents.

The clinical use of anticancer drugs is the province of the specialist, who selects treatment regimens appropriate to the patient with the objective of curing, prolonging life or providing palliative therapy. [6] There are hundreds of drugs available in the UK

for this purpose and they are often used in combination. The principal clinically used treatments are listed in **Table 57.1**. For reasons of space, we restrict our discussion of mechanisms of action to the more common examples from each group. Anticancer pharmacology is a rapidly expanding and changing field of new chemical entities (NCEs), with new drugs continuously being brought onto the market, and other drugs falling out of favour in the clinic. Further reading (**Goldberg and Airley, 2020**; **Sun et al., 2017**) provides more detailed information.

Table 57.1

ALK, Anaplastic lymphoma kinase; *AR,* androgen receptor; *BCMA*, B-cell maturation antigen; *BCR-A*, breakpoint cluster region protein-Abelson chimeric tyrosine kinase (Philadelphia chromosome); *BRAF*, B-Raf kinase; *BTK*, Bruton's tyrosine kinase; *CAR-T*, chimeric antigen receptor T-cell therapy *CCR*, chemokine receptor; *CD*, cluster of differentiation; *CDK*, cyclin-dependent kinases; *CRBN*, cereblon; *EGF,* epidermal growth factor; *EGFR*, EGF receptor; *EGP*, epithelial glycoprotein-1; *EpCAM,* epithelial cell adhesion molecule; *ER*, estrogenic receptor; *FGF*, fibroblast growth factor; *FGFR*, FGF receptor; *FLT3*, fms like tyrosine kinase 3; *FR*, folate receptor; *GR*; gonadotrophin-releasing hormone receptor; *HIF*, Hypoxia-inducible factor; *HSV*, herpes simplex virus; *IDH*, isocitrate dehydrogenase-1; *IFNAR*, interferon-α receptor; *ILxR*, interleukin-x receptor; *JAK*, Janus tyrosine kinase; *MEK*, MAP-kinase kinase; *MET*, protein tyrosine kinase; *MHC*, or histocompatibility complex; *PD*, programmed cell death protein; *PI3K*, phosphoinositide 3-kinase; *PR*, progesterone receptor; *PSA*, prostate specific antigen; *PSMB*, proteasome *RET*, receptor tyrosine kinase; β; *SHH*, Sonic hedgehog ligand; *SLAMF7*, surface antigen CD319; *SMO*, smoothened receptor of SHH; *SSR*, somatostatin receptor; *TGF*, transforming growth factor; *TLR7*, toll-like receptor-7; *TNFRSF*, tumour necrosis factor receptor super family; *TNFSF*, tumour necrosis factor super family;*VEGF,* vascular endothelial growth factor; *VEGFR*, VEGF receptor.

[a] A combination of oestrogen and chlormethine. Drugs in parentheses have similar pharmacological actions but are not

necessarily chemically related.

Alkylating Agents and Related Compounds

Alkylating agents and related compounds contain chemical groups that can form covalent bonds with particular nucleophilic substances in the cell (such as DNA). With alkylating agents themselves, the first step is the formation of a *carbonium ion* – a carbon atom with only six electrons in its outer shell. Such ions are highly reactive and react instantaneously with an electron donor such as an amine, hydroxyl or sulfhydryl group. Most of the cytotoxic anticancer alkylating agents are *bifunctional*, i.e. they have two alkylating groups (**Fig. 57.3**).

The nitrogen at position 7 (N7) of guanine, being strongly nucleophilic, is probably the main molecular target for alkylation in DNA (see **Fig. 57.3**), although N1 and N3 of adenine and N3 of cytosine may also be affected. A bifunctional agent, by reacting with two groups, can cause intra- or inter-chain cross-linking. This interferes and prevents not only with transcription, but also with DNA replication, which is probably the critical effect of anticancer alkylating agents.

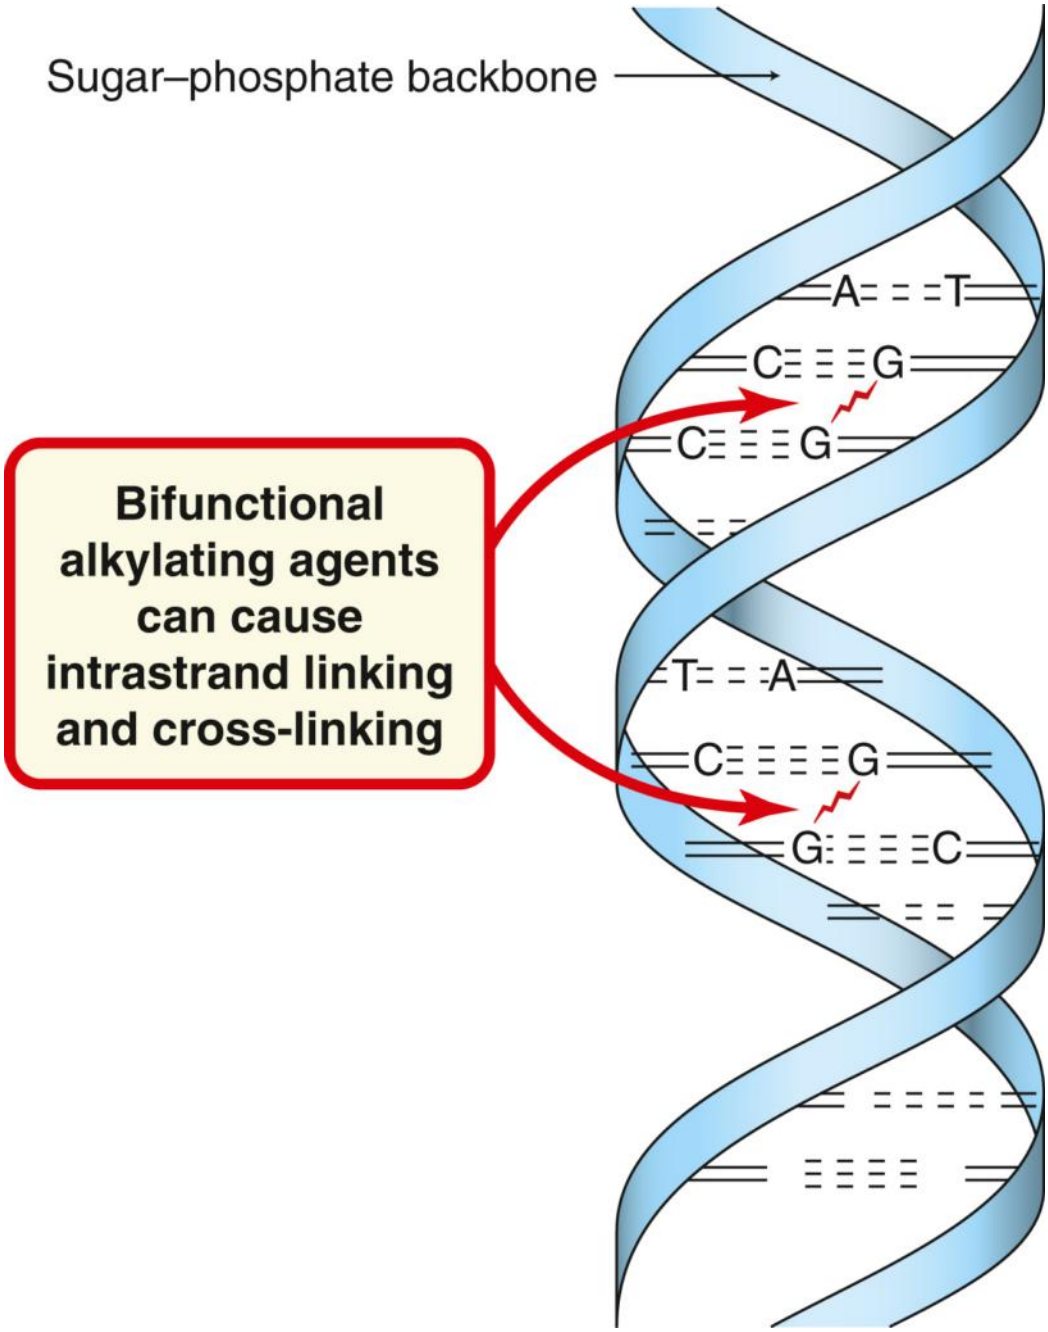


FIG. 57.3 The effects of bifunctional alkylating agents on DNA.Note the cross-linking of two guanines. *A*, Adenine; *C*, cytosine; *G*, guanine; *T*, thymine.

All alkylating agents depress bone marrow function and cause hair loss and diarrhoea. Depression of gametogenesis, leading to sterility, and an increased risk of a second malignancy occur with prolonged use.

Alkylating agents are among the most commonly employed of all anticancer drugs. Only a few commonly used examples will be dealt with here.

Nitrogen mustards

Nitrogen mustards are related to the 'mustard gas' used during the First World War [7] ; their basic formula (R-*N*-*bis*-[2-chloroethyl]) is shown in **Fig. 57.4**. In the body, each 2-chloroethyl side-chain undergoes an intramolecular cyclisation with the release of a Cl^-. The highly reactive *ethylene immonium* derivative so formed can interact with DNA (see Figs **57.3** and **57.4**) and other molecules.

Cyclophosphamide is a commonly used alkylating agent. It is inactive until metabolised in the liver by the P450 mixed function oxidases (see **Ch. 10**). It has a pronounced effect on lymphocytes and can also be used as an immunosuppressant (see **Ch. 25**). It is given orally or by intravenous injection. Important toxic effects are nausea and vomiting, bone marrow depression and haemorrhagic cystitis. This last effect (which also occurs with the related drug **ifosfamide**) is caused by the metabolite acrolein and can be ameliorated by increasing fluid intake and administering compounds that are sulfhydryl donors, such as **N-acetylcysteine** or **mesna** (sodium-2-mercaptoethane sulfonate). These agents react with acrolein, to then form a non-toxic compound. (See also Chs **10** and **58**.)

Other nitrogen mustards used include **bendamustine**, ifosfamide, **chlorambucil** and **melphalan**. **Estramustine** is a combination of **chlormethine** (mustine) with an oestrogen. It has both cytotoxic and hormonal action and is used for the treatment of prostate cancer.

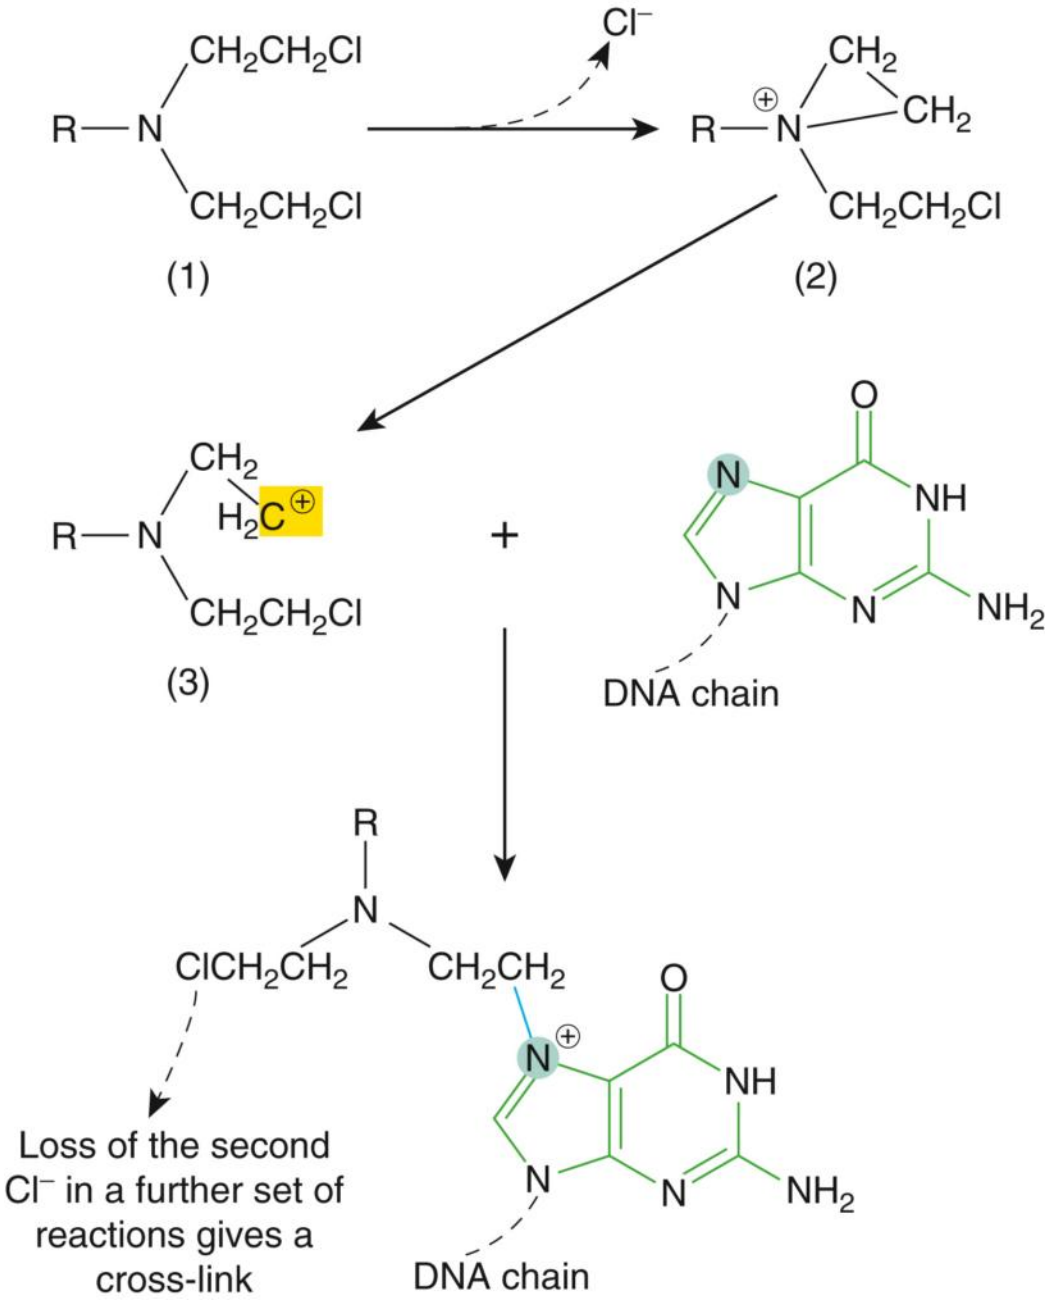

FIG. 57.4 An example of alkylation and cross-linking of DNA by a nitrogen mustard.A bis(chloroethyl)amine *(1)* undergoes intramolecular cyclisation, forming an unstable ethylene immonium cation *(2)* and releasing Cl^-, the tertiary amine being transformed to a

quaternary ammonium compound. The strained ring of the ethylene immonium intermediate opens to form a reactive carbonium ion (in *yellow box*) *(3)*, which reacts immediately with N7 of guanine (in *green circle*) to give 7-*alkylguanine* (bond shown in *blue*), the N7 being converted to a quaternary ammonium nitrogen. These reactions can then be repeated with the other $–CH_2CH_2Cl$ to give a cross-link.

Nitrosoureas

Examples include **lomustine** and **carmustine**. As they are lipid soluble and cross the blood–brain barrier, they are used to treat tumours of the brain and meninges. However, most nitrosoureas have a severe cumulative depressive effect on the bone marrow that starts 3–6 weeks after initiation of treatment.

Other alkylating agents

Busulfan has a selective effect on the bone marrow, depressing the formation of granulocytes and platelets in low dosage and of red cells in higher dosage. It has little or no effect on lymphoid tissue or the GI tract. It is used in chronic myeloid leukaemia (CML) and myelodysplastic syndromes, and also in patients with other haematological cancers before they undergo stem cell or bone marrow transplants

Dacarbazine, a prodrug, is activated in the liver, and the resulting compound is subsequently cleaved in the target cell to release an alkylating derivative. Unwanted effects include

myelotoxicity and severe nausea and vomiting. **Temozolomide** is a related compound with a restricted usage (malignant glioma).

Procarbazine inhibits DNA and RNA synthesis and interferes with mitosis at interphase. Its effects may be mediated by the production of active metabolites. It is given orally, and its main use is in Hodgkin's disease. It causes **disulfiram**-like actions with alcohol (see **Ch. 50**), exacerbates the effects of central nervous system depressants and, because it is a weak monoamine oxidase inhibitor, can produce hypertension if given with certain sympathomimetic agents (see **Ch. 48**). Other alkylating agents in clinical use include **hydroxycarbamide**, **mitobronitol**, **thiotepa** and **treosulfan**.

Platinum compounds

Cisplatin is a water-soluble planar coordination complex containing a central platinum atom surrounded by two chlorine atoms and two ammonia groups. Its action is analogous to that of the alkylating agents. When it enters the cell, Cl^- dissociates, leaving a reactive complex that reacts with water and then interacts with DNA. It causes intrastrand cross-linking, probably between N7 and O6 of adjacent guanine molecules, which results in local denaturation of DNA.

Cisplatin is clinically useful across a wide range of tumours, and is particularly important for solid tumours of the testes and ovary. Therapeutically, it is given by slow intravenous injection or infusion. It is seriously nephrotoxic, and strict regimens of hydration and diuresis must be instituted. It has low myelotoxicity but causes very severe nausea and vomiting which is best managed

through prophylactic use of various combinations of antiemetic drugs (see below and **Ch. 30**). Tinnitus and hearing loss in the high-frequency range may occur, as may peripheral neuropathies, hyperuricaemia and anaphylactic reactions.

The newer cisplatin derivatives (**carboplatin** and **oxaliplatin)** are considered to have different patterns of toxicity and are potentially easier to administer because they are less likely to cause nephrotoxicity.

Anticancer drugs: alkylating agents and related compounds

- Alkylating agents have groups that form covalent bonds with cell substituents; a carbonium ion is the reactive intermediate. Most have two alkylating groups and can cross-link DNA. This causes defective replication and chain breakage.
- Their principal effect occurs during DNA synthesis and the resulting damage triggers apoptosis.
- Unwanted effects include myelosuppression, sterility and risk of non-lymphocytic leukaemia.
- The main alkylating agents are:
  - nitrogen mustards, for example **cyclophosphamide**, which is converted to phosphoramide mustard (the cytotoxic molecule); **cyclophosphamide** myelosuppression affects particularly the lymphocytes.
  - nitrosoureas, for example **lomustine**, may act on non-dividing cells, can cross the blood–brain barrier and

cause delayed, cumulative myelotoxicity.

- Platinum compounds (e.g. **cisplatin**) cause intrastrand linking in DNA. **Cisplatin** has low myelotoxicity but causes severe nausea and vomiting, and carries high risk of nephrotoxicity.

Antimetabolites

Folate antagonists

The main folate antagonist in cancer chemotherapy is **methotrexate** (see also **Ch. 25** for its use as an immunosuppressant in rheumatology). Folates are essential for the synthesis of purine nucleotides and thymidylate, which in turn are essential for DNA synthesis and cell division. (This topic is also dealt with in Chs 24, **51** and **55**.) The main action of the folate antagonists is to interfere with thymidylate synthesis. Folates consist of three elements: a pteridine ring, *p*-aminobenzoic acid and glutamic acid; methotrexate is structurally closely related (**Fig. 57.5**). Its effect on thymidylate synthesis is summarised in **Fig. 57.6**.

Methotrexate is usually given orally but can also be given intramuscularly, intravenously or intrathecally. It has low lipid solubility and thus does not readily cross the blood–brain barrier. It is, however, actively taken up into cells by the folate transport system and is metabolised to polyglutamate derivatives, which are retained in the cell for weeks or months even in the absence of continued extracellular drug. Resistance to methotrexate may develop in tumour cells by a variety of mechanisms.

Unwanted effects include depression of the bone marrow and damage to the epithelium of the GI tract. Pneumonitis can occur. In addition, high-dose regimens – doses 10 times greater than the standard doses, sometimes used in patients with methotrexate resistance – can lead to nephrotoxicity. This is caused by precipitation of the drug or a metabolite in the renal tubules. High-dose regimens must be followed by 'rescue' with folinic acid (a form of FH_4).

Also chemically related to folate are **raltitrexed**, which inhibits thymidylate synthetase, and **pemetrexed**, which inhibits thymidylate transferase.

Pyrimidine analogues

Fluorouracil, an analogue of uracil, also interferes with 2′-deoxythymidylate (dTMP) synthesis (see **Fig. 57.6**). It is converted into a 'fraudulent' nucleotide, *fluorodeoxyuridine monophosphate* (FdUMP). This interacts with thymidylate synthetase but cannot be converted into dTMP. The result is inhibition of DNA but not RNA or protein synthesis.

Fluorouracil is usually given parenterally, but it can be delivered in a more convenient oral formulation using its oralpro-drugs, **capecitabine** and **tegafur**. The main unwanted effects are GI epithelial damage and myelotoxicity. Cerebellar disturbances can also occur. Pharmacogenetic testing is recommended for patients receiving these agents so that treatment adjustments can be made based on metaboliser status and risk of toxicity (see **Ch. 12**).

Cytarabine (cytosine arabinoside (ara-C)) is an analogue of the naturally occurring nucleoside 2′-deoxycytidine. The drug enters the

target cell and undergoes the same phosphorylation reactions as the endogenous nucleoside to give cytosine arabinoside trisphosphate, which inhibits DNA polymerase (**Fig. 57.7**). The main unwanted effects are on the bone marrow and the GI tract.

Gemcitabine, an analogue of cytarabine, has fewer unwanted actions, the main ones being an influenza-like syndrome and mild myelotoxicity. It is often given in combination with other drugs such as cisplatin. **Azacitidine** and **decitabine** inhibit DNA methylase.

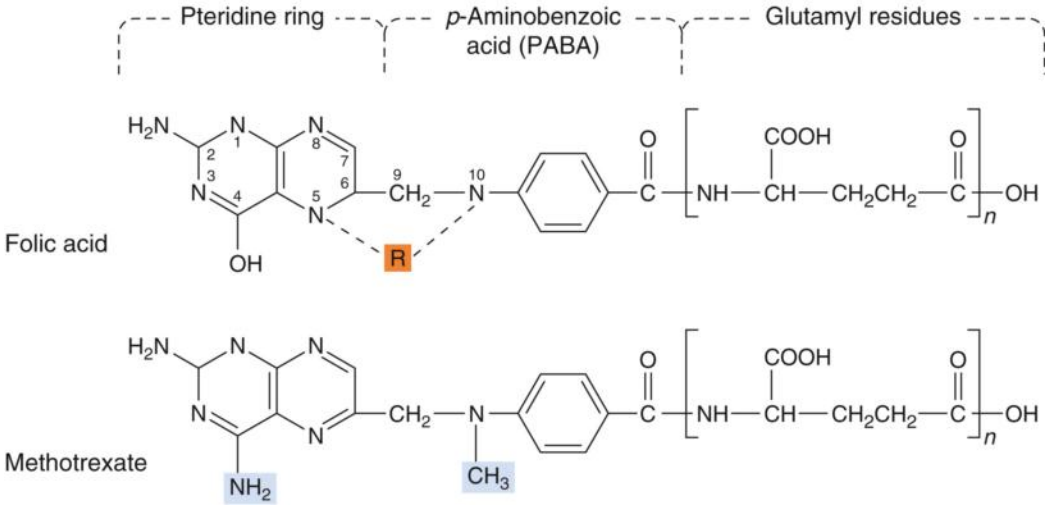

FIG. 57.5 Structure of folic acid and methotrexate.Both compounds are shown as polyglutamates. In tetrahydrofolate, one-carbon groups (R, in *orange box*) are transported on N5 or N10 or both (shown *dotted*). The points at which methotrexate differs from endogenous folic acid are shown in the *blue boxes*.

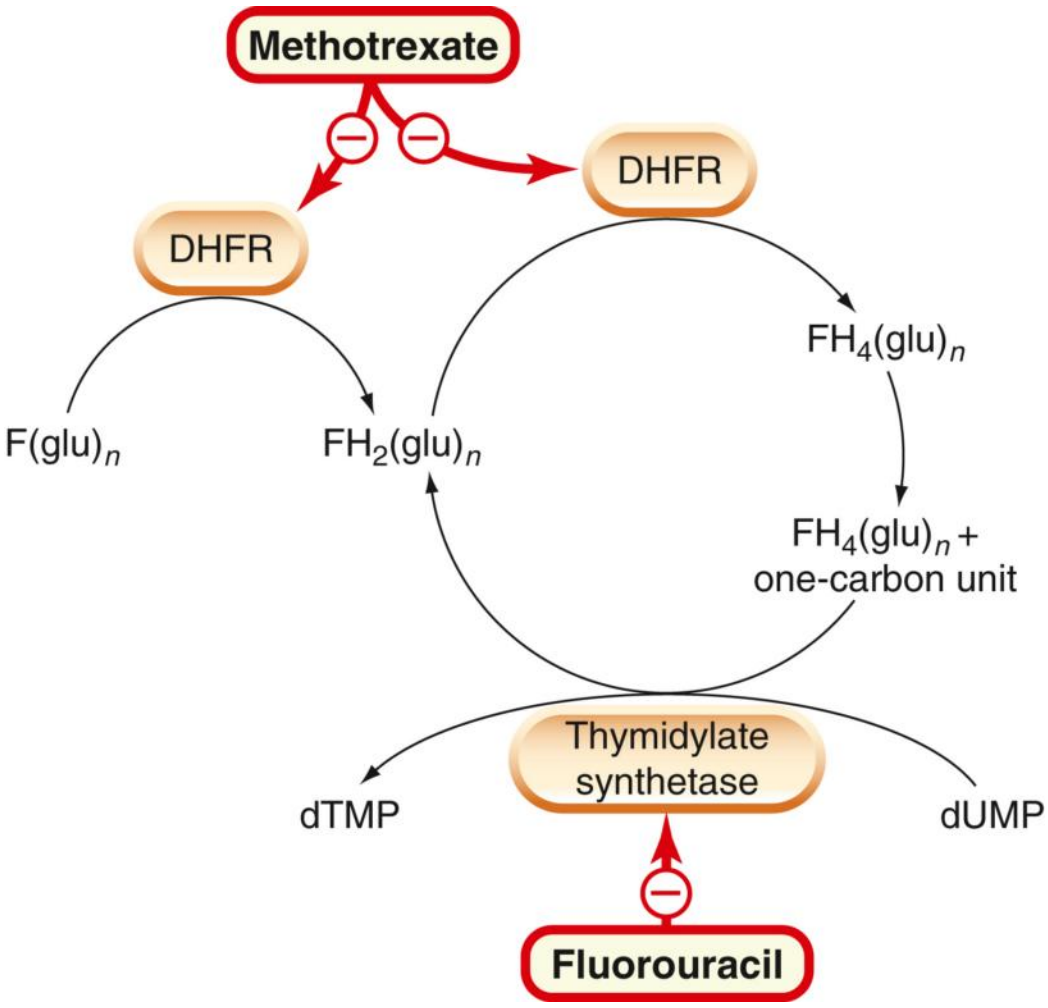

FIG. 57.6 Simplified diagram of action of methotrexate and fluorouracil on thymidylate synthesis.Tetrahydrofolate polyglutamate $FH_4(glu)_n$ functions as a carrier of a one-carbon unit, providing the methyl group necessary for the conversion of 2′-deoxyuridylate (dUMP) to 2′-deoxythymidylate (dTMP) by *thymidylate synthetase*. This one-carbon transfer results in the oxidation of $FH_4(glu)_n$ to $FH_2(glu)_n$. Fluorouracil is converted to FdUMP, which

inhibits thymidylate synthetase. *DHFR,* Dihydrofolate reductase.

Purine analogues

The main anticancer purine analogues include cladribine, clofarabine, fludarabine, pentostatin, nelarabine, mercaptopurine and thioguanine.

Fludarabine is metabolised to the trisphosphate and inhibits DNA synthesis by actions similar to those of cytarabine. It is myelosuppressive. Pentostatin has a different mechanism of action. It inhibits adenosine deaminase, the enzyme that transforms adenosine to inosine. This action interferes with critical pathways in purine metabolism and can have significant effects on cell proliferation. Cladribine, mercaptopurine and thioguanine (tioguanine) are used mainly in the treatment of leukaemia.

Anticancer drugs: antimetabolites

Antimetabolites block or subvert pathways of DNA synthesis.

- *Folate antagonists*. **Methotrexate** inhibits dihydrofolate reductase, preventing generation of tetrahydrofolate interfering with thymidylate synthesis.
- *Pyrimidine analogues*. **Fluorouracil** is converted to a 'fraudulent' nucleotide and inhibits thymidylate synthesis. **Cytarabine** in its trisphosphate form inhibits DNA polymerase. They are potent myelosuppressives.

- *Purine analogues*. **Mercaptopurine** is converted into fraudulent nucleotide. **Fludarabine** in its trisphosphate form inhibits DNA polymerase and is myelosuppressive. **Pentostatin** inhibits adenosine deaminase – a critical pathway in purine metabolism.

Cytotoxic Antibiotics

This is a widely used group of drugs that mainly produce their effects through direct action on DNA. As a rule, they should not be given together with radiotherapy, as the cumulative burden of toxicity is very high.

Doxorubicin and the anthracyclines

Doxorubicin, **idarubicin**, **daunorubicin** and **epirubicin** are widely used anthracycline antibiotics; **mitoxantrone** (**mitozantrone**) is a derivative.

Doxorubicin has several cytotoxic actions. It binds to DNA and inhibits both DNA and RNA synthesis, but its main cytotoxic action appears to be mediated through an effect on topoisomerase II (a DNA gyrase; see **Ch. 51**), the activity of which is markedly increased in proliferating cells. During replication of the DNA helix, reversible swivelling needs to take place around the replication fork in order to prevent the daughter DNA molecule becoming inextricably entangled during mitotic segregation. The 'swivel' is produced by topoisomerase II, which 'nicks' both DNA strands and subsequently reseals the breaks. Doxorubicin intercalates in the DNA, and its effect is, in essence, to stabilise the DNA–topoisomerase II complex

after the strands have been nicked, thus halting the process at this point.

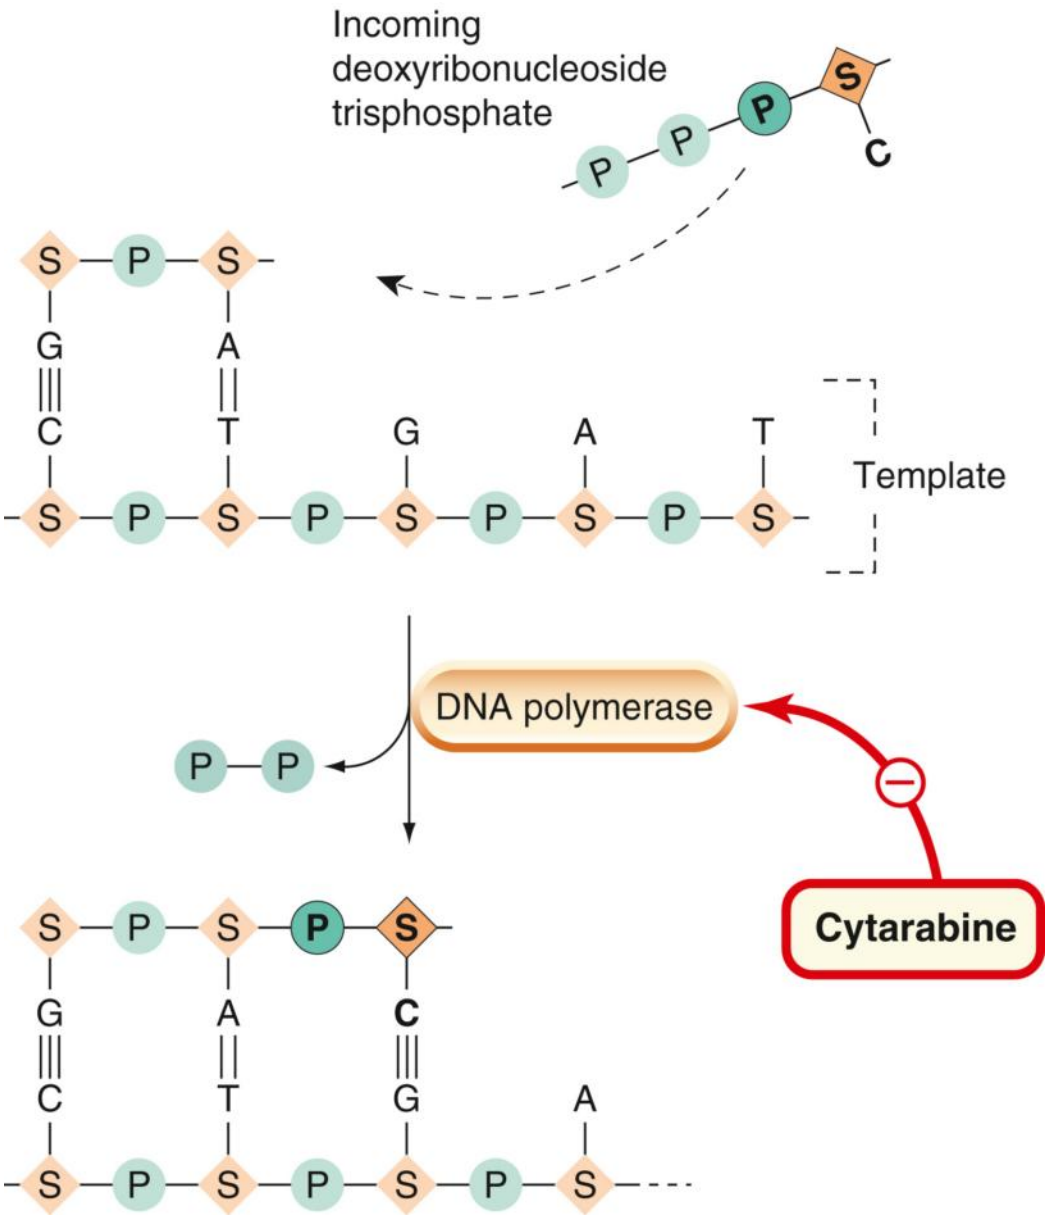

FIG. 57.7 The mechanism of action of cytarabine (cytosine arabinoside).For details of DNA polymerase action, see Fig. 51.5. *Cytarabine* is an analogue of cytosine.

Doxorubicin is given by intravenous infusion. Extravasation at the injection site can cause local necrosis. The anthracyclines as a class a have very serious dose-related adverse effects on the heart, resulting in dysrhythmias and heart failure. This action may be the result of generation of iron-dependent free radical oxidative stress, as well as inhibition of topoisomerase 2β. Cardiac toxicity can be reduced through careful monitoring, limiting the maximal dose and prophylactic use of dexrazoxane (which binds metal ions) in high-risk patients.

Dactinomycin

Dactinomycin intercalates in the minor groove of DNA between adjacent guanosine–cytosine pairs, interfering with the movement of RNA polymerase along the gene and thus preventing transcription. There is also evidence that it has a similar action to that of the anthracyclines on topoisomerase II. It produces most of the toxic effects outlined previously, except cardiotoxicity. It is mainly used for treating paediatric cancers.

Bleomycins

The bleomycins are a group of metal-chelating glycopeptide antibiotics that degrade preformed DNA, causing chain fragmentation and release of free bases. This action is thought to involve chelation of ferrous iron and interaction with oxygen, resulting in the oxidation of the iron and generation of superoxide and/or hydroxyl radicals. **Bleomycin** is most effective in the G_2 phase of the cell cycle and mitosis, but it is also active against non-dividing cells (i.e. cells in the G_0 phase; **Ch. 6**, **Fig. 6.4**). It is often used to treat germline cancer. In contrast to most anticancer drugs,

bleomycin causes little myelosuppression: its most serious toxic effect is pulmonary fibrosis, which occurs in 10% of patients treated and is reported to be fatal in 1%. Allergic reactions can also occur. About half the patients manifest mucocutaneous reactions (the palms are frequently affected), and many develop hyperpyrexia.

Mitomycin

Following enzymic activation, **mitomycin** functions as a bifunctional alkylating agent, binding preferentially at O6 of the guanine nucleus. It cross-links DNA and may also degrade DNA through the generation of free radicals. It causes marked delayed myelosuppression and can also cause kidney damage and fibrosis of lung tissue.

Anticancer drugs: cytotoxic antibiotics

- **Doxorubicin** inhibits DNA and RNA synthesis; the DNA effect is mainly through interference with topoisomerase II action. Unwanted effects include nausea, vomiting, myelosuppression and hair loss. The major problem is cardiotoxicity with high cumulative doses.
- **Bleomycin** causes fragmentation of DNA chains. It acts on non-dividing cells. Unwanted effects include fever, allergies, mucocutaneous reactions and pulmonary fibrosis. There is virtually no myelosuppression.
- **Dactinomycin** intercalates in DNA, interfering with RNA polymerase and inhibiting transcription. It also interferes

with the action of topoisomerase II. Unwanted effects include nausea, vomiting and myelosuppression.

- **Mitomycin** is activated to give an alkylating metabolite.

Plant Derivatives

As with all branches of pharmacology, several naturally occurring plant products exert potent cytotoxic effects and have a use as anticancer drugs.

Vinca alkaloids

The vinca alkaloids are derived from the Madagascar periwinkle (*Catharanthus roseus*). The principal members of the group are **vincristine**, **vinblastine** and **vindesine**. **Vinflunine**, a fluorinated vinca alkaloid, and **vinorelbine** are semisynthetic vinca alkaloids with similar properties. The drugs bind to tubulin and inhibit its polymerisation into microtubules, preventing spindle formation in dividing cells and causing arrest at metaphase. Their effects become manifest only during mitosis. They also inhibit other cellular activities that require functioning microtubules, such as leukocyte phagocytosis and chemotaxis, as well as axonal transport in neurons.

As you would expect, the adverse effects of vinca alkaloids differ from other anticancer drugs. Vincristine has very mild myelosuppressive activity but is neurotoxic and commonly causes *paraesthesia* (sensory changes), abdominal pain and weakness. Vinblastine is less neurotoxic but causes leukopenia, while

vindesine has both moderate myelotoxicity and neurotoxicity. All members of the group can cause reversible hair loss.

Paclitaxel and related compounds

These *taxanes* are derived from a naturally occurring compound found in the bark of the Pacific yew tree (*Taxus* spp.). The group includes **paclitaxel** and the semisynthetic derivatives **docetaxel** and **cabazitaxel**. These agents act on microtubules, stabilising them (in effect 'freezing' or 'trapping' them) in the polymerised state, achieving a similar effect to that of the vinca alkaloids. These drugs are usually given by intravenous infusion. They are generally used to treat breast and lung cancer, and paclitaxel, given with carboplatin, is the treatment of choice for ovarian cancer.

Unwanted effects, which can be serious, include bone marrow suppression and cumulative neurotoxicity. Resistant fluid retention (particularly oedema of the legs) can occur with docetaxel. Hypersensitivity to these compounds is common and requires pretreatment with corticosteroids and antihistamines.

Camptothecins

The camptothecins **irinotecan** and **topotecan**, isolated from the stem of the tree *Camptotheca acuminata*, bind to and inhibit topoisomerase I, high levels of which are present throughout the cell cycle. Diarrhoea and reversible bone marrow depression occur but, in general, these alkaloids have fewer unwanted effects than most other anticancer agents.

Etoposide

Etoposide is derived from mandrake root (*Podophyllum peltatum*). Its mode of action is not clearly known, but it may act by inhibiting mitochondrial function and nucleoside transport, as well as having an effect on topoisomerase II similar to doxorubicin. *Unwanted effects* include nausea and vomiting, myelosuppression and hair loss.

Compounds from marine sponges. Eribulin and trabectedin are naturally occurring compounds from marine sponges. Eribulin's main inhibitory action on cell division is through inhibition of microtubule function and it is used for the treatment of advanced breast cancer. **Trabectedin** also disrupts DNA but utilises a superoxide-related mechanism. It is used for treatment of soft-tissue sarcoma, as well as ovarian cancer.

Anticancer drugs: plant derivatives

- **Vincristine** (and related alkaloids) inhibits mitosis at metaphase by binding to tubulin. It is relatively non-toxic but can cause unwanted neuromuscular effects.
- **Etoposide** inhibits DNA synthesis by an action on topoisomerase II and also inhibits mitochondrial function. Common unwanted effects include vomiting, myelosuppression and alopecia.
- **Paclitaxel** (and other taxanes) stabilise microtubules, inhibiting mitosis; it is relatively toxic and hypersensitivity reactions occur.
- **Irinotecan** and **topotecan** inhibit topoisomerase I. Acute cholinergic syndrome can occur with irinotecan.

Hormones

All tissues are sensitive to hormonal actions, but tumours arising in the more hormone-sensitive tissues (e.g. breast, uterus, prostate gland) may be fundamentally *hormone dependent*, an effect related to the enhanced presence of hormone receptors in those malignant cells, gauged by the receptors present in screened biopsy samples. Crucially, their growth can be inhibited by hormone agonists or antagonists, or by agents that inhibit the synthesis of the hormone.

Hormones or their analogues that have inhibitory actions on target tissues can be used in treatment of tumours of those tissues. Such procedures alone rarely effect a cure but do retard tumour growth and mitigate the symptoms of the cancer, and thus play an important part in the clinical management of sex hormone-dependent tumours.

Glucocorticoids

Glucocorticoids such as **prednisolone** have marked inhibitory effects on lymphocyte proliferation (see Chs **25** and **33**) and are used in the treatment of leukaemias and lymphomas. The ability of **dexamethasone** to lower raised intracranial pressure is exploited in treating patients with brain tumours. Glucocorticoids mitigate some of the side effects of anticancer drugs, such as nausea and vomiting, making them useful as supportive co-therapies when treating other cancers, as well as in palliative care.

Oestrogens

Diethylstilboestrol and **ethinyloestradiol** are still occasionally used in the palliative treatment of androgen-dependent prostatic tumours. These tumours can also be treated with gonadotrophin-releasing hormone analogues (see **Ch. 33**).

Progestogens

Progestogens such as **megestrol**, **norethisterone** and **medroxyprogesterone** have a role in treatment of endometrial cancer.

Gonadotrophin-releasing hormone analogues

As explained in **Chapter 35**, analogues of the gonadotrophin-releasing hormones, such as **goserelin**, **buserelin**, **leuprorelin** and **triptorelin**, can, when administered chronically, inhibit gonadotrophin release. These agents are therefore used to treat advanced breast cancer in premenopausal women and prostate cancer. The effect of the transient surge of testosterone secretion that can occur in patients treated in this way for prostate cancer must be prevented by an antiandrogen such as **cyproterone**. **Degarelix** is a gonadotrophin-releasing hormone antagonist used for the treatment of prostate cancer.

Somatostatin analogues

Analogues of somatostatin such as **octreotide** and **lanreotide** (see **Ch. 33**) are used to relieve the symptoms of neuroendocrine tumours, including hormone-secreting tumours of the GI tract such as VIPomas, glucagonomas, carcinoid tumours and gastrinomas. These tumours express somatostatin receptors, activation of which inhibits cell proliferation as well as hormone secretion.

Hormone Antagonists

In addition to the hormones themselves, hormone antagonists can also be effective in the treatment of several types of hormone-sensitive tumours.

Antioestrogens

An antioestrogen, **tamoxifen**, is effective in some cases of hormone-dependent breast cancer and may have a role in preventing these cancers. In breast tissue, tamoxifen competes with endogenous oestrogens for the oestrogen receptors (ERs) and therefore inhibits the transcription of oestrogen-responsive genes. Tamoxifen has less disruptive effects due to it being a partial agonist at the ER types found in endometrium, bone and the cardiovascular system. Other ER antagonists include **toremifene** and **fulvestrant**.

Unwanted effects are similar to those experienced by women following the menopause. Potentially more serious are hyperplastic events in the endometrium, which may progress to malignant changes, and the risk of thromboembolism. Drugs such as **raloxifene** are known as selective oestrogen receptor modulators (SERMs), meaning they have a mixture of both agonistic and antagonistic properties at the ER combinations in different tissues. For example it can be oestrogenic in bone (preventing osteoporosis) and simultaneously be anti-oestrogenic in breast and uterine tissue, if it is desirable to prevent oestrogen's positive effects in breast and uterine cancer treatment.

Aromatase inhibitors such as **anastrozole**, **letrozole** and **exemestane**, which suppress the synthesis of oestrogen from

androgens in the adrenal cortex (but not in the ovary), are also effective in the treatment of breast cancer in postmenopausal (but not in premenopausal) women, in whom they are somewhat more effective than tamoxifen.

Antiandrogens

The androgen antagonists **flutamide**, **cyproterone** and **bicalutamide** may be used either alone or in combination with other agents to treat tumours of the prostate. They are also used to control the testosterone surge ('flare') that is seen when treating patients with gonadorelin analogues. Degarelix does not cause this flare. An interesting gene in prostate cancer is the transmembrane protease, serine 2 (TMPRSS2) gene that is up-regulated by androgenic hormones and down-regulated in androgen-independent prostate cancers. Some viruses such as SARS-CoV-2 use the TMPRSS2 protease activity to enter and infect their host cells.

Anticancer agents: hormones

Hormones or their antagonists are used in hormone-sensitive tumours:

- **Glucocorticoids** for leukaemias and lymphomas.
- **Tamoxifen** for breast tumours.
- **Gonadotrophin-releasing hormone analogues** for prostate and breast tumours.
- **Antiandrogens** for prostate cancer.
- **Aromatase inhibitors** for postmenopausal breast cancer.

Monoclonal Antibodies

Monoclonal antibodies (see **Ch. 5**) are relatively recent additions to the anticancer armamentarium and are becoming a whole new class of go-to drugs in cancer treatment. [8] In some cases, binding of the antibody to its target activates the host's immune mechanisms and the cancer cell is killed by complement-mediated lysis or by killer T cells (see **Ch. 7**). Other monoclonal antibodies attach to and inactivate growth factors or their receptors on cancer cells, thus inhibiting the survival pathway and promoting apoptosis (see **Ch. 6**, **Fig. 6.5**). Unlike most of the cytotoxic drugs described earlier, they offer the prospect of a more highly targeted therapy without many of the side effects of conventional chemotherapy. This advantage is offset in most instances as they are often given in combination with more traditional drugs. More than 50 separate anticancer monoclonals are currently used clinically (see **Table 57.1**). Their high costs of development and manufacture are still significant problems. Here are some key examples of the monoclonals used to treat cancer.

Rituximab

Rituximab is a monoclonal antibody (mAb) that is used (in combination with other chemotherapeutic agents) for treatment of certain types of *lymphoma*, including non-Hodgkin's lymphoma. It lyses B lymphocytes by binding to the calcium-channel forming CD20 protein and activating complement. It also sensitises resistant cells to other chemotherapeutic drugs. It provides progression-free survival in 40%–50% of cases when combined with standard chemotherapy (in the clinic called **R-CHOP**; rituximab–

cyclophosphamide, hydroxydaunorubicin (doxorubicin), oncovin (vincristine) plus prednisolone).

Rituximab is given by infusion, and its elimination half-life is approximately 3–4 weeks.

Unwanted effects include hypotension, chills and fever during the initial infusions and subsequent hypersensitivity reactions. A cytokine release reaction can occur and has been fatal. Rituximab (like several common anticancer drugs) may exacerbate cardiovascular disorders.

Alemtuzumab is another mAb that lyses B lymphocytes, and is used in the treatment of resistant chronic lymphocytic leukaemia. It may also cause a similar cytokine release reaction to that with rituximab. **Ofatumumab** is similar. **Brentuximab** additionally targets T cells but in a different manner. It is a conjugate of a cytotoxic drug attached to an antibody that binds to CD30 on malignant cells. It is used to treat *Hodgkin's lymphoma.*

HER2-receptor antibodies

Trastuzumab (Herceptin) is a humanised murine mAb that binds to an oncogenic protein termed *HER2* (the human epidermal growth factor receptor (EGFR) 2), a member of the wider family of receptors with integral tyrosine kinase activity (see **Fig. 57.1**). There is some evidence that, in addition to inducing host immune responses, trastuzumab induces cell cycle inhibitors p21 and p27 (see **Ch. 6**, **Fig. 6.2**). Immunological studies are conducted on breast tumour tissue to identify the roughly one in five breast cancers that overexpress this receptor and proliferate rapidly. Trastuzumab and related antibodies (e.g. pertuzumab,

margetuximab) have demonstrable efficacy in various stages of HER2-positive breast cancer. However, heart failure is a recognised adverse effect that requires careful monitoring during chemotherapy with these agents.

Two mechanistically related compounds are **cetuximab** and **panitumumab**, which bind to EGFRs (also overexpressed in a high proportion of tumours). They are used for the treatment of colorectal cancer usually in combination with other agents.

Bevacizumab

Bevacizumab is a humanised mAb that is used for the treatment of colorectal cancer and now used in a wide range of other cancers. It neutralises *VEGF* (vascular endothelial growth factor), thereby preventing the angiogenesis that is crucial to tumour survival. It is administered by intravenous infusion and is generally combined with other agents. Bevacizumab and other related VEGF inhibitors are also given by direct injection into the eye to retard the progression of wet-*acute macular degeneration* and other pathologies associated with ocular neovascularisation (see **Ch. 27**).

Catumaxomab

Catumaxomab attaches to an epithelial adhesion molecule, EpCAM, which is overexpressed in some malignant cells. It is given by intraperitoneal injection to treat malignant ascites, a collection of fluid and cancer cells in the peritoneal cavity. The antibody binds to this adhesion molecule and also to T lymphocytes and antigen-presenting cells, thus facilitating the action of the immune system in clearing the cancer.

Gemtuzumab

Gemtuzumab ozogamicin is a drug-conjugate linking a DNA-targeting calicheamicin cytotoxin (ozogamicin) to a mAb directed against the CD33 cell surface receptor. CD33 is found on the myeloid lineage of blood cells and gemtuzumab ozogamicin (aka Mylotarg) is used to treat acute myeloid leukaemias. Similarly, **inotuzumab ozogamicin** was approved in 2017, it being directed against CD22 instead, for the treatment of acute lymphocytic leukaemia. **Moxetumomab pasudotox** CD22 conjugate treats hairy cell leukaemia.

Nivolumab

Nivolumab is a fully humanised mAb against **p**rogrammed cell **d**eath protein-1 (PD-1) which is a cell surface receptor that dampens down the immune system to promote self-tolerance and suppress T-cell activation. Its ligand is PD-L1. Nivolumab has been used to re-prime the immune system so that it will re-recognise and destroy cancer cells that have previously evaded immunosurveillance. It has been approved for the treatment of metastatic melanoma, lymphoma, lung, kidney and head and neck cancers.
Pembrolizumab is another approved variant of a PD-1 mAb.
Atezolizumab is a mAb against PD-L1 approved in 2016 for the treatment of bladder cancer.

Ipilimumab

Approved in 2011 for the treatment of melanoma, **ipilimumab** targets the immune checkpoint system known as cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) which functions

similarly to the PD-1 system to 'stand down' the immune system. Cancers often employ both these mechanisms to evade immunodetection. Inhibitors of both systems are called 'immune *checkpoint inhibitors*'. Ipilimumab has been used in the treatment of melanoma, with efficacy shown in combating lung and pancreatic cancers. Trials combining both PD-1 and CTLA-4 inhibitors have proven that combined therapy of these checkpoint inhibitors is a useful strategy to reactivate our immune systems and target it against cancer cells in general.

These checkpoint inhibitor antibodies targeting PD-1/PD-L1 and CTLA-4 (see **Table 57.1**) represent a paradigm shift in cancer treatment, where drugs reactivate our immune system to render it once again capable of hunting out and destroying 'hidden' cancer cells (the immune system's day job).

Protein Kinase Inhibitors

Imatinib

Hailed as a conceptual breakthrough in targeted chemotherapy, **imatinib** (see **Savage and Antman, 2002**) is a small-molecule inhibitor of signalling pathway kinases. It inhibits an oncogenic cytoplasmic kinase (BCR-Abl (the Philadelphia chromosome), see Figs **57.1**. and **57.8**), considered to be a unique factor in the pathogenesis of CML. It has transformed the (hitherto poor) prognosis of patients with CML. It also inhibits two other tyrosine kinases, platelet-derived growth factor receptor (see **Fig. 57.1**) and the c-kit receptor (CD117), whose ligand is stem cell factor (SCF), and is licensed for the treatment of c-kit positive **GI s**tromal **t**umours (GISTs), not susceptible to surgery.

The drug is given orally. The half-life is about 18 h, and the main site of metabolism is in the liver, where approximately 75% of the drug is converted to a metabolite that is also biologically active. The bulk (81%) of the metabolised drug is excreted in the faeces.

Unwanted effects include GI symptoms (pain, diarrhoea, nausea), fatigue, headaches and sometimes rashes. Resistance to imatinib, resulting from mutation of the kinase gene, is a growing clinical problem. It results in little or no cross-resistance to other kinase inhibitors. Various second (**nilotinib**, **dasatinib**, **bosutinib**) and third (**ponatinib**) generation BCR-Abl tyrosine kinase inhibitors have been developed to combat, to varying degrees, a typical drug-resistant mutation in BCR-Abl (T315I) occurring in imatinib-treated CML patients.

Many similar tyrosine kinase inhibitors have recently been developed, including **axitinib**, **crizotinib**, **erlotinib**, **gefitinib**, **imatinib**, **lapatinib**, **pazopanib**, **sunitinib** and **vandetanib**. **Ruxolitinib** inhibits the JAK1 and JAK2 kinases and **vemurafenib** inhibits BRAF kinase. **Sorafenib**, **everolimus** and **temsirolimus** are pan-kinase inhibitors with a similar utility. **Ibrutinib, acalabrutinib** and **zanubrutinib** inhibit Bruton's tyrosine kinase (BTK) (see **Ch. 7**). They covalently modify residue C481 on BTK and irreversibly inhibit its cellular actions, which include chemotaxis and secretion of factors necessary for adhesion to the microenvironment. Interestingly their effectiveness in B lymphoid leukaemias and lymphomas derives from the ability to prevent migration and adhesion of these cancer cells to their resident tissues. Lymphocytosis (the extrusion of B cells from lymph nodes, spleen and bone marrow into the peripheral blood) is

one of the first effects of these drugs, and is a marker of their chemotherapeutic effect. Thus, similar in nature to checkpoint inhibitors, such anticancer drugs with cellular responses other than simple direct cytotoxic actions represent a new approach to chemotherapeutics.

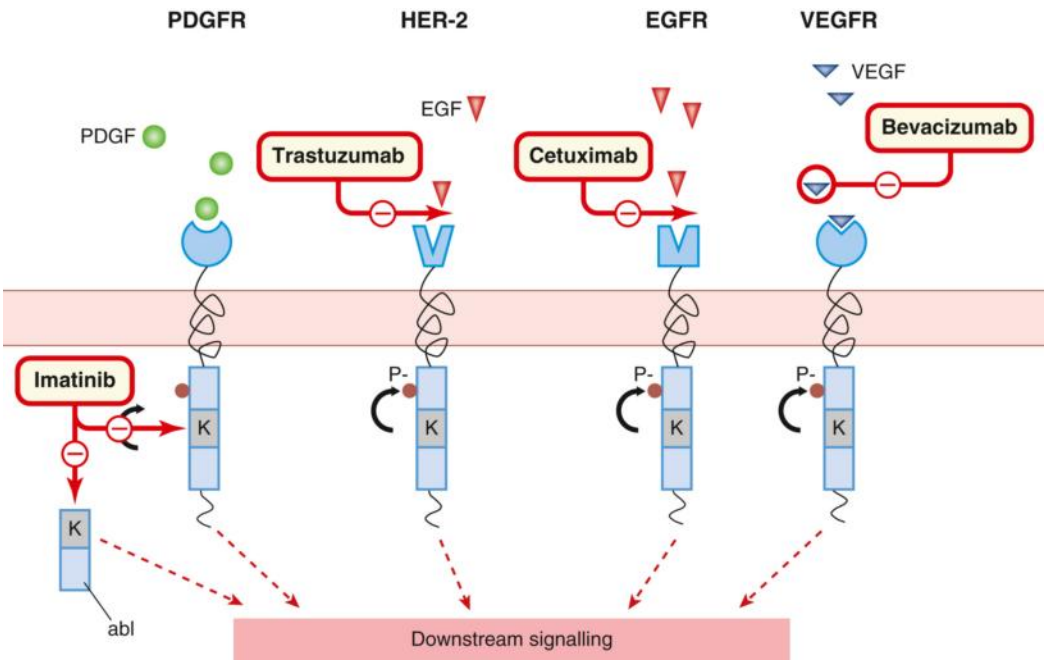

FIG. 57.8 The mechanism of action of anticancer monoclonal antibodies and protein kinase inhibitors.Many tumours overexpress growth factor receptors such as epidermal growth factor receptor *(EGFR)*, the proto-oncogene human epidermal growth factor 2 *(HER2)* or vascular endothelial growth factor receptor *(VEGFR)*. Therapeutic monoclonals can prevent this by interacting directly with the receptor itself (e.g. *trastuzumab, cetuximab*) or with the ligand (e.g. *bevacizumab*). An alternate way of reducing this drive on cell proliferation is by inhibiting the downstream signalling cascade. The receptor tyrosine kinases are good targets as are some oncogenic kinases such as BCR-Abl. *K,* Kinase domain in receptor; *P-,* phosphate group; *PDGFR,* platelet-derived growth factor receptor.

Anticancer drugs: monoclonal antibodies and protein kinase inhibitors

- Many tumours overexpress growth factor receptors that therefore stimulate cell proliferation and tumour growth. This can be inhibited by:
  - monoclonal antibodies, which bind to the extracellular domain of the epidermal growth factor (EGF) receptor (e.g. **panitumumab**), the oncogenic receptor HER2 receptor (e.g. **trastuzumab**), or which neutralise the growth factors themselves (e.g. VEGF; **bevacizumab**);
  - protein kinase inhibitors, which prevent downstream signalling triggered by growth factors by inhibiting specific oncogenic kinases (e.g. **imatinib**; BCR-Abl) or by inhibiting specific receptor tyrosine kinases (e.g. EGF receptor, **erlotinib;** BTK, **ibrutinib**) or several receptor-associated kinases as once (e.g. **sorafenib**).
  - checkpoint inhibitors (**nivolumab**, **ipilimumab**) act through PD-1/PD-L1 or CTLA-4 pathways to unblind cancer cells, allowing their targeting by a reawakened immune system
- Some monoclonals act directly on lymphocyte cell surface proteins to cause lysis (e.g. **rituximab**), thereby preventing proliferation.

Miscellaneous Agents

Crisantaspase

Crisantaspase is a preparation of the enzyme *asparaginase*, given by injection. It converts asparagine to aspartic acid and ammonia, and is active against tumour cells, such as those of acute lymphoblastic leukaemia, which have lost the capacity to synthesise asparagine and therefore require an exogenous source. As most normal cells are able to synthesise asparagine, the drug has a fairly selective action and has very little suppressive effect on the bone marrow, the mucosa of the GI tract or hair follicles. The most clinically important adverse effects are hypersensitivity reactions and vascular thrombosis.

Hydroxycarbamide

Hydroxycarbamide (hydroxyurea) is a urea analogue that inhibits ribonucleotide reductase, thus interfering with the conversion of ribonucleotides to deoxyribonucleotides. It is mainly used to treat *polycythaemia rubra vera* (a myeloproliferative disorder of the red cell lineage) and (in the past) chronic myelogenous leukaemia. Its use (in somewhat lower dose) in sickle cell anaemia is described in **Chapter 24**. It has the familiar spectrum of unwanted effects, bone marrow depression being significant.

Bortezomib

Bortezomib is a boron-containing tripeptide that inhibits cellular proteasome function. For some reason, rapidly dividing cells are more sensitive than normal cells to this drug, making it a useful anticancer agent. Bortezomib inhibits components of the

constitutive 26S proteasome β (PMSB) complex subunits (β5, β2 and β1). It is mainly used for the treatment of myeloma (a clonal malignancy of plasma cells).

Thalidomide

Investigations of the notorious teratogenic effect of **thalidomide** showed that it has multiple effects on gene transcription, angiogenesis and proteasome function, leading to trials of its efficacy as an anticancer drug. [9] In the event, it proved efficacious in myeloma, for which it is now widely used. The main adverse effect of thalidomide, apart from teratogenesis (irrelevant in myeloma treatment), is peripheral neuropathy, leading to irreversible weakness and sensory loss (see **Ch. 58**). It also increases the incidence of thrombosis and stroke.

A thalidomide derivative **lenalidomide** is thought to have fewer adverse effects, but unlike thalidomide, it can cause bone marrow depression and neutropenia. **Pomalidomide** is a newer derivative brought onto the market. These drugs act similarly to inhibit proteasomal degradation through modifying cereblon (CRBN), a receptor substrate of the E3 ubiquitin ligase complex.

PARP inhibitors

Poly ADP ribose polymerase (PARP) is an enzyme found in the nucleus that is involved in DNA repair to maintain genomic stability. Chemical or radiation-induced single-strand breaks are detected and repaired by PARP, to prevent DNA damage-induced apoptosis of our cells. Similar to proteasomal inhibition previously, cancer cells have evolved to ignore DNA damage-induced cell death mechanisms compared to normal non-cancerous cells, but are

relatively susceptible to PARP inhibition. More recently developed anticancer agents, PARP inhibitors such as **olaparib**, **rucaparib**, **niraparib** and **talazoparib** are a newer branch of anticancer agents that are useful in the treatment of ovarian cancers and peritoneal cancer, particularly those cancers possessing mutations in their BRCA DNA repair enzymes. PARP inhibitors are often given alongside radiotherapy, which itself induces DNA damage of the tumourous tissues.

Biological response modifiers and others

Agents that enhance the host's response are referred to as *biological response modifiers*. Some, for example **interferon-α** (and its pegylated derivative), are used in treating some solid tumours and lymphomas, and **aldesleukin** (recombinant interleukin-2) is used in some cases of renal tumours. **Tretinoin** (a form of vitamin A/ATRA (all-trans retinoic acid); see **Ch. 26**) is a powerful inducer of differentiation in leukaemic cells and is used as an adjunct to chemotherapy to induce remission. A related compound is **bexarotene**, a retinoid X receptor antagonist (see **Ch. 3**) that inhibits cell proliferation and differentiation.

Porfimer and **temoporfin** are haematoporphyrin photosensitising agents. They accumulate in cells and kill them when excited by the appropriate wavelength light. They are administered intravenously as part of photodynamic therapy where the laser light source can be selectively aimed at the tumour (e.g. in the case of obstructing oesophageal tumours, or in head and neck squamous cancers).

Resistance to Anticancer Drugs

The resistance that neoplastic cells manifest to cytotoxic drugs is said to be *primary* (present when the drug is first given) or *acquired* (developing during treatment with the drug). Acquired resistance may result from either *adaptation* of the tumour cells or *mutation*, with the emergence of cells that are less susceptible or resistant to the drug and consequently have a selective advantage over the sensitive cells. Resistance can be derived from a so-called selective therapeutic pressure (see **Vasan et al., 2019**). The following are examples of various mechanisms of resistance. See **Mimeault et al. (2008)** for a critical appraisal of this issue.

- *Decreased accumulation of cytotoxic drugs* in cells as a result of the increased expression of cell surface, energy-dependent drug transport proteins. These are responsible for multidrug resistance to many structurally dissimilar anticancer drugs (e.g. doxorubicin, vinblastine and dactinomycin; see **Gottesman et al., 2002**). An important member of this transporter group is *P-glycoprotein* (P-gp/MDR1; see **Ch. 9**). P-gp protects cells against environmental toxins. It functions as a hydrophobic 'vacuum cleaner', picking up foreign chemicals, such as drugs, as they enter the cell membrane and expelling them. Non-cytotoxic agents that reverse multidrug resistance are being investigated as potential adjuncts to treatment.
- *A decrease in the amount of drug taken up by the cell* (e.g. in the case of methotrexate).
- *Insufficient activation of the drug*. Some drugs require metabolic activation to manifest their antitumour activity. If this fails, they may no longer be effective. Examples include

conversion of fluorouracil to FdUMP, phosphorylation of cytarabine and conversion of mercaptopurine to a fraudulent nucleotide.

- *Increase in inactivation* (e.g. cytarabine and mercaptopurine).
- *Increased concentration of target enzyme* (methotrexate).
- *Decreased requirement for substrate* (crisantaspase).
- *Increased utilisation of alternative metabolic pathways* (antimetabolites).
- *Rapid repair of drug-induced DNA damage* (alkylating agents).
- *Altered activity of target*, for example modified topoisomerase II (doxorubicin).
- *Mutations in various genes*, giving rise to resistant target molecules, for example, the *p53* gene, C481S mutation in BTK gene developing in ibrutinib resistance and overexpression of the *Bcl-2* gene family (several cytotoxic drugs).

Combination Therapies

Treatment with combinations of anticancer agents increases the cytotoxicity against cancer cells without necessarily increasing the general toxicity. For example, methotrexate, which mainly has myelosuppressive toxicity, may be used in a regimen with vincristine, which has mainly neurotoxicity. The few drugs we possess with low myelotoxicity, such as cisplatin and bleomycin, are good candidates for combination regimens. Treatment with combinations of drugs also decreases the possibility of the

development of resistance to individual agents. Drugs are often given in large doses intermittently in several courses, with intervals of 2–3 weeks between courses, rather than in small doses continuously, because this permits the bone marrow to regenerate during the intervals. Furthermore, it has been shown that the same total dose of an agent is more effective when given in one or two large doses than in multiple small doses.

Common combinations of drugs given together as standard therapy regimens include **ADE** (cytarabine, daunorubicin, etoposide), **FAC** (fluorouracil, doxorubicin, cyclophosphamide), **FEC** (fluorouracil, epirubicin, cyclophosphamide), **FOLFIRI** (leucovin, fluorouracil, irinotecan), **FOLFOX** (leucovin, fluorouracil, oxilaplatin), **XELIRI** (capecitabine, irinotecan), **PAD** (bortezomib, doxorubicin dexamethasone), **CHOP** (cyclophosphamide, doxorubicin, vincristine, prednisolone), **OFF** (gemcitabine, fluorouracil, leucovin), **BEP** (bleomycin, etoposide, cisplatin) and **VIP** (vinblastine, ifosfamide. cisplatin).

Control of Emesis and Myelosuppression

Emesis

The nausea and vomiting induced by many cancer chemotherapy agents are a serious deterrent to patient compliance. This problem can now be prevented by using combinations of different antiemetics which may include $5HT_3$ antagonists, corticosteroids, neurokinin antagonists or nabilone (see **Ch. 30**).

Myelosuppression

Myelosuppression limits the use of many anticancer agents. Red cell and platelet transfusions can be used to support the patient, but febrile neutropaenia continues to pose a significant risk. Here, recombinant human granulocyte-colony stimulating factor (rhG-CSF) can be used after cytotoxic chemotherapy to stimulate neutrophil production and shorten the duration of the at-risk period for serious infections. Filgastrim (and its related compounds) can be given by daily injection at the end of each chemotherapy cycle to restore the white cell count.

Future Developments

As the reader will have judged by now, our current approach to cancer chemotherapy embraces an eclectic mixture of drugs – some very old and some very new – in an attempt to target cancer cells selectively. Real therapeutic progress has been achieved, although 'cancer' as a disease (actually many different diseases with a similar outcome) remains a massive challenge for future generations of researchers. In this therapeutic area, probably more than in any other, the debate about the risk–benefit of treatment and the patient quality of life issues has taken centre stage and remains a major area of concern (see **Duric and Stockler, 2001**; **Klastersky and Paesmans, 2001**).

Of the recent advances in drug therapy, the tyrosine kinase inhibitors and the biopharmaceuticals have arguably been the most innovative advances. Many drugs of the kinase inhibitor type have successfully entered the therapeutic arena and this area continues to be under active investigation (see **Vargas et al., 2013**; **Cohen et al., 2021**). Additionally, recent advances in BTK inhibitors

primarily targeting non-cytotoxic signalling mechanisms, plus the use of immune checkpoint inhibitors to reset our immune systems so it can once more recognise and destroy cancer cells, are interesting paradigms for the future of intelligent cancer drug design. Moreover, the use of genetically modified cells as 'living drug' anticancer therapies is becoming a reality. For example, chimeric antigen receptor T cells (CAR-T cells) have been approved for the treatment of acute lymphoblastic leukaemia, with trials underway for other cancer types (see **Table 57.1** for up-to-date examples). These cells express modified antigens that target and kill cancer cells. Advances in gene-editing technology (e.g. CRISPR-Cas9 (clustered regularly interspaced short palindromic repeats; CRISPR-associated protein 9) and TALENs (transcription activator-like effector nucleases)) have made it possible for patients to receive cancer-killing altered T cells generated from either their own T cells or from a donor (**Delhove and Qasim, 2017**). Impressive breakthroughs have been seen with these 'living drugs' in cancer patients whose previous treatment failed using standard chemotherapy.

Genotyping and immunological testing of tumour tissue are now widely used in clinical practice to guide selection of the optimal combination for personalising medicine, based on the particular characteristics of the tumour cells (see **Ch. 12**).

QUESTIONS

QUESTION 57.1

Cancer cells demonstrate specific characteristics that distinguish them from normal cells.

Which of the following is not generally a feature of malignant cells?

OPTIONS:

A. Increased rate of proliferation

B. De-differentiation

C. Genetic and epigenetic changes

D. Telomerase expression

E. Angiogenesis

QUESTION 57.2

Cytotoxic drugs, along with surgery and radiotherapy, remain the mainstay of cancer treatment and most act to target cell division.

Which of the following statements about the mechanisms of the cytotoxic agents is incorrect?

OPTIONS:

A. Cisplatin causes intrastrand cross-linking.

B. Methotrexate interferes with thymidylate synthesis.

C. Fluorouracil inhibits RNA synthesis.

D. Doxorubicin interferes with DNA–topoisomerase II function.

E. Paclitaxel inhibits microtubule depolymerisation.

ANSWERS

ANSWER 57.1

RATIONALE:

A.

B. Normal cells arising from the asymmetrical division of undifferentiated stem cells differentiate to become mature non-dividing cells, ready to perform functions appropriate to that

differentiated tissue. One of the main characteristics of cancer cells is that they de-differentiate to varying degrees and lose the ability to carry out the specialised function of the tissue. In general, poorly differentiated cancers carry a worse prognosis than well-differentiated cancers.

C. The changes in proliferation reflect altered patterns of gene expression in the cancer cells, resulting from inherited or acquired mutations. Genetic changes involve gain of function in proto-oncogenes to create oncogenes and loss of function of tumour suppressor genes.

D. About 95% of late-stage malignant tumours express telomerase enzymes to continuously rebuild the telomeres at the ends of the chromosomes and extend the cell's replicative ability, thus effectively conferring 'immortality' on cancer cells.

E. Angiogenesis is the development of new blood vessels in response to growth factors produced by the growing tumour itself to provide the tumour with nutrients.

CORRECT ANSWER WITH EXPLANATION:

A. Increased rate of proliferation

It is not generally true that cancer cells proliferate faster than normal cells. The significant issue is that cancer cells have escaped from the mechanisms that normally regulate cell division and tissue growth; the normal brakes on cell division, present in a healthy cell, have been cut. It is this, rather than their rate of proliferation, that distinguishes them from normal cells.

ANSWER 57.2

RATIONALE:

A. When cisplatin enters the cell, Cl^- dissociates, leaving a reactive complex that reacts with water and then interacts with DNA. It causes intrastrand cross-linking which results in local denaturation of DNA.

B. Folates are essential for the synthesis of purine nucleotides and thymidylate, which in turn are essential for DNA synthesis and cell division. The main action of the folate antagonists such as methotrexate is to inhibit dihydrofolate reductase, preventing generation of tetrahydrofolate interfering with thymidylate synthesis.

C.

D. During replication of the DNA helix, reversible swivelling needs to take place around the replication fork in order to prevent the daughter DNA molecule from becoming inextricably entangled during mitotic segregation. Doxorubicin intercalates in the DNA, and stabilises the DNA–topoisomerase II complex after the strands have been nicked, thus halting the process at this point.

E. Paclitaxel acts on microtubules, stabilising them (in effect 'freezing' or 'trapping' them) in the polymerised state and interfering with spindle formation during mitosis.

CORRECT ANSWER WITH EXPLANATION:

C. Fluorouracil inhibits RNA synthesis.

Fluorouracil, an analogue of uracil, is converted into a 'fraudulent' nucleotide, *fluorodeoxyuridine monophosphate* (FdUMP). This interacts with thymidylate synthetase but cannot be

converted into 2′-deoxythymidylate (dTMP). The result is inhibition of DNA but not RNA or protein synthesis.

[1] Cancer in general is a disease of older age – you have to be around long enough for all the mutations to accumulate in a cell and create a cancer phenotype that escapes the body's immune surveillance system. Clinical oncologists are gradually improving their treatment. Their goal is to keep you alive long enough so that you die of something other than cancer: a measure of their success.

[2] Blood cell malignancies – lymphomas and leukaemias – are non tumour forming, and at times not referred to as cancers. Along with myelomas, they are generally classed as 'blood cancers'. In this account, 'cancer' is used to cover all malignancy types.

[3] Once eroded down, telomere ends signal cells to stop replicating forever, which is why we humans have a limited life-span. Cancer cells however express telomerases to constantly build upon the telomere-end, and as such have lost this 'end replication' signal to limit their lifetime – some cancer cell lines have been replicating in the laboratory for many decades. The entire weight of an individual tumour line grown in all laboratories worldwide means that the original single cancer cell has now amassed many, many tonnes of itself in total – much heavier than the individual tumour it was derived from. The patient may have mouldered in the grave, but their cancer cells go marching on – theoretically forever!

[4] Although not widely accepted, there is a school of thought that maintaining the primary tumour's integrity and stopping it spreading would prolong life in the cancer sufferer. It may seem

anathema to nurture a tumour to keep it happy and avoid stressing it, to prevent any metastatic behaviour.

5 The term *cytotoxic drug* applies to any drug that can damage or kill cells. In practice, it is used more restrictively to refer to drugs that inhibit cell division and are therefore potentially useful in cancer chemotherapy.

6 You will have gathered that many anticancer drugs are toxic. 'To be an oncologist,' one practitioner commented, 'one has to hate cancer more than one loves life.'

7 It was the clinical insight of Alfred Goodman and Louis Gilman that led to the testing of (what became the first effective anticancer drug) mustine, a modified and stable version of 'mustard gas', to treat lymphomas. They also wrote what was to become a famous textbook of pharmacology.

8 In 2022, 10 of the top 15 globally sold cancer drugs were monoclonal antibodies, and their proportion is only estimated to increase.

9 Thalidomide had earlier been found, unexpectedly when used as a sedative, to cause shrinkage of the cutaneous swellings of leprosy (Ch. 52) and is approved for this indication as well as for myeloma.

58: Harmful effects of drugs

OVERVIEW

This chapter addresses the harmful effects of drugs, both in the context of therapeutic use – so-called adverse drug reactions – and of deliberate or accidental overdose. We are concerned here with serious harm, sometimes life-threatening or irreversible, distinct from the minor side effects that virtually all drugs produce, as described throughout this book. The classification of adverse drug reactions is considered, followed by aspects of drug toxicity, namely toxicity testing in drug development, mechanisms of toxin-induced cell damage, mutagenesis and carcinogenicity, teratogenesis and allergic reactions.

Introduction

Paracelsus, a 16th-century alchemist, is credited with the aphorism that all drugs are poisons: '… the dosage makes it either a poison or a remedy'. Today, toxic effects of drugs remain clinically important in the context of overdose (self-poisoning accounts for approximately 10% of the workload of emergency medicine departments in the United Kingdom; by contrast, homicidal poisoning is extremely uncommon). Some susceptible individuals may experience dose-related toxicity even during therapeutic dosing and some of this susceptibility is genetically determined. There are

now a wide range of genetic tests for identification and risk prediction of susceptible individuals, although relatively few of these tests are routinely used in current clinical practice (see **Ch. 12**).

Rigorous toxicity testing in animals (see later), including tests for carcinogenicity, teratogenicity and organ-specific toxicities, is carried out on potential new drugs during development (see **Ch. 60**), often leading to abandonment of the compound before it is tested in humans. These toxicity studies form part of the package of information routinely submitted to regulatory agencies by drug companies seeking approval to market a new drug. Nevertheless, harmful effects are often encountered after a drug is marketed for human use, due to the emergence of adverse effects not detected in animals. These harms are usually referred to as 'adverse drug reactions' (ADRs) and are of great concern to drug regulatory authorities, which are charged with establishing the safety, as well as the efficacy, of drugs. Unpredictable events are of particular concern. Some ADRs are predictable as a consequence of the main pharmacological effect of the drug and are relatively easily recognised, but some (e.g. immunological reactions) are unpredictable, sometimes serious, and likely to occur only in some patients.

Clinically important ADRs are common causes of hospital admission, costly and often avoidable (see **Pirmohamed et al., 2004**). [1] Any organ can be the principal target, and several organ systems can be involved simultaneously. The symptoms and signs sometimes closely shadow drug administration and discontinuation, but in other cases adverse effects only occur during prolonged use

(*osteoporosis* during continued high-dose glucocorticoid therapy [see **Ch. 33**], or *tardive dyskinesia* during continuous use of antipsychotic drugs [see **Ch. 47**], for example). Some adverse effects occur on ending treatment, either within a few days (e.g. tachycardia on abrupt discontinuation of β-adrenoceptor blockade) or after a delay, first appearing months or years after treatment is discontinued, as in the case of some second malignancies following successful chemotherapy. Consequently, anticipating, avoiding, recognising and responding to ADRs are among the most challenging and important parts of clinical practice.

Evaluation of harm from unexpected or rare adverse reactions after long periods of therapy is especially problematic. Precise estimates of risk are seldom obtainable in such circumstances. Randomised trials may not have sufficiently large sample sizes or duration of follow-up for severe rare events, particularly if the trial excluded frail and multi-morbid patients who are most susceptible to adverse reactions. Although spontaneous reporting systems and healthcare database studies may lack the rigour of randomised trials, due especially to the difficulty in excluding various sources of bias between treated and untreated patient populations, these observational datasets are key contributors to our understanding of long-term or rare adverse reactions in large real-world populations. Here, it is worth noting that rare, serious harms such as vaccine-induced thrombotic-thrombocytopaenia or myocarditis were not picked up in thousands of randomised participants during clinical trials of COVID-19 vaccines, and these adverse events only became clear after millions of people had been vaccinated (see **Ch. 53**).

Classification of Adverse Drug Reactions

The harmful effects of drugs may or may not be related to the main known mechanism of action of the drug. In either case, individual variation (see **Ch. 12**) is a major factor in determining the response of a particular patient and their susceptibility to harm. **Aronson and Ferner (2003)** have suggested that ADRs are described according to the **do**se, **t**ime course and **s**usceptibility (DoTS). Potential susceptibility factors such as age and co-morbid conditions are thereby explicitly considered.

Adverse Effects Related to the Known Pharmacological Action of the Drug

Many adverse effects related to the known pharmacological actions of the drug are predictable, at least if these actions are well understood. They are sometimes referred to as type A ('augmented') adverse reactions in a classification proposed by **Rawlins and Thompson (1977)** and are related to dose and individual susceptibility. Many such reactions have been described in previous chapters. For example, postural hypotension occurs with α_1-adrenoceptor antagonists, bleeding with anticoagulants, sedation with anxiolytics and so on. In many instances, this type of unwanted effect is reversible, and the problem can often be dealt with by adjusting the dose to obtain a more favourable balance between efficacy and safety. Such effects are sometimes serious (e.g. intracerebral bleeding caused by anticoagulants, hypoglycaemic coma from insulin), and occasionally they are not easily reversible, for example, drug dependence produced by opioid analgesics (see **Ch. 50**).

Some adverse effects related to the main action of a drug result in discrete events rather than graded symptoms and can be difficult to detect. For example, drugs that block cyclo-oxygenase (COX)-2 (including 'coxibs', for example, **rofecoxib**, **celecoxib** and **valdecoxib**, as well as conventional non-steroidal anti-inflammatory drugs [NSAIDs]) increase the risk of myocardial infarction in a dose-dependent manner (see **Ch. 25**). This potential was predictable from the ability of these drugs to inhibit prostacyclin biosynthesis and increase arterial blood pressure, and early studies gave a hint of such problems. The effect was difficult to prove because of the background incidence of coronary thrombosis, and it was only when placebo-controlled trials were performed for another indication (in the hope that COX-2 inhibitors could prevent bowel cancer) that this effect was confirmed unequivocally.

Adverse Effects Unrelated to the Known Pharmacological Action of the Drug

Adverse effects unrelated to the main pharmacological effect may be predictable when a drug is taken in excessive dose, for example, **paracetamol** hepatotoxicity (see later) or **aspirin**-induced tinnitus, or when susceptibility is increased, for example, during pregnancy or by a predisposing disorder such as glucose 6-phosphate dehydrogenase deficiency (see **Ch. 12**).

Unpredictable reactions unrelated to the main effect of the drug (sometimes termed *idiosyncratic reactions*, or type B for Bizarre in the Rawlins and Thompson classification) are often initiated by a chemically reactive metabolite rather than the parent drug.

Examples of such ADRs, which are often immunological in nature, include drug-induced hepatic or renal damage, bone marrow suppression, carcinogenesis and disordered fetal development. Uncommon but severe unpredictable adverse effects that have been mentioned in earlier chapters include aplastic anaemia from **chloramphenicol** and anaphylaxis in response to **penicillin**. They are usually severe – otherwise they would go unrecognised – and their existence is important in establishing the safety of medicines. The unpredictable nature of such reactions means that adjustment of the recommended therapeutic regimen (e.g. using a lower dose) may not prevent them.

Meyler's Side Effects of Drugs is an encyclopaedic source of regularly updated and detailed textbook coverage of ADRs and their clinical manifestations (**Aronson, 2016**).

Drug Toxicity

Toxicity Testing

Toxicity testing in animals is carried out on new drugs to identify potential hazards before they are administered to humans. It involves the use of a wide range of tests in different species, with long-term administration of the drug, regular monitoring for physiological or biochemical abnormalities and a detailed postmortem examination at the end of the trial to detect any gross or histological abnormalities. Toxicity testing is performed with doses well above the expected therapeutic range, and establishes which tissues or organs are likely 'targets' of toxic effects of the drug. Recovery studies are performed to assess whether toxic effects are reversible, and particular attention is paid to irreversible

changes such as carcinogenesis or neurodegeneration. The basic premise is that the toxic effects caused by a drug are similar in humans and other animals. There are, however, wide interspecies variations, especially in drug-metabolising enzymes; consequently, a toxic metabolite formed in one species may not be formed in another, and so toxicity testing in animals is not always a reliable guide. **Pronethalol**, the first β-adrenoceptor antagonist synthesised, was not developed because it caused carcinogenicity in mice; it subsequently emerged that carcinogenicity occurred only in the one strain tested – but by then other β-blockers were already in development.

Toxic effects can range from negligible to so severe as to preclude further development of the compound. Intermediate levels of toxicity are more acceptable in drugs intended for severe illnesses (e.g. AIDS or cancers), and decisions on whether or not to continue development are often difficult. If development does proceed, safety monitoring can be concentrated on the system 'flagged' as a potential target of toxicity by the animal studies. [2] However, there may be a mismatch between the preclinical data and the subsequent clinical studies where low-risk but potentially effective new compounds are erroneously halted in the development pathway (see **Vargas et al., 2021**, for a thoughtful debate on QT prolongation and proarrhythmic risk). The *safety* of a drug (as distinct from toxicity) can be established only during use in humans.

Types of drug toxicity

- Toxic effects of drugs can be:

  - related to the principal pharmacological action (e.g. bleeding with anticoagulants), and can usually be predicted from knowledge of the target sites;
  - unrelated to the principal pharmacological action (e.g. liver damage with **paracetamol**), This can be difficult to predict, and is sometimes referred to as 'off-target', collateral or bystander damage.
- Some adverse reactions that occur with ordinary therapeutic dosage are initially unpredictable, serious and uncommon (e.g. agranulocytosis with **carbimazole**). Such reactions (termed idiosyncratic) are almost inevitably detected only after widespread use of a new drug. It is sometimes possible to develop a test to exclude susceptible subjects from drug exposure (e.g. human leucocyte antigen status in patients who may need abacavir).
- Adverse effects unrelated to the main action of a drug are often caused by reactive metabolites and/or immunological reactions.

General Mechanisms of Toxin-Induced Cell Damage and Cell Death

Toxic concentrations of drugs or drug metabolites can cause necrosis; however, programmed cell death (apoptosis; see **Ch. 6**) is increasingly recognised to be of equal or greater importance, especially in chronic toxicity.

Chemically reactive drug metabolites can form covalent bonds with target molecules or can damage tissue by non-covalent

mechanisms. The liver is of great importance in drug metabolism (see **Ch. 10**), and hepatocytes are exposed to high concentrations of nascent metabolites. Drugs and their polar metabolites are concentrated in renal tubular fluid as water is reabsorbed, so renal tubules are exposed to higher concentrations than are other tissues. Several hepatotoxic drugs (e.g. paracetamol) are also nephrotoxic. Consequently, hepatic or renal damage are common reasons for abandoning development of drugs during toxicity testing and chemical pathology tests of hepatic damage (usually levels of transaminase enzymes measured in blood plasma or serum) and renal function (usually serum creatinine concentration) are routine.

Non-Covalent Interactions

Reactive metabolites of drugs are implicated in several potentially cytotoxic, non-covalent processes, including:

- lipid peroxidation, which can initiate a chain reaction throughout the membrane lipids
- generation of toxic reactive oxygen species
- depletion of reduced glutathione (GSH)
- modification of sulfhydryl groups

Covalent Interactions

Targets for covalent interactions include DNA, proteins/peptides, lipids and carbohydrates. Covalent bonding to DNA is a basic mechanism of mutagenic chemicals; this is dealt with later. Several non-mutagenic chemicals also form covalent bonds with macromolecules, but the relationship between this and cell damage is incompletely understood. For example, the cholinesterase

inhibitor paraoxon (the active metabolite of the insecticide parathion) binds acetylcholinesterase at the neuromuscular junction (see **Ch. 14**) and causes necrosis of skeletal muscle. One toxin from an exceptionally poisonous toadstool, *Amanita phalloides*, binds actin, and another binds RNA polymerase, interfering with actin depolymerisation and protein synthesis, respectively.

General mechanisms of cell damage and cell death

- Drug-induced cell damage/death is usually caused by reactive metabolites of the drug, involving non-covalent and/or covalent interactions with target molecules. Cell death often occurs by apoptosis.
- Non-covalent interactions include:
  - lipid peroxidation via a chain reaction;
  - generation of cytotoxic reactive oxygen species;
  - depletion of reduced glutathione;
  - modification of sulfhydryl groups on key enzymes (e.g. Ca^{2+}-ATPase) and structural proteins.
- Covalent interactions, for example adduct formation between a metabolite of **paracetamol** (*N*-acetyl-*p*-benzoquinone imine [NAPBQI]) and cellular macromolecules (see **Fig. 58.1**). Covalent binding to protein can produce an immunogen; binding to DNA can cause carcinogenesis and teratogenesis.

Hepatotoxicity

Many therapeutic drugs cause liver damage, manifested clinically as hepatitis or (in less severe cases) only by laboratory tests (e.g. increased activity of plasma aspartate transaminase, an enzyme released from damaged liver cells). **Paracetamol** and **halothane** cause hepatotoxicity by the mechanisms of cell damage outlined earlier. Genetic differences in drug metabolism (see **Ch. 12**) have been implicated in some instances (e.g. **isoniazid**, **phenytoin**). Mild drug-induced abnormalities of liver function are not uncommon, but the mechanism of liver injury is often uncertain (e.g. *statins*; see **Ch. 22**). It is not always necessary to discontinue a drug when such mild laboratory abnormalities occur, but the occurrence of cirrhosis as a result of long-term low-dose **methotrexate** treatment for arthritis or psoriasis (see Chs **25** and **26**) argues for regular monitoring of liver function. Hepatotoxicity of a different kind, namely reversible obstructive jaundice, occurs with **chlorpromazine** (see **Ch. 47**) and androgens (see **Ch. 35**).

Hepatotoxicity caused by **paracetamol** overdose remains a common cause of death following self-poisoning. An outline is given in **Chapter 25**. Paracetamol poisoning exemplifies many of the general mechanisms of cell damage outlined previously. With toxic doses of paracetamol, the enzymes catalysing the normal conjugation reactions are saturated, and mixed-function oxidases instead convert the drug to the reactive metabolite NAPBQI. As explained in **Chapter 10**, paracetamol toxicity is increased in patients in whom P450 enzymes have been induced, for instance by chronic excessive consumption of alcohol. NAPBQI initiates several of the covalent and non-covalent interactions described previously

and illustrated in **Fig. 58.1**. Oxidative stress from GSH depletion is important in leading to cell death. Regeneration of GSH from glutathione disulfide (GSSG) depends on the availability of cysteine, the intracellular availability of which can be limiting. *Acetylcysteine* or *methionine* can substitute for cysteine, increasing GSH availability; intravenous N-acetylycysteine is the main treatment for paracetamol poisoning.

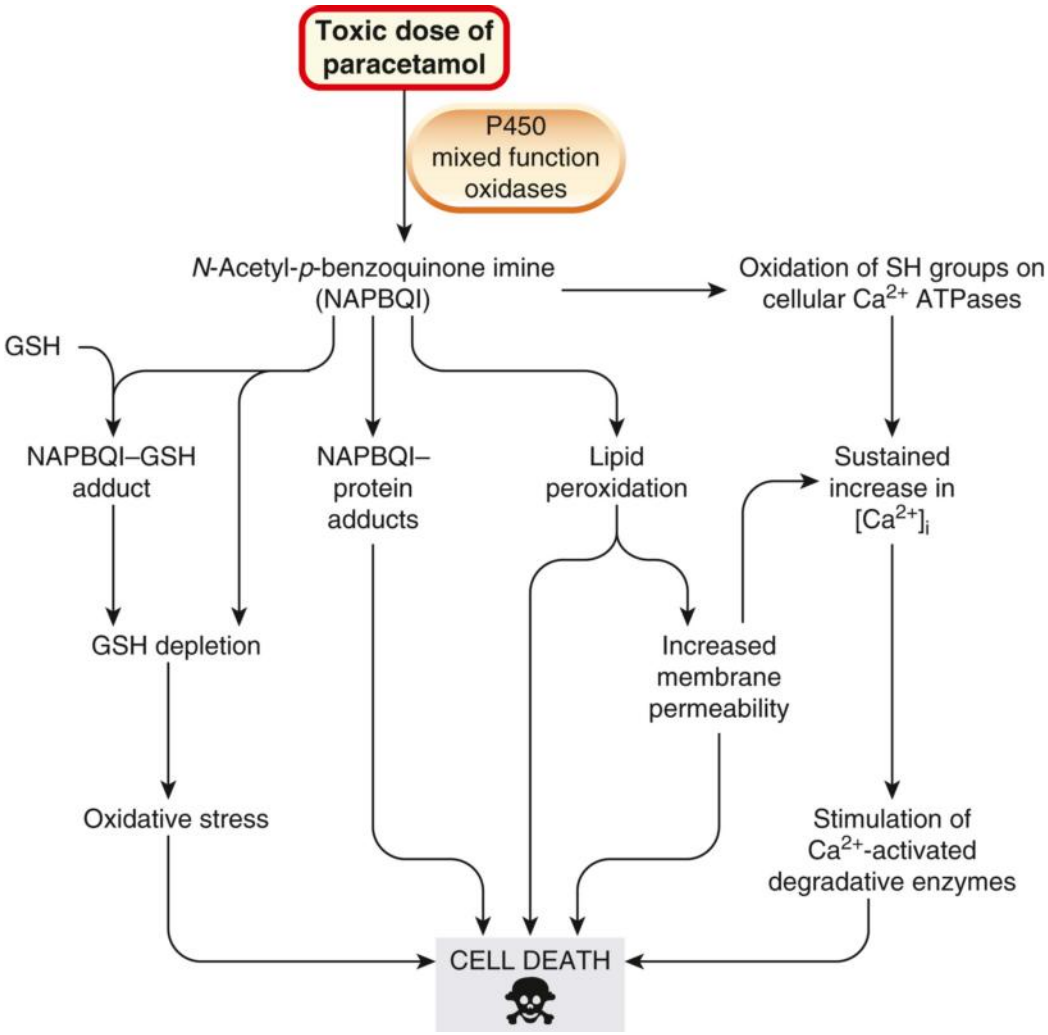

FIG. 58.1 Potential mechanisms of liver cell death resulting from the metabolism of paracetamol to *N*-acetyl-*p*-benzoquinone imine (NAPBQI). *GSH,* Glutathione. Based on data from Boobis, A.R., et al., 1989. Trends Pharmacol. Sci. 10, 275–280; and Nelson, S.D., Pearson, P.G., 1990. Annu. Rev. Pharmacol. Toxicol. 30, 169.

Liver damage can also be produced by immunological mechanisms (see later), which have been particularly implicated in

halothane hepatitis (see **Ch. 41**).

Hepatotoxicity

- Hepatocytes are exposed to reactive metabolites of drugs as these are formed by P450 enzymes.
- Liver damage is produced by several mechanisms of cell injury; **paracetamol** exemplifies many of these (see **Fig. 58.1**).
- Some drugs (e.g. **chlorpromazine**, co-amoxiclav) can cause reversible cholestatic jaundice.
- Immunological mechanisms are sometimes implicated (e.g. **halothane**).

Nephrotoxicity

Drug-induced nephrotoxicity is a common clinical problem: NSAIDs (**Table 58.1**) and angiotensin-converting enzyme (ACE) inhibitors are among the commonest precipitants of acute renal failure, usually caused by the principal pharmacological actions of these drugs. Chronic kidney disease, associated with renal tubular or papillary damage, may be caused by a wide range of drugs, including aminoglycoside antibiotics, antiviral drugs and lithium. Nephrotoxic drugs are often well tolerated in healthy people but can cause renal failure in old people or children, or those with concurrent renal disease.

Nephrotoxicity

- Renal tubular cells are exposed to high concentrations of drugs and metabolites as urine is concentrated.
- Renal damage can cause papillary and/or tubular necrosis.
- Inhibition of prostaglandin synthesis by NSAIDs causes vasoconstriction and lowers glomerular filtration rate.

Table 58.1

Adapted from Murray and Brater (1993).

Mutagenesis and Assessment of Genotoxic Potential

Drug-induced mutagenesis is one important cause of carcinogenesis and teratogenesis. Registration of pharmaceuticals requires a comprehensive assessment of their genotoxic potential. Because no single test is adequate, the usual approach is to carry out a battery of in vitro and in vivo tests for genotoxicity, usually comprising tests for gene mutation in bacteria, in vitro and in vivo tests for chromosome damage, and in vivo tests for reproductive toxicity and carcinogenicity (see later).

Biochemical Mechanisms of Mutagenesis

Chemical agents cause mutation by covalent modification of DNA. Certain mutations result in carcinogenesis, because the affected DNA sequence codes for a protein that regulates cell growth. It usually requires more than one mutation in a cell to initiate the changes that result in malignancy, mutations in proto-oncogenes

(which regulate cell growth) and tumour suppressor genes (which code for products that inhibit the transcription of oncogenes) being particularly implicated (see Chs **6**, **12** and **57**).

Mutagenesis and carcinogenicity

- Mutagenesis involves modification of DNA.
- Mutation of proto-oncogenes or tumour suppressor genes leads to carcinogenesis. More than one mutation is usually required.
- Drugs are relatively uncommon (but not unimportant) causes of birth defects and cancers.

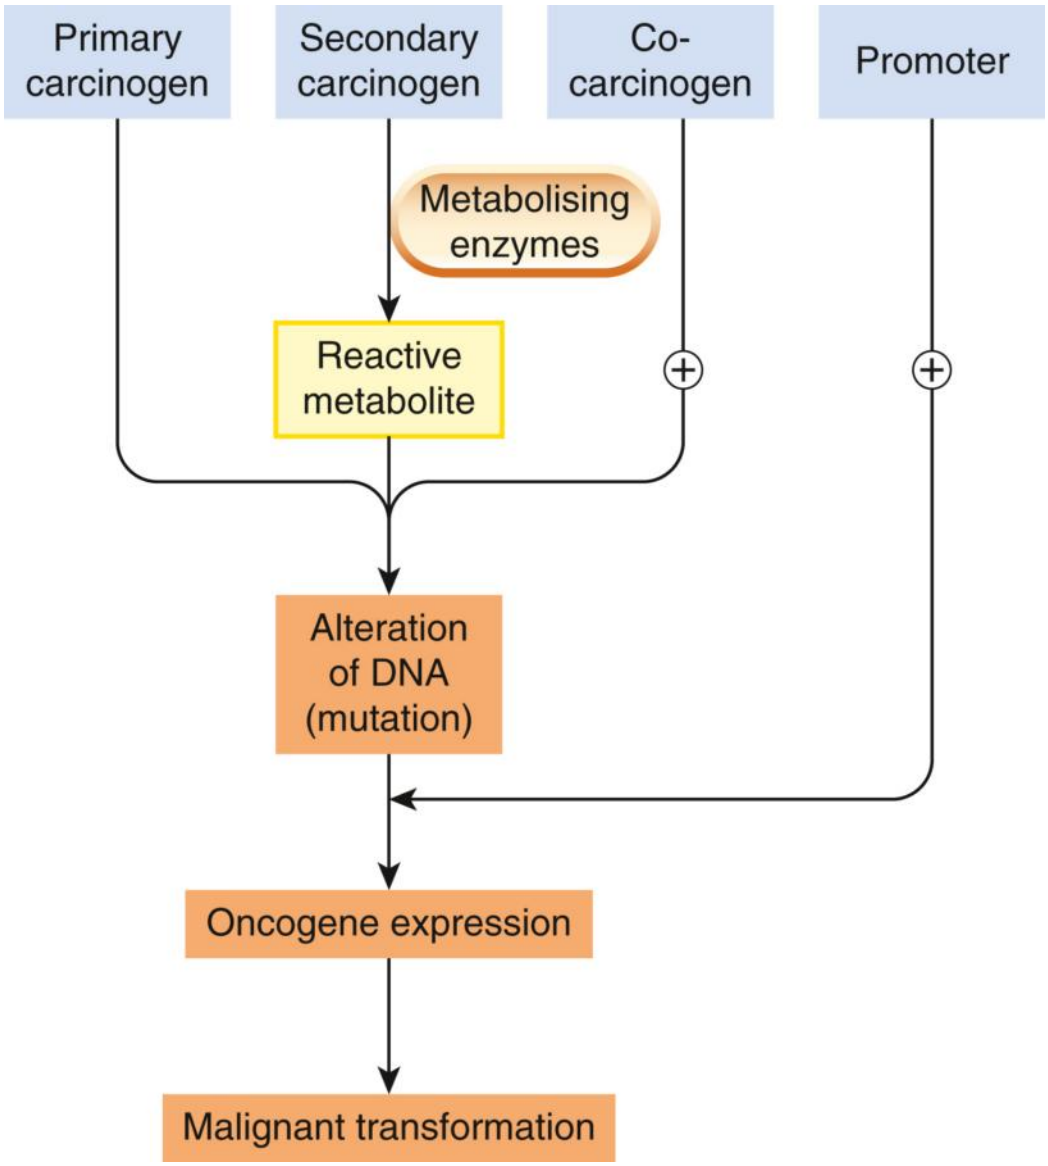

FIG. 58.2 Sequence of events in mutagenesis and carcinogenesis.Alterations to methylation and acetylation patterns of DNA and histones in an epigenetic manner can change gene expression during transcription, translation or even after translation, to increase the likelihood of carcinoma formation.

Carcinogenesis

Alteration of DNA is the first step in carcinogenesis (see Chs **6** and **57**). Carcinogenic compounds can interact directly with DNA (genotoxic carcinogens) or act at a later stage to increase the likelihood that mutation will result in a tumour (epigenetic carcinogens; **Fig. 58.2**).

Measurement of Mutagenicity and Carcinogenicity

Much effort has gone into developing assays to detect mutagenicity and carcinogenicity. In vitro tests for *mutagenicity* are used to screen large numbers of compounds but are unreliable as predictors of carcinogenicity. Whole-animal tests for carcinogenicity are expensive and time-consuming but are usually required by regulatory authorities before a new drug is licensed for use in humans. The main limitation of this kind of study is that there are important species differences, mainly to do with the metabolism of the foreign compound and the formation of reactive products.

The widely used *Ames test* for mutagenicity measures the effect of substances on the rate of back-mutation (i.e. reversion from mutant to wild-type form) in *Salmonella typhimurium*. Additionally, the in vitro micronucleus test is used to detect formation of micronuclei that contain chromosomal fragments (breakage of DNA), or entire chromosomes from damage to the mitotic structure.

Other short-term in vitro tests for genotoxic chemicals include measurements of mutagenesis in mouse lymphoma cells, and assays for chromosome aberrations and sister chromatid exchanges

in Chinese hamster ovary cells. However, all the in vitro tests give some false-positive and some false-negative results.

In vivo tests for carcinogenicity entail detection of tumours in groups of test animals. Carcinogenicity tests are inevitably slow, because there is usually a latency of months or years before tumours develop. Furthermore, tumours can develop spontaneously in control animals, and the results often provide only equivocal evidence of carcinogenicity of the test drug, making it difficult for industry and regulatory authorities to decide on further development and possible licensing of a product. None of the tests so far described can reliably detect epigenetic carcinogens. To do this, tests that measure the effect of the substance on tumour formation in the presence of a threshold dose of a separate genotoxic agent are being evaluated.

Few therapeutic drugs in clinical use are known to increase the risk of cancer, the most important groups being drugs that act on DNA, i.e. cytotoxic and immunosuppressant drugs (Chs **57** and **25**, respectively), and sex hormones (e.g. *oestrogens*, see **Ch. 35**).

Carcinogens

- Carcinogens can be:
  - genotoxic, i.e. causing mutations directly (primary carcinogens) or after conversion to reactive metabolites (secondary carcinogens);
  - epigenetic, i.e. increasing the possibility that a mutagen will cause cancer, although not themselves mutagenic.
- New drugs are tested for mutagenicity and carcinogenicity.

- In vitro testing for mutagenicity includes the Ames test, as well as evaluation of micronuclei formation as evidence of chromosomal damage. Carcinogenicity testing:
  - involves chronic dosing of groups of animals;
  - is expensive and time-consuming;
  - does not readily detect epigenetic carcinogens.

Teratogenesis and Drug-Induced Congenital Anomalies

Teratogenesis signifies the production of gross structural malformations during fetal development, in distinction from other kinds of drug-induced fetal damage such as growth impairment dysplasia (e.g. iodide-associated goitre) or the asymmetrical limb reduction resulting from vasoconstriction caused by **cocaine** (see **Ch. 50**) in an otherwise normally developing limb.

Other congenital anomalies may relate to neurobehavioural function. For instance, many psychoactive drugs (see **Ch. 46**) administered during pregnancy are known, or suspected, to increase the risk of cognitive and behavioural problems in offspring. Examples of drugs that affect fetal development adversely are given in **Table 58.2**.

The importance of X irradiation and rubella infection as causes of fetal malformation was recognised early in the 20th century, but it was not until 1960 that drugs were implicated as causative agents in teratogenesis: the shocking experience with **thalidomide** led to a widespread reappraisal of many other drugs in clinical use, and to the setting up of drug regulatory bodies in many countries. Most birth defects (about 70%) occur with no recognisable causative

factor. Drug or chemical exposure during pregnancy is estimated to account for only approximately 1% of all fetal malformations. Fetal malformations are common, so the absolute numbers of children affected are substantial.

Mechanism of Teratogenesis

The timing of the teratogenic insult in relation to fetal development is critical in determining the type and extent of damage. Mammalian fetal development passes through three phases (**Table 58.3**):

1. Blastocyst formation
2. Organogenesis
3. Histogenesis and maturation of function

Cell division is the main process occurring during blastocyst formation. During this phase, drugs can kill the embryo by inhibiting cell division, but provided the embryo survives, its subsequent development does not generally seem to be compromised. Ethanol is an exception, affecting development even at this very early stage (see **Ch. 50**).

Drugs can cause gross malformations if administered during organogenesis (days 17–60 in humans). The structural organisation of the embryo occurs in a well-defined sequence: eye and brain, skeleton and limbs, heart and major vessels, palate, genitourinary system. The type of malformation produced thus depends on the time of exposure to the teratogen.

The cellular mechanisms by which teratogenic substances produce their effects are not at all well understood. There is a

considerable overlap between mutagenicity and teratogenicity. In one large survey, among 78 compounds, 34 were both teratogenic and mutagenic, 19 were negative in both tests and 25 (among them thalidomide) were positive in one but not the other. Damage to DNA is important but not the only factor. The control of morphogenesis is poorly understood; vitamin A derivatives (retinoids) are involved and are potent teratogens (see later and **Ch. 26**). Known teratogens also include several drugs (e.g. **methotrexate** and **phenytoin**) that do not react directly with DNA but which inhibit its synthesis by their effects on folate metabolism (see **Ch. 24**). Administration of **folate** during pregnancy reduces the frequency of both spontaneous and drug-induced malformations, especially neural tube defects.

The fetus depends on an adequate supply of nutrients during the final stage of histogenesis and functional maturation, and development is regulated by a variety of hormones. Gross structural malformations do not arise from exposure to mutagens at this stage, but drugs that interfere with the supply of nutrients or with the hormonal milieu may have deleterious effects on growth and development. Exposure of a female fetus to androgens at this stage can cause masculinisation. **Stilbestrol** (a synthetic oestrogen, now seldom used, licensed to treat breast or prostate cancer) was commonly given to pregnant women with a history of recurrent miscarriage during the 1950s (for unsound reasons). Used in this way it caused dysplasia of the vagina of female infants and an increased incidence of carcinoma of the vagina, a rare malignancy with almost no background incidence, in such offspring in their teens and twenties. Angiotensin II plays an important part in the

later stages of fetal development and in renal function in the fetus, and ACE inhibitors and angiotensin receptor antagonists (see **Ch. 21**) cause oligohydramnios and renal failure if administered during later stages of pregnancy, and fetal malformations if given earlier.

Table 58.2

Table 58.3

Testing for Teratogenicity

The thalidomide disaster dramatically brought home the need for teratogenicity and fetal developmental studies on new therapeutic drugs. Regulatory authorities typically require testing in a rodent as well as non-rodent species (e.g. rabbit), involving dosing both males and females. However, poor cross-species correlation means that tests of this kind are not reliably predictive in humans. Equally, the use of in vitro embryo testing has not yet reached the level where it can be fully relied upon as an accurate predictive tool for teratogenicity.

Detection of drug-induced teratogenesis in humans is a particularly difficult problem because the 'spontaneous' malformation rate is high (3%–10%, depending on the definition of a significant malformation) and highly variable between different regions, age groups and social classes. Nowadays, large-scale long-term studies are conducted on specific pregnancy or disease registries, but the results are often inconclusive because of difficulties controlling for the diversity of factors that pre-dispose to teratogenicity and developmental anomalies.

Some Definite and Probable Human Teratogens

Although many drugs have been found to be teratogenic in varying degrees in experimental animals, relatively few are known to be teratogenic in humans (see **Table 58.2**). Some of the more important ones are discussed here.

Thalidomide

Thalidomide is almost unique in producing, at therapeutic dosage, virtually 100% malformed infants when taken in the first 3–6 weeks of gestation. It was introduced in 1957 as a hypnotic and sedative with the special feature that it was much less hazardous in overdosage than barbiturates, and it was even recommended specifically for use in pregnancy (with the advertising slogan 'the safe hypnotic'). It had been subjected to toxicity testing only in mice, which are resistant to thalidomide teratogenicity. Thalidomide was marketed energetically and successfully, and the first suspicion of its teratogenicity arose early in 1961 with reports of a sudden increase in the incidence of phocomelia ('seal limbs', an absence of development of the long bones of the arms and legs) that had

hitherto been virtually unknown. At this time, a million tablets were being sold daily in West Germany. Reports of phocomelia came simultaneously from Hamburg and Sydney, and the connection with thalidomide was made. [3] The drug was withdrawn late in 1961, by which time an estimated 10,000 malformed babies had been born (**Fig. 58.3** illustrates the use of data linkage in detecting delayed ADRs). Epidemiological investigation showed very clearly the correlation between the time of exposure and the type of malfunction produced (**Table 58.4**). Although the mechanism is not clearly understood, inhibition of blood vessel formation (angiogenesis) is thought to be involved.

Cytotoxic drugs

Many alkylating agents (e.g. **chlorambucil** and **cyclophosphamide**) and antimetabolites (e.g. **azathioprine** and **mercaptopurine**) cause malformations when used in early pregnancy but more often lead to abortion (see **Ch. 57**). Folate antagonists (e.g. **methotrexate**) produce a much higher incidence of major malformations, especially neural tube defects evident in both liveborn and stillborn fetuses.

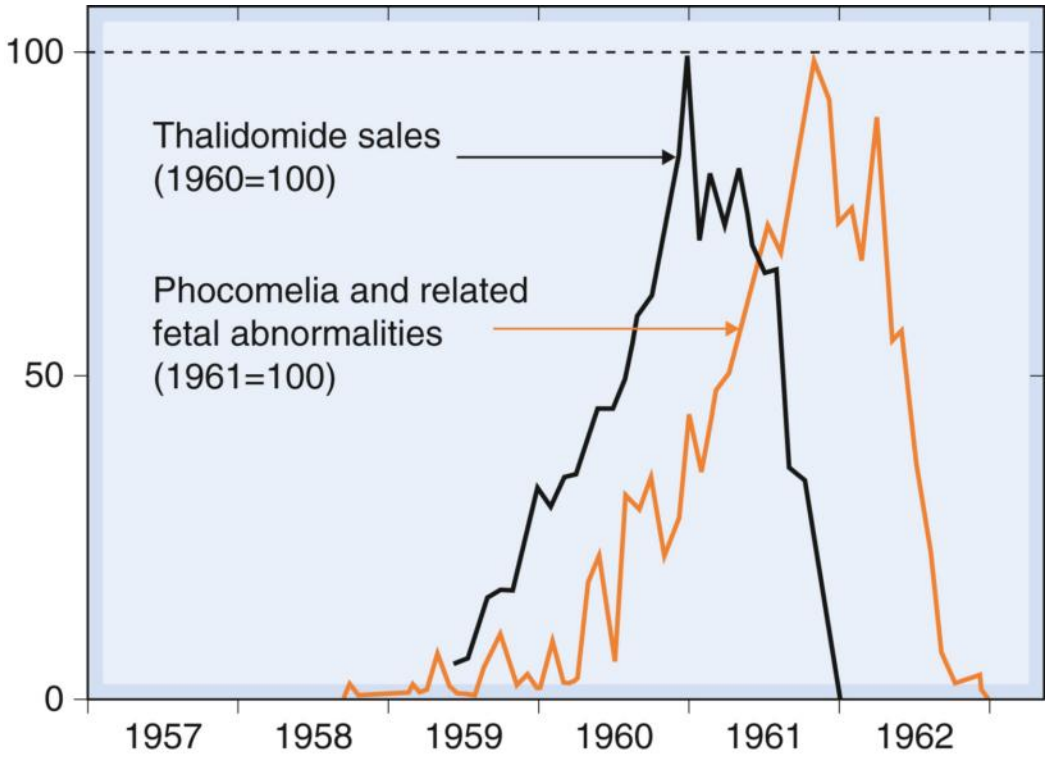

FIG. 58.3 Incidence of major fetal abnormalities in Western Europe following the introduction and withdrawal of thalidomide, linked to sales data for thalidomide.

Table 58.4

Retinoids

Etretinate, a retinoid (i.e. vitamin A derivative) with marked effects on epidermal differentiation, is a known teratogen and causes a high proportion of serious abnormalities (notably skeletal deformities) in exposed fetuses. Dermatologists use retinoids to treat skin diseases, including several, such as acne and psoriasis, that are common in young women. Etretinate accumulates in subcutaneous fat and is eliminated extremely slowly, detectable

amounts persisting for many months after chronic dosing is discontinued. Because of this, women should avoid pregnancy for at least 2 years after treatment. **Acitretin** is an active metabolite of etretinate. It is equally teratogenic, but tissue accumulation is less pronounced and elimination may be more rapid.

Heavy metals

Lead, *cadmium* and *mercury* all cause fetal malformation in humans. The main evidence comes from *Minamata disease*, named after the locality in Japan where an epidemic occurred when the local population ate fish contaminated with methylmercury that had been used as an agricultural fungicide. This impaired brain development in exposed fetuses, resulting in cerebral palsy and developmental delay, often with microcephaly. Mercury, like other heavy metals, inactivates many enzymes by forming covalent bonds with sulfhydryl and other groups, and this is believed to be responsible for these developmental abnormalities.

Antiepileptic drugs (see Ch. 46)

Congenital malformations are increased two- to three-fold in babies of epileptic mothers, especially of mothers treated with two or more antiepileptic drugs during the first trimester, and in association with above-therapeutic plasma concentrations. Many antiepileptic drugs have been implicated, including **phenytoin** (particularly cleft lip/palate), **valproate** (neural tube defects) and **carbamazepine** (spina bifida and hypospadias, a malformation of the male urethra) (see **Ch. 46**). The relative risks attributable to different antiepileptic drugs are not well defined, but valproate is considered to be particularly harmful (rate of congenital anomalies of about

10%, compared with 2%–3% in the general population), and is contraindicated in women of childbearing age.

Warfarin

Administration of **warfarin** (see **Ch. 23**) in the first trimester is associated with nasal hypoplasia and various central nervous system abnormalities, affecting roughly 25% of exposed babies. In the last trimester, it must not be used because of the risk of intracranial haemorrhage in the baby during delivery.

Teratogenesis and drug-induced fetal damage

- Teratogenesis means production of gross structural malformations of the fetus (e.g. the absence of limbs after **thalidomide**). Less comprehensive damage can be produced by several drugs (see **Table 58.2**). Less than 1% of congenital fetal defects are attributed to drugs given to the mother.
- Gross malformations are produced only if teratogens act during organogenesis. This occurs during the first 3 months of pregnancy but after blastocyst formation. Drug-induced fetal damage is rare during blastocyst formation (exception: fetal alcohol syndrome) and after the first 3 months (exception: ACE inhibitors and sartans).
- The mechanisms of action of teratogens are not clearly understood, although DNA damage is a factor.

Immunological Reactions to Drugs

Biological agents (see **Ch. 5**) may provoke an immune response; antidrug antibodies to insulin are common in diabetic patients, although they seldom cause problems, but antidrug antibodies to erythropoietin and thrombopoietin can have serious consequences for patients treated with these agents (see **Ch. 24**). Measurement of antidrug antibodies is now routine during the development of biological products. Seemingly trivial differences in manufacturing process (e.g. between different batches, or when a new manufacturer makes a copy of a biological product after it is no longer protected by patent – so-called biosimilar products) can result in marked changes in immunogenicity.

Allergic reactions of various kinds are a common form of ADR. Low-molecular-weight drugs are not immunogenic in themselves. A drug or its metabolites can, however, act as a *hapten* by interacting with protein to form a stable immunogenic conjugate (see **Ch. 7**). The immunological basis of some allergic drug reactions has been well worked out, but often it is inferred from the clinical characteristics of the reaction, and direct evidence of an immunological mechanism is lacking. The existence of an allergic reaction is suggested by its delayed onset, or occurrence only after repeated exposure to the drug. Allergic reactions are generally unrelated to the main action of the drug, and conform to syndromes associated with types I, II, III and IV of the Gell and Coombs classification (see later and **Ch. 7**).

The overall incidence of allergic drug reactions is variously reported as being between 2% and 25%. Most are minor skin eruptions. Serious reactions (e.g. anaphylaxis, haemolysis and bone

marrow depression) are rare. Penicillins, which are the commonest cause of drug-induced anaphylaxis, produce this response in an estimated 1 in 50,000 patients exposed. Rashes can be severe, and fatalities occur with the Stevens–Johnson syndrome/toxic epidermal necrolysis continuum (a group of life-threatening diseases affecting the skin, often provoked by drugs, for example, by sulfonamides, **allopurinol** or **carbamazepine**). The association between severe **carbamazepine**-induced skin disease and the gene for a particular human leukocyte antigen (HLA) allele *HLAB**1502* in people of Asian ancestry is mentioned in **Chapter 12**. Susceptibility to severe rashes in response to **abacavir** is closely linked to the variant *HLAB**5701* and this forms the basis of a clinically useful genomic test (see **Ch. 12**).

Immunological Mechanisms

The formation of an immunogenic conjugate between a small molecule and an endogenous protein requires covalent bonding. In most cases, reactive metabolites, rather than the drug itself, are responsible. Such reactive metabolites can be produced during drug oxidation or by photoactivation in the skin. They may also be produced by the action of toxic oxygen metabolites generated by activated leukocytes. Rarely (e.g. in drug-induced lupus erythematosus), the reactive moiety interacts to form an immunogen with nuclear components (DNA, histone) rather than proteins. Conjugation with a macromolecule is usually essential, although penicillin is an exception because it can form sufficiently large polymers in solution to elicit an anaphylactic reaction in a

sensitised individual even without conjugation to protein, although penicillin–protein conjugates can also act as the immunogen.

Clinical Types of Allergic Response to Drugs

Hypersensitivity reactions of types I, II and III (see **Ch. 7**) are antibody-mediated reactions, while type IV is cell mediated. Unwanted reactions to drugs involve both antibody- and cell-mediated reactions. The more important clinical manifestations of hypersensitivity include anaphylactic shock, haematological reactions, allergic liver damage and other hypersensitivity reactions.

Anaphylactic Shock

Anaphylactic shock – see also **Chapters 7** and 28 – is a type I hypersensitivity response. It is a sudden and life-threatening reaction that results from the release of histamine, leukotrienes and other mediators. The main features include urticarial rash, swelling of soft tissues, bronchoconstriction and hypotension.

Penicillins account for about 75% of anaphylactic deaths, reflecting the frequency with which they are used in clinical practice. Other drugs that can cause anaphylaxis include enzymes, such as **asparaginase** (see **Ch. 57**); therapeutic monoclonal antibodies (see **Ch. 5**); hormones, for example, **corticotropin** (see **Ch. 33**); dextrans; radiological contrast agents; vaccines; and other serological products. Anaphylaxis can also be caused by local anaesthetics (see **Ch. 44**), the antiseptic chlorhexidine and many other medications (sometimes as a consequence of contaminants such as latex used to seal reusable vials or of excipients and colouring agents rather than the drug itself). Treatment of anaphylaxis is mentioned in **Chapter 28**.

It is sometimes feasible to carry out a skin test for the presence of hypersensitivity, which involves injecting a minute dose intradermally. A patient who reports that she or he is allergic to a drug such as penicillin may actually be allergic to fungal contaminants, which were common in early preparations, rather than to penicillin itself. The use of penicilloylpolylysine as a skin test reagent for penicillin allergy is an improvement over the use of penicillin itself, because it bypasses the need for conjugation of the test substance, thereby reducing the likelihood of a false-negative. Other specialised tests are available to detect the presence of specific immunoglobulin E in the plasma, or to measure histamine release from the patient's basophils, but these are not used routinely.

Haematological Reactions

Drug-induced haematological reactions can be produced by type II, III or IV hypersensitivity. Type II reactions can affect any or all of the formed elements of the blood, which may be destroyed by effects either on the circulating blood cells themselves or on their progenitors in the bone marrow. They involve antibody binding to a drug–macromolecule complex on the cell surface membrane. The antigen–antibody reaction activates complement, leading to lysis, or provokes attack by killer lymphocytes or phagocytic leukocytes (see **Ch. 7**). *Haemolytic anaemia* has been most commonly reported with sulfonamides and related drugs (see **Ch. 52**) and with an antihypertensive drug, **methyldopa** (see **Ch. 15**), which is still used to treat hypertension during pregnancy. With methyldopa, significant haemolysis occurs in less than 1% of patients, but the

appearance of antibodies directed against the surface of red cells is detectable in 15% by the direct antiglobulin test. The antibodies are directed against Rh antigens, but it is not known how methyldopa produces this effect.

Drug-induced *agranulocytosis* (complete absence of circulating neutrophils) is usually delayed 2–12 weeks after beginning drug treatment but may then be sudden in onset. It often presents with mouth ulcers, a severe sore throat or other infection. Serum from the patient lyses leukocytes from other individuals, and circulating antileukocyte antibodies can usually be detected immunologically. Drugs associated with agranulocytosis include **carbimazole** (see **Ch. 34**), **clozapine** (see **Ch. 47**) and **sulfonamides** and related drugs (e.g. *thiazides* and *sulfonylureas*). Agranulocytosis is rare but life-threatening. Recovery when the offending drug is stopped is often slow or absent. Antibody-mediated leukocyte destruction must be distinguished from the direct effect of cytotoxic drugs (see **Ch. 57**), which cause granulocytopenia that is rapid in onset, predictably related to dose and reversible.

Thrombocytopenia (reduction in platelet numbers) can be caused by type II reactions to **quinine** (see **Ch. 55**), and **heparin** (see **Ch. 23**).

Some drugs (notably **chloramphenicol**) can suppress all three haemopoietic cell lineages, giving rise to *aplastic anaemia* (anaemia with associated agranulocytosis and thrombocytopenia).

The distinction between type III and type IV hypersensitivity reactions in the causation of haematological reactions is not clear cut, and either or both mechanisms can be involved.

Allergic Liver Damage

Most drug-induced liver damage results from the direct toxic effects of drugs or their metabolites, as described earlier. However, hypersensitivity reactions are sometimes involved, a particular example being **halothane**-induced hepatic necrosis (see **Ch. 41**). *Trifluoracetylchloride*, a reactive metabolite of halothane, couples to a macromolecule to form an immunogen. Most patients with halothane-induced liver damage have antibodies that react with halothane–carrier conjugates. Halothane–protein antigens can be expressed on the surface of hepatocytes. Destruction of the cells occurs by type II hypersensitivity reactions involving killer T cells, and type III reactions can also contribute.

Other Hypersensitivity Reactions

The clinical manifestations of type IV hypersensitivity reactions are diverse, ranging from minor rashes to generalised autoimmune disease. Fever may accompany these reactions. Rashes can be antibody mediated but are usually cell mediated. They range from mild eruptions to fatal exfoliation. Stevens–Johnson syndrome/toxic epidermal necrolysis is now believed to be a continuum of very severe generalised rash extending into the alimentary tract and with blistering or exfoliation. In some cases, the lesions are photosensitive, probably because ultraviolet light converts the drug to reactive products.

Allergic reactions to drugs

- Drugs or their reactive metabolites can bind covalently to proteins to form immunogens. **Penicillin** (which can also

form immunogenic polymers) is an important example.

- Drug-induced allergic (hypersensitivity) reactions may be antibody mediated (types I, II, III) or cell mediated (type IV). Important clinical manifestations include the following:
  - anaphylactic shock (type I): many drugs can cause this, and most deaths are caused by **penicillin**;
  - haematological reactions (type II, III or IV): including haemolytic anaemia (e.g. **methyldopa**), agranulocytosis (e.g. **carbimazole**), thrombocytopenia (e.g. **quinine**) and aplastic anaemia (e.g. **chloramphenicol**);
  - hepatitis (types II, III): for example, **halothane**, **phenytoin**;
  - rashes (type I, IV): are usually mild but can be life-threatening (e.g. Stevens–Johnson syndrome);
  - drug-induced systemic lupus erythematosus (mainly type II): antibodies to nuclear material are formed (e.g. **hydralazine**).

QUESTIONS

QUESTION 58.1

Adverse drug reactions occur with many agents and may or may not be related to the main known mechanism of action of the drug.

Which of the following would be classified as an idiosyncratic adverse drug reaction?

OPTIONS:

A. Paracetamol hepatotoxicity

B. Rofecoxib-induced increase in the risk of myocardial infarction

C. Postural hypotension occurring with α_1-adrenoceptor antagonists

D. Chloramphenicol-induced aplastic anaemia

E. Aspirin-induced tinnitus

QUESTION 58.2

Many drugs can cause toxin-induced cell damage and cell death.

Which of the following statements about drug-induced cell damage and death is incorrect?

OPTIONS:

A. Covalent interactions can result in adduct formation between a drug metabolite and cellular macromolecules.

B. Drug-induced cell damage/death is usually caused by reactive metabolites of the drug.

C. Cell death often occurs by apoptosis.

D. Non-covalent interactions often result in tissue damage.

E. Increased activity of plasma aspartate transaminase is an indicator of renal toxicity.

QUESTION 58.3

Penicillins are responsible for the commonest cause of drug-induced anaphylaxis, producing this response in an estimated 1 in 50,000 patients exposed to these agents.

Penicillin induced anaphylaxis is usually due to...

OPTIONS:

A. Its ability to form immunogenic polymers

B. The presence of particular human leukocyte antigen (HLA) alleles

C. The generation of toxic oxygen metabolites by immune cells

D. Its conjugation to DNA

E. Its ability to act as a hapten

ANSWERS

ANSWER 58.1

RATIONALE:

A. Adverse effects unrelated to the main pharmacological effect may be predictable when a drug is taken in excessive dose, for example, paracetamol hepatotoxicity.

B. The adverse effects seen with rofecoxib are related to the main action of a drug. It increases the risk of myocardial infarction in a dose-dependent manner which was predictable from the ability of these drugs to inhibit prostacyclin biosynthesis and increase arterial blood pressure.

C. Postural hypotension occurring with α_1-adrenoceptor antagonists is an adverse effect related to the known pharmacological actions of the drug and is therefore predictable.

D.

E. Aspirin-induced tinnitus is an adverse effect unrelated to its main pharmacological effect but is predictable when a drug is taken in excessive dose.

CORRECT ANSWER WITH EXPLANATION:

D. Chloramphenicol-induced aplastic anaemia

Idiosyncratic reactions are unpredictable reactions unrelated to the main effect of the drug and are often initiated by a chemically reactive metabolite rather than the parent drug. Uncommon but

severe unpredictable adverse effects that are often immunological in nature include aplastic anaemia from chloramphenicol.

ANSWER 58.2

RATIONALE:

A. Covalent interactions can involve adduct formation, for example between a metabolite of paracetamol and cellular macromolecules.

B. Drug-induced cell damage/death is usually caused by reactive metabolites of the drug, involving non-covalent and/or covalent interactions with target molecules.

C. Toxic concentrations of drugs or drug metabolites can cause necrosis; however, apoptosis is increasingly recognised to be of equal or greater importance, especially in chronic toxicity.

D. Chemically reactive drug metabolites can damage tissue by non-covalent mechanisms.

E.

CORRECT ANSWER WITH EXPLANATION:

E. Increased activity of plasma aspartate transaminase is an indicator of renal toxicity.

Increased activity of plasma aspartate transaminase is indicative of liver damage as the enzyme is released from damaged liver cells.

ANSWER 58.3

RATIONALE:

A.

B. The reaction to penicillin has not been linked to the presence of particular HLA alleles.

C. Cellular damage can be produced by the action of toxic oxygen metabolites generated by activated leukocytes but this is not the main mechanism of toxicity for penicillin.

D. Conjugation of penicillin occurs with proteins rather than DNA.

E. Penicillin or its metabolites can act as a *hapten* by interacting with protein to form a stable immunogenic conjugate but it can also form sufficiently large polymers in solution to elicit an anaphylactic reaction in a sensitised individual, even without conjugation to protein.

CORRECT ANSWER WITH EXPLANATION:

A. Its ability to form immunogenic polymers

Penicillin can form sufficiently large polymers in solution to elicit an anaphylactic reaction in a sensitised individual even without conjugation to protein, although penicillin–protein conjugates can also act as the immunogen.

---

[1] Of hospital admissions in the United Kingdom, 6.5% were due to ADRs, at a projected annual cost of £466 million. Antiplatelet drugs, diuretics, non-steroidal anti-inflammatory drugs and anticoagulants between them accounted for 50% of the ADRs, and 2.3% of the patients died. Most events were avoidable.

[2] The value of toxicity testing is illustrated by experience with **triparanol**, a cholesterol-lowering drug marketed in the United States in 1959. Three years later, a team from the FDA, acting on a tip-off, paid the manufacturer a surprise visit that revealed falsification of toxicology data demonstrating cataracts in rats and dogs. The drug was withdrawn, but some patients who had been

taking it for a year or more did develop cataracts. Regulatory authorities now require that toxicity testing is performed under a tightly defined code of practice (Good Laboratory Practice), which incorporates many safeguards to minimise the risk of error or fraud.

3 A severe peripheral neuropathy, leading to irreversible paralysis and sensory loss, was reported within a year of the drug's introduction and subsequently confirmed in many reports. The drug company responsible was less than punctilious in acting on these reports (see Sjöström and Nilsson, 1972), which were soon eclipsed by the discovery of teratogenic effects, but the neurotoxic effect was severe enough in its own right to have necessitated restriction of the drug from general use. Today, use of thalidomide has had a resurgence related to several highly specialised applications. It is prescribed by specialists (in dermatology, haematology, and oncology) under tightly controlled and restricted conditions. **Lenalidomide**, a teratogen and structural analogue of thalidomide, is used in treating myeloma (Ch. 57) and haematologic dysplastic syndromes with close supervision involving pregnancy testing every 4 weeks.

59: Lifestyle and drugs in sport

OVERVIEW

Drugs used for nontherapeutic reasons, but rather for cosmetic purposes, purely social reasons or to enhance athletic or other abilities are collectively referred to as *lifestyle drugs*. It is a diverse category of unrelated drugs and since many are also used for other conventional clinical purposes, their pharmacology is described elsewhere in this book. In this chapter we present an overview of lifestyle drugs illustrating the topic with three specific examples: cognitive enhancers, 'pharmacosex' and the use of drugs in sport. We also introduce some of the ethical, social and medico-legal problems associated with the 'lifestyle drug phenomenon' and also the related concept of 'human enhancement'.

What are Lifestyle Drugs?

Some commentators would describe lifestyle drugs as those which are used to treat 'lifestyle diseases' such as smoking or alcoholism but generally (and specifically in this chapter) the term refers to drugs or medicines that are taken by choice to satisfy an aspiration or a non-health-related goal rather than to treat an illness or disease. Since many are conventional therapeutics already used

clinically for some purpose, a better term for this group might be *lifestyle uses* for drugs.

Some examples may make this clear. The vast majority of women who take the contraceptive pill are not 'ill'; they take these powerful drugs so they can plan their families, in other words, for lifestyle purposes. Likewise, while **sildenafil** is used clinically to treat male erectile dysfunction, this drug is mostly used by normal men who wish to improve their sexual prowess. Many people who use cognitive enhancers do so for lifestyle purposes, to improve concentration or exam performance for example, and not because they suffer from attention deficit hyperactivity disorder (ADHD). In the words of one commentator, lifestyle drugs are used to treat 'non-diseases' (**Smith, 2002**).

The lifestyle drug 'sector' is growing rapidly, with sales sometimes outstripping those of conventional medicines. Public demand is increased by the widespread availability of medical information on the internet and 'self-diagnosis'. Anyone with a computer can now look up their 'symptoms', their likely cause and the appropriate medical remedy. It is easy to locate advice on how drugs may ease your real or imagined problem or help with the realisation of some other physical or mental goal. Internet sites hosting 'patient support groups' provide a convenient forum where one can compare notes with others, learn which drugs are the best and even obtain advice on what to tell your doctor in order to ensure you receive your drug of choice. If this fails, online pharmacies are sure to oblige.

The lifestyle drug 'phenomenon' forms part of a larger debate which also embraces the concept of *human enhancement*, the use of

pharmaceutical, genetic and other biotechnologies to augment human capabilities beyond those normally enjoyed by mankind. As you might imagine, these are controversial ideas, which will likely keep bioethicists and drug regulators busy for some time to come. The possibility, intensively pursued but so far regrettably unrealised, of finding drugs that prolong life by retarding the functional and degenerative changes characteristic of old age is another social and ethical minefield.

Whilst we touch upon some of these thorny issues later, we focus our attention mainly on the pharmacological aspects of lifestyle drugs, leaving other unresolved ethical issues to our more philosophically minded colleagues. For a more complete discussion of human enhancement by pharmacological means, see **Buchanan (2011)**, **Flower (2012)** and **Hofmann (2017)**.

Classification of Lifestyle Drugs

The 'lifestyle drug' category comprises a variety of chemically and pharmacologically unrelated groups of drugs and medicines. The classification scheme in **Table 59.1** is based upon the work of several authors and since these drugs cut across the pharmacological classification used throughout this book, it includes the appropriate chapter cross-references.

The list embraces drugs that have been used for lifestyle choices based on historical precedent, such as oral contraceptives, agents used to manage potentially debilitating lifestyle illnesses such as addiction to smoking (e.g. **bupropion**), drugs such as **caffeine** and **alcohol** that are consumed on a massive scale around the world as components of drinks, nutritional supplements as well as drugs of

abuse such as **cocaine** and 'NSPs' (novel psychoactive substances), increasing common street drugs.

Perhaps illustrating the potential pitfalls of any attempt to define lifestyle drugs, we may note how, over time, drugs can alternate between 'lifestyle' and 'clinical' categories, often depending upon the social mores of the day. For example, **cocaine** was used as a lifestyle drug by the indigenous peoples of South America. Early explorers commented that it 'satisfies the hungry, gives new strength to the weary and exhausted and makes the unhappy forget their sorrows'. Originally adopted into European medicine as a local anaesthetic, it is now largely returned to lifestyle drug status and, regrettably, is the basis of an illegal multimillion dollar international drugs industry. **Cannabis** is another good example of a drug that has been considered (in the West at least) as a purely recreational drug but which is now (as a plant extract containing **tetrahydrocannabinol** and **cannabidiol**) licensed for various clinical uses. There are many other examples (**Flower, 2004**).

Table 59.1

ADHD, Attention deficit hyperactivity disorder; *MDMA*, methylenedioxy-methamphetamine ('ecstasy').

[a] Obviously only in men.

[b] In addition, there are countless herbal preparations and other natural products, largely unregulated, which are marketed as health-promoting, life-enhancing and beneficial for many disorders, despite lack of rigorous evidence of therapeutic efficacy. Examples include numerous vitamin preparations, fish oils, melatonin, ginseng, *Echinacea*, *Ginkgo* and much besides.

From Flower, 2004, after Gilbert et al., 2000, and Young, 2003.

Aside from those mentioned in **Table 59.1**, many widely used lifestyle 'drugs' or 'sports supplements' consist of natural products (e.g. *Ginkgo* extracts, melatonin, St John's wort, *Cinchona* extracts), the manufacture and sale of which have historically not been regulated. [1] Their composition is therefore highly variable, and their efficacy and safety generally untested. Many are 'spiked' with synthetic pharmacologically active drugs giving an illusion of efficacy (**Rocha et al., 2016**), or contain naturally occurring biologically active substances which, like synthetic drugs, can produce harmful as well as beneficial effects.

Because of the breadth of the lifestyle drug debate, we will consider only three particular topics in this chapter: cognitive enhancers, lifestyle drugs and sex and drugs in sport.

Cognitive Enhancers

At the time of writing, the lifestyle use of cognitive enhancers – *nootropic agents* – has become a topical (and divisive) issue much aired in the popular press. [2] Whilst the clinical use of drugs that improve cognitive defects in clinical conditions such as *attention deficit hyperactivity disorder* (ADHD), dementia, schizophrenia and depression is well established (see Chs **40** and **47–49**), what has provoked controversy has been their use (mostly off-prescription) for improving intellectual performance or stamina in healthy people, particularly it appears, in academics and students (see **d'Angelo et al., 2017**).

The most common 'neuro-enhancers' (see also **Ch. 49**) used clinically include **modafinil**, **dextroamphetamine** (**Adderall**) and **methylphenidate**. Some anticholinergic agents such as **donepezil,** which are used to retard the mental decline associated with Alzheimer's disease, have also been also tested as cognitive enhancers. While their clinical actions are not disputed, evidence of their presumed activity on *healthy* people is often far from clear; as Sahakian's group put it '*…it may be that expectations of the effectiveness of these drugs exceed their actual effects*' (**d'Angelo et al., 2017**) although better and more effective drugs may well be forthcoming in the future. There are several reasons for this apparent disconnect, including the diversity of tests used to assess cognitive functioning by different groups, the ability of these drugs to produce effects on several neurotransmitter systems simultaneously as well as the fact that some of these drugs have bell-shaped dose–response curves, with larger doses producing reduced, rather than enhanced, scores. Another problem is the

'baseline effect'. While some cognitive enhancers such as **Adderall** and **methylphenidate** increase aspects of cognitive function when this is below par because of say, lack of sleep or jet lag, they have much less effect on 'normal' functioning. Of those drugs already mentioned, **modafinil** seems to produce consistent enhancement of cognitive indices effects in normal healthy, non-sleep-deprived, subjects. **Donepezil** has been reported in studies on pilots to improve training performance and ability to cope with emergencies but, in terms of other measures of effectiveness, seems once again to be more effective in sleep-deprived subjects than in rested subjects.

Notwithstanding some reservations about their real effects in normal people, the potential cognitive enhancers have been enthusiastically adopted by those faced with tasks requiring mental rather than physical application because of their potential benefits of. The scale of their use is striking. According to Sahakian's group (**d'Angelo et al., 2017**; **Mohamed and Sahakian, 2012**; **Sahakian and Morein-Zamir, 2007**), there has been a steep increase in this type of usage particularly among academic communities. In the United States, 16% of college students reported having illicitly obtained new prescription stimulants and, in the United Kingdom, a survey showed that 10% of students in 2009 were taking prescription drugs for cognitive enhancement, with 10%–20% of students at Oxford and Cambridge admitting to using them (cited in **Teodorini et al., 2020**). In 2008, the journal *Nature* conducted a poll (**Maher, 2008**) to gauge the usage of these drugs by healthy academics and some of the results were surprising. Responses from 1400 scientists from 60 countries

revealed that about 20% used drugs for cognitive enhancement and approximately one-third of respondents had obtained these from internet sites where little, if any, medical assessment would have been made prior to supplying the drug.

The military too has long employed stimulants and cognitive enhancers to increase stamina, and to reduce the requirement for sleep among troops, and in military aviation, use of these substances to facilitate a pilot's concentration during long sorties is common (**Tracey and Flower, 2014**).

The apparent scale of student usage has led many to call for tighter rules to ensure that some students do not gain an unfair advantage in exams [3] although, as Sahakian has argued, it is difficult to know where to draw the line on such prohibitions. Presumably no one would complain if students took double espressos before an exam? And yet **caffeine** is a very effective stimulant in its own right being, perhaps equal too if not superior to many other 'enhancers' and only overlooked only because of its familiarity. So what is the difference?

Drugs and Sex

The use of lifestyle drugs to reduce inhibitions or increase the desire for, or the experience of, sex has become known as *pharmacosex*. The concept of 'aphrodisiac' drugs (usually in the form of plant extracts) is as old as history. A myriad of foods and natural products have been claimed to increase sexual desire (the original definition of an 'aphrodisiac') although there are actually very few agents with well-validated libidinous effects. In fact, drugs which actually enhance libido, as opposed to loosening inhibition

(such as alcohol), are few, with **testosterone** being the obvious exception (in both sexes), although an aphrodisiac effect may be an incidental outcome of some drugs when used therapeutically: for example, **pramipexole**, a dopamine receptor agonist, is sometimes used to counteract the decrease in libido induced by serotonin-selective reuptake inhibitor (SSRI) antidepressant drugs. In a similar way, the antidepressant **fibanserin** (a 5-$HT_{1A/2A}$ agonist) has found a secondary utility in treating hypoactive sexual desire in premenopausal women.

The range of drugs which impact in some way or other upon the sexual experience is huge (see **Table 59.2**). A review of the experiences of people of many sexual orientations by **Moyle et al. (2020)** reports the use of many agents including **methylenedioxy-methamphetamine** (**MDMA)** ('ecstasy), **cocaine** and **GHB** (g-hydroxybutyrate) to intensify the experience of sex and in some cases produce an 'empathic effect' on their consumers, leading to feelings of greater intimacy and 'connectedness' (regrettably, usually only temporary). Often, such drugs are used in combinations ('polydrug' use) and there is some evidence that those who use such drugs in this way may be more likely to explore 'non-traditional' sexual behaviour (**McCormack et al., 2021**). However, it is sometimes difficult to disentangle the effects of agents which lower the inhibitory barriers to intimacy from those producing a genuine aphrodisiac effect.

Most other drugs in **Table 59.2** would probably be more correctly termed 'sexual accessories' or 'enhancers', either promoting the ability to perform sex (e.g. **sildenafil** and other PDE5 inhibitors) or prolonging (e.g. **benzocaine**) or increasing

(e.g. **MDMA**) the pleasure obtained from sexual activity. [4] The remainder are mainly drugs used to prevent negative consequences of sex such as unwanted pregnancies and HIV infection.

Table 59.2

GHB, γ-Hydroxybutyrate; *MDMA*, methylenedioxy-methamphetamine ('ecstasy').

A subset of pharmacosexual practices is termed *chemsex*. This is usually applied to the use of drugs by gay men to increase the intensity and duration of sex, often with multiple partners, in sessions lasting several hours or days (see **Moyle et al., 2020**; **McCall et al., 2015**, for a fuller description). The drugs commonly taken include combinations of psychoactive drugs such as **mephedrone**, **γ-hydroxybutyrate** (GHB), and **methamphetamine** and **amyl nitrite**.

Lifestyle drugs

- More accurately called *lifestyle uses* for drugs, this is the term used to describe an unrelated group of drugs and medicines taken for non-medical reasons, including the illicit enhancement of athletic prowess in competitive sport.
- They include prescription drugs such as **sildenafil** and **methylphenidate**, substances such as **alcohol** and **caffeine**, drugs of abuse including other 'street' drugs and various nutritional preparations.

- Their use is linked to the concepts of ‘self-diagnosis’ and ‘non-disease’.
- It is a growing sector of the pharmaceutical market.
- They are often brought to the consumer’s attention through the internet or direct marketing.
- They form part of a larger debate on ‘human enhancement’.

Drugs in Sport

Although the use of drugs to enhance performance (‘doping’) in elite sporting competitions such as the Olympic Games is officially prohibited, it is evidently widespread. *The World Anti-Doping Agency* (WADA), which was established partly in response to some high-profile doping cases and drug-induced deaths among athletes, publishes an annually updated list of prohibited substances that may not be used by sportsmen or sportswomen either in or out of competition. This proscription is enforced by random and routine drug testing of an athlete’s blood or urine using gas chromatography/mass spectrometry or immunoassay techniques. The testing protocols for such samples are strictly defined and must be performed by approved laboratories. Drug use by athletes for bona fide clinical reasons is allowed under the ‘*Therapeutic Use Exemptions*’ scheme. According to this arrangement, which was introduced in the 1990s, an athlete may use a medicine (say, glucocorticoids for asthma) if it is determined clinically that this exemption is justified. Clearly, this system is open to abuse and has been so exploited on several occasions.

Infringements of the anti-doping regulations in professional sport are strictly punished but despite the threat of sanctions, there have been many instances where they have been flouted both by individual athletes and, in some cases, by entire teams. The American cyclist Lance Armstrong, for example, was a national hero. Having overcome testicular cancer, he went on to win the *Tour de France* on no less than seven occasions. For years, persistent accusations of drug abuse were strenuously denied but in January 2013, Armstrong finally admitted having used a cocktail of drugs to enhance his performance over the course of many years. [5] And it is not just individual athletes who have been caught out. An investigation into Russian athletics by WADA in 2016 concluded that a large-scale state-sponsored doping programme was routinely operating to conceal drug use by their athletes. This led to a ban on Russian participation in the subsequent Summer Olympics and other events although whether this had the desired salutary effect is debatable: at the 2022 Beijing Winter Olympics, the 15-year-old Russian skater, Kamila Valieva, already considered one of the top athletes in the sport, was found to have taken **trimetazidine,** a metabolic modulator used to improve coronary blood flow (and banned by WADA). According to a statement from the International Testing Agency she was provisionally suspended pending a further investigation. Shameful episodes such as these have prompted more than one commentator to despair of the 'charade of drug-free sport' (**Sparling, 2013**) with many believing that professional sport has been permanently damaged. Sadly, the practice is increasingly being extended to amateur and recreational sport also.

While athletes are easily persuaded of the potential of a wide variety of drugs to increase their chances of winning, controlled trials of such claims are difficult. In many cases these agents probably produce little or no effect, although of course, marginal improvements in performance (often 1% or less), which are difficult to measure experimentally, may make the difference between winning and losing, and the competitive instincts of athletes and their trainers generally carry more weight than scientific evidence.

Table 59.3 summarises the main classes of drugs used in sport, most of which are banned by WADA. A brief account of some of the more important drugs in common use follows. For a broader and more complete coverage, see **La Gerche and Brosnan (2017)**, **Reardon and Creado (2014)** and **Mottram (2005)**. **Gould (2013)** has reviewed the potential use of gene therapy in promoting athletic performance: another potential nightmare for the regulators!

Anabolic Steroids and Related Compounds

Anabolic steroids (**Ch. 35**) include a large group of compounds with testosterone-like effects and include about 50 named compounds on the prohibited list. Together they constitute over half the number of 'doping' cases detected. They are often used in combination with **erythropoietin** (**EPO)** or other drugs to enhance performance in both endurance and strength events.

When given in combination with training and high protein intake, anabolic steroids undoubtedly reduce body fat, increase muscle mass and strength but probably not other parameters of sporting performance. They also have serious long-term effects, including

male infertility, female masculinisation, liver and kidney tumours, hypertension, increased cardiovascular risk and (in adolescents) premature skeletal maturation causing irreversible cessation of growth. Anabolic steroids produce a feeling of physical well-being, increased competitiveness and aggressiveness, sometimes progressing to actual psychosis. Depression is common when the drugs are stopped and sometimes leads to long-term psychiatric problems. Mortality is increased among habitual users, with cardiac abnormalities being the principal cause of death. In attempt to circumvent the testing protocols, other drugs that release androgens (e.g. **human chorionic gonadotrophin; hCG**) or which modify their action, such as androgen receptor modulators, are increasingly used.

In addition to endogenous steroids, synthetic compounds such as **stanozolol** and **nandrolone** are also used and novel chemical derivatives ('designer steroids'), such as **tetrahydrogestrinone** (THG), are regularly developed and offered illicitly to athletes, posing a continuing problem to the authorities charged with detecting and identifying them. Since some are endogenous compounds (or their metabolites), their concentration can vary dramatically for physiological reasons, so results significantly above normal range are required to confirm illicit usage. Fortunately, isotope ratio techniques, based on the fact that endogenous and exogenous steroids have a slightly different ^{12}C:^{13}C composition, now enable the two to be distinguished analytically. Since anabolic steroids produce long-term effects and are normally used throughout training, rather than during the event itself, out-of-competition testing is essential.

Clenbuterol is a β-adrenoceptor agonist. Through an unknown mechanism of action, it produces anabolic effects similar to those of androgenic steroids, with apparently fewer adverse effects. It can be detected in urine and its use in sport is banned.

The use of **human growth hormone** (**hGH**) by athletes followed the availability of the recombinant form of the hormone, used clinically to treat endocrine disorders. It is given by injection and its effects appear to be similar to those of anabolic steroids. **hGH** is also reported to produce a similar feeling of well-being, although without the accompanying aggression and changes in sexual development and behaviour. It increases lean body mass, reduces fat and improves sprint capacity, but its effects on other aspects of athletic performance are unclear. It is claimed to increase the rate of recovery from tissue injury, allowing more intensive training routines. The main adverse effect of **hGH** is the development of acromegaly, causing overgrowth of the jaw and thickening of the fingers, but it may also lead to cardiac hypertrophy and cardiomyopathy, and possibly also an increased cancer risk.

Detection of **hGH** administration is difficult because physiological secretion is pulsatile, so normal plasma concentrations vary widely. The plasma half-life is short (20–30 min), and only trace amounts are excreted in urine. However, physiological **hGH** consists of three isoforms varying in molecular weight, whereas recombinant **hGH** contains only one, so measuring the relative amounts of the isoforms can be used to detect the exogenous material. Growth hormone acts partly by releasing insulin-like growth factor (**IGF-1**) from the liver, and this hormone itself is sometimes used by athletes. It also increases lean body

mass, reduces fat and may accelerate recovery from tissue injury but also may cause cardiac hypertrophy, acromegaly, liver damage and increase cancer risk

Table 59.3

CNS, Central nervous system; *NSAIDs*, non-steroidal anti-inflammatory drugs.

[a] 'Blood doping' (removal of 1–2 L of blood ahead of the competition, followed by re-transfusion immediately prior to the event) has a similar effect and is even more difficult to detect. Training at altitude or in a hypoxic environment achieves a similar effect and is not banned.

Drugs that Increase Oxygen Delivery to Muscles

EPO, which increases erythrocyte formation and oxygen transport, is given by injection for days or weeks prior to the competition to increase the erythrocyte count and hence boost the O_2-carrying capacity of blood. It is undoubtedly highly effective and is used extensively in endurance sports. The development of recombinant **EPO** has made it widely available and difficult to detect. Since **EPO** increases blood viscosity, it can cause hypertension and increase the risk of strokes and coronary attacks and neurologic disease. A doubling of the **EPO** plasma concentration is reported to increase heart failure by 25% over the following decade (cited in **La Gerche and Brosnan, 2017**). The administration of synthetic **EPO** agonists mimics the action of the native hormone itself and represents an alternate way to achieve the desired effect.

Another related way of increasing oxygen delivery to the muscle is by shifting the oxyhaemoglobin dissociation curve to the right which increases oxygen off-loading from blood to the tissues. The synthetic compound **efaproxiral** is said to improve tissue oxygenation in this way although there is little evidence that this happens in humans. Nevertheless, it is banned by WADA as a 'prohibited method' for enhancing performance. A further agent with similar effects is cobalt. Soluble cobalt salts such as cobalt chloride, probably acting through the hypoxia signalling mechanisms, stimulates erythropoiesis and angiogenesis producing a qualitatively similar effect to **EPO** and **efaproxiral**.

Insulin is sometimes used (with glucose so as to avoid hypoglycaemia) to promote glucose uptake and energy production in muscle but it is probably ineffective in improving athletic performance.

Cardiovascular Drugs

β_2-Adrenoceptor agonists (e.g. **salbutamol**) have been used by runners, cyclists, swimmers, etc., to increase oxygen uptake (by bronchodilatation) and increase cardiac function, although controlled studies have shown little or no increase in performance. β-Adrenoceptor antagonists (e.g. **propranolol**) are taken by competitors to reduce tremor and anxiety in 'precision' sports (e.g. darts, snooker, shooting, gymnastics, diving) as does small amounts of alcohol. They are not explicitly banned in many sports because they may actually impair performance. **Sildenafil** is reportedly taken by athletes on the presumption that it will increase pulmonary blood flow yielding a concomitant increase in cardiac

performance with less right ventricular load, although this has not been rigorously confirmed, at least in normoxic conditions.

Cognitive Enhancers and Stimulant Drugs

Drugs of this type are used by athletes to improve focus and concentration (**Smith et al., 2020**) with some athletes apparently justifying their use on the basis of their alleged ADHD or other cognitive disorder. The apparent benefits include an increased ability to prepare mentally for forthcoming events, superior recall of important details of competitor strategies or of an opponent's team's strengths and weaknesses. Precision sports such as archery and shooting may particularly benefit from such drugs as well as those 'sports' which impose a substantial cognitive burden on the player (e.g. chess). The most commonly used are **methylephedrine**; various amphetamines and related compounds such as **modafinil** and **methylphenidate**; **cocaine**; and a variety of other central nervous system stimulants such as **nikethamide**, **amiphenazole** (no longer used clinically) and **strychnine**. **Caffeine** is also used: some commercially available 'energy drinks' contain **taurine** as well as **caffeine**. However, **taurine** is an agonist at glycine and extrasynaptic $GABA_A$ receptors. Its effects on the brain are therefore likely to be inhibitory rather than stimulatory. In this regard, **taurine** may be responsible for the post-energy-drink low that is experienced once the stimulatory effect of **caffeine** has worn off.

The psychological effect of stimulants is probably as important as their physiological effects. Rather surprisingly, and in contrast to anabolic steroids, some trials have shown stimulant drugs such as

ephedrine improve performance in events such as sprinting, and under experimental conditions they increase muscle strength and reduce muscle fatigue significantly. Surprisingly, **caffeine** also appears to be more consistently effective in improving muscle performance than other more powerful stimulants and is among a few drugs (including **nicotine** and **alcohol**) that are not prohibited.

Regrettably, several deaths have occurred among athletes taking amphetamines and **ephedrine**-like drugs in endurance events. The main causes are coronary insufficiency, associated with hypertension; hyperthermia, associated with cutaneous vasoconstriction; and dehydration. The cyclist Tommy Simpson collapsed and died during the 1967 *Tour de France* as he attempted to ascend Mont Ventoux [6] . Amphetamines and alcohol were found in his blood stream.

Drugs in sport

- Drugs of many different types are used by athletes with to improve performance in competition.
- The main types used are:
  - anabolic agents, usually androgenic steroids and **clenbuterol**;
  - hormones, particularly **erythropoietin** and **human growth hormone**;
  - stimulants, mainly **amphetamine, ephedrine** derivatives and **caffeine**;

  - β-adrenoceptor antagonists, which reduce anxiety and tremor in ‘precision’ sports.
- The use of drugs in sport is officially prohibited – in most cases, in or out of competition.
- Detection depends mainly on analysis of the drug or its metabolites in urine or blood samples. Detection of abuse is difficult in the case of endogenous hormones such as **EPO**, **growth hormone** and **testosterone.**
- Controlled trials have shown that while some drugs (e.g. **EPO**) are extremely effective, many other drugs produce little improvement in sporting performance. Anabolic agents increase body weight and muscle volume but without clearly increasing strength. The effect of stimulants is often psychological rather than physiological.

Regulatory, Societal and Ethical Issues

Few aspects of the human enhancement/lifestyle drug debate have attracted more moral opprobrium than the use of drugs in sport. Doping is banned in professional sports because it is deemed to constitute an unfair advantage for the athletes who ‘cheat’ over those who don’t. Many feel that it undermines the very purpose of sport which should surely be to encourage a sense of ‘fair play’, to inspire others to achieve physical excellence with (hopefully) a concomitant benefit to public health and wellbeing. Such critics feel that the very notion of professional sports has already been irrevocably tarnished and has become in reality, a competition not

of athletic prowess, but rather the pharmaceutical ingenuity of their team physicians.

However, many factors are important in determining why one athlete may have an advantage over another – genetic makeup, for example – so one could argue that there is no real 'level playing field' to begin with. Indeed, one school of thought argues that athletes should have unrestricted access to performance-enhancing drugs with the proviso that they do not impair the athlete's health (see **Savulescu et al., 2004**), although this view seems unlikely to gain public acceptance in the near future.

The financial and reputational inducements for athletes to take performance-enhancing drugs are great while the chance of getting caught is quite small, fuelling the search for better and less detectable agents. There are even reports that athletes have been used to test novel or experimental enhancers without the usual health and safety regulatory checks and balances. This in turn poses further analytical problems for the regulators who must devise screening tests to monitor an increasing range of agents, some of which are difficult to assay. The contest continues as new 'designer' drugs, *masking agents* (which make it more difficult to detect a particular substance in the blood or urine) or other procedures are devised by ingenious chemists and physicians to foil drug testing protocols.

While it easy to take sides in the polarised intellectual debate about lifestyle drugs and their use, some authors (see **Chatterjee, 2004**) have personalised the ethical quandaries by inviting us to answer some challenging questions about our own likely behaviour. Would you, for example, take cognitive enhancers yourself if it

meant that you could accomplish a difficult task such as finishing your thesis on time, learn a language more rapidly or master a musical instrument? Would you give them to your child ahead of an exam if the other students in their class were known to be taking them? Since **donepezil** has been shown to speed reaction times of pilots in an aviation emergency, would you choose an airline which specified that its staff had received the drug?

Peer pressure and personal expediency, rather than bioethics, is likely to be a major determinant of your decision in many cases because ultimately one does not want to be disadvantaged when compared to one's colleagues.

Conclusion

The lifestyle drug phenomenon is one aspect of a broader debate about what actually constitutes 'disease', where the boundaries actually lie between therapy and enhancement and how far medical science and already overstretched healthcare systems should go to satisfy these aims.

Citizens of the affluent developed world are the principal consumers of lifestyle drugs, and the pharmaceutical industry is therefore incentivised to cater for this lucrative market, maybe even relying upon them to provide valuable income that can be diverted to other less profitable lines of research and development.

Despite the advantages that they can undoubtedly bring to their users, there are several reasons why lifestyle drugs – no matter how we choose to define them – are of concern to us as pharmacologists. Medicines have traditionally been developed to combat disease and the question of how one should search for, test or regulate, drugs

designed to produce effects in healthy people suffering only 'non-diseases' has yet to be settled. The increasing availability of drugs (some counterfeit) from 'e-pharmacies', coupled with the lobbying power of patients, creates demands for these drugs, regardless of their potential costs or proven utility. This inevitably causes problems for physicians, drug regulators and ultimately those who set healthcare priorities for state-funded systems of social medicine.

Discussion of these complex issues is beyond the scope of this book but can be found in articles cited at the end of this chapter (e.g. **Buchanan, 2011**; **Flower, 2004**, **2012**). The debate about the ethics and management of lifestyle drugs will undoubtedly run for a long time to come.

QUESTIONS

QUESTION 59.1

Whilst the use of drugs to enhance performance in elite sporting competitions is officially prohibited it is, unfortunately, widespread.

Which of the following compounds would be most likely to enhance athletic performance?

OPTIONS:

A. Caffeine

B. Modafinil

C. Insulin

D. Taurine

E. Propranolol

QUESTION 59.2

Detection of ‘doping’ is very difficult and depends mainly on analysis of the drug or its metabolites in urine or blood samples.

Which of the following factors facilitates the detection of substances of abuse in the body?

OPTIONS:

A. Similarity to endogenous substances

B. Half-life of the agent

C. Presence of different isotypes and isoforms

D. Plasma concentration

E. Concentration in urine

ANSWERS

ANSWER 59.1

RATIONALE:

A.

B. Modafinil is classified as a cognitive enhancer and is used by athletes to improve focus and concentration but does not affect performance.

C. Insulin is sometimes used (with glucose so as to avoid hypoglycaemia) to promote glucose uptake and energy production in muscle but it is probably ineffective in improving athletic performance.

D. β_2-Adrenoceptor agonists (e.g. salbutamol) have been used to increase oxygen uptake (by bronchodilatation) and increase cardiac function, although controlled studies have shown little or no increase in performance.

E. β-Adrenoceptor antagonists (e.g. propranolol) are taken by competitors to reduce tremor and anxiety in 'precision' sports. They are not explicitly banned in many sports because they may actually impair performance.

CORRECT ANSWER WITH EXPLANATION:

A. Caffeine

Caffeine appears to be more consistently effective in improving muscle performance than many other more powerful stimulants.

ANSWER 59.2

RATIONALE:

A. The use of natural and recombinant forms of steroids and hormones makes it difficult to distinguish between endogenous and exogenous substances.

B. The plasma half-life of many of the recombinant agents is short (20–30 min) making them difficult to detect.

C.

D. Plasma concentrations of the endogenous substances can vary dramatically for physiological reasons so results significantly above normal range are required to confirm illicit usage.

E. Often only trace amounts of the compounds are excreted in urine.

CORRECT ANSWER WITH EXPLANATION:

C. Presence of different isotypes and isoforms

Endogenous and exogenous steroids have a slightly different ^{12}C:^{13}C composition which enables the two to be distinguished analytically. Physiological human growth hormone (hGH) consists of three isoforms varying in molecular weight, whereas recombinant hGH contains only one, so measuring the relative amounts of the isoforms can be used to detect the exogenous material.

---

[1] Happily, this has now changed. Since 2014, the United Kingdom Medicines and Healthcare Products Regulatory Agency has a *Herbal Medicines Advisory Committee* designed to fulfil this demanding

role. Many such compounds elude this regulation by implying some health benefit while avoiding any specific medical claims.

[2] See 'Smart drugs "as common as coffee": media hype about neuroenhancement' (Partridge et al., 2011).

[3] '"*Exam boost" drugs that are said to improve cognitive ability are on sale to students for just £2, report shows*.' Mail Online, 8 April 2022.

[4] We have not included the numerous proprietary preparations such as 'vaginal-tightening creams' with names such as '*Forever Virgin*' and '*Virgin Again'*, which promise rather alarming increases in vaginal grip strength.

[5] Among these were EPO, testosterone, diuretics, glucocorticoids and human growth hormone. He also used 'blood doping' techniques and presented fake documents to support his claims that he was 'drug free'.

[6] A memorial erected at the spot has become something of a site of pilgrimage for competitive cyclists.

60: Drug discovery and development

OVERVIEW

With the emergence of the pharmaceutical industry towards the end of the 19th century, drug discovery became a highly focused and managed process and moved from the domain of inventive doctors to that of scientists hired for the purpose. The bulk of modern therapeutics, and of modern pharmacology, is based on drugs that originated from the laboratories of these pharmaceutical companies, without which neither the practice of therapeutics nor the science of pharmacology would be more than a pale fragment of what they have become.

In this chapter, we outline the main stages of the process, namely (1) the discovery phase, i.e. the identification of a new chemical entity as a potential therapeutic agent; and (2) the development phase, during which the compound is tested for safety and efficacy in one or more clinical indications, and suitable formulations and dosage forms devised. The aim is to achieve registration by one or more regulatory authorities, to allow the drug to be marketed legally as a medicine for human use. We also briefly mention some of the other routes to licensing which a new medicine can take, including repurposing, where a drug with an established preclinical and often a clinical development portfolio is trialled for a different

indication. The rapidly initiated clinical trials and subsequent approval of new treatments for COVID-19 are excellent examples of this approach.

Our account is necessarily brief, and there are many detailed textbooks and review articles dedicated to this topic (for example **Hill and Richards, 2021**).

Drug Discovery: Background

Diethyl ether ('sweet oil of vitriol') was synthesised in 1540 but not administered as an anaesthetic until 1846, while **morphine** was purified from poppy extract in 1806 and shown to be the active principle of opium. The impact of these seminal drug discoveries can be seen today, notably that chemistry is necessary but not sufficient – pharmacology is necessarily interdisciplinary – and that natural products remain potentially fertile starting points. Creating effective safe new drugs is difficult and expensive, and in this background section we briefly overview the relative importance of *serendipity* (exemplified by Fleming's culture plate on which the penicillium spores alighted) versus *rational drug design* – the design of new chemical entities predicted to have particular biological effects on the basis of the chemical structures of drugs and their targets. Currently both approaches remain highly productive.

Historically, chemists modified the structures of pharmacologically active drugs derived from plants or synthesised in the dye-stuffs industry and many 20th century drug discoveries stemmed from chemical modification of lead compounds. These approaches soon progressed to a more rational strategy based on the

understanding of basic biochemical and physiological processes. Each of these discoveries required functional assays for their recognition driving the development of new technologies including, most recently, sophisticated in silico and even the introduction of methods incorporating artificial intelligence (AI).

George Hitchings and Gertrude Elion were among the first to design drugs directed at specific biochemical targets, which can be regarded as the forefather of structure-based drug discovery. They collaborated in the biochemistry laboratory of Burroughs Wellcome, and focused on the folic acid pathway which is key for the action of the sulfonamides and in particular on dihydrofolate reductase (see **Ch. 52**). They synthesised a series of purine and pyrimidine 'antimetabolites' with selectivity for different forms (mammalian, bacterial, protozoal) of the enzyme. Drugs that emerged from their program include the antibacterial **trimethoprim** (see **Ch. 52**), the antimalarial **pyrimethamine** (see **Ch. 55**), the antineoplasic **6-mercaptopurine** (see **Ch. 57**) and its prodrug the immunosuppressant **azathioprine** (see **Ch. 25**); spin-offs included **allopurinol** (xanthine oxidase inhibitor used to prevent gout – see **Ch. 25** – and the urate-related complications of tumour lysis – see **Ch. 57**), **aciclovir** (one of the first antiviral drugs – see **Ch. 53**) and **zidovudine** (the first therapeutic reverse transcriptase inhibitor, still used in combination treatment for HIV – see **Ch. 53**). As with James Black's receptor-targeted drugs (β-adrenoceptor antagonists and H_2 antagonists among others) these outstanding discoveries were made using synthetic schemes where each step results in a single product, and capitalised on the

interdisciplinary nature of pharmacology with collaborations between chemists, pharmacologists and physicians.

Meanwhile, *combinatorial chemistry* (see later) where large numbers (tens to millions) of compounds are prepared as product libraries was conceived and developed together with methods to deconvolute the compound libraries and extract those products with the desired properties from the complex mixtures of end-products. These methods were developed in parallel with sequencing of the human genome, which has enabled rapid cloning and synthesis of large quantities of purified proteins, and of determining the three-dimensional structures of many potential drug–target protein complexes. Much of modern drug discovery involves selection of a potential target protein such as a receptor for a neurotransmitter or an enzyme in a key pathophysiological pathway, followed by high-throughput screening to establish 'hit' molecules for testing on cells or tissues (see later). The evolution of in silico methods enabling detailed modelling of drug docking as well as cryogenic electron microscopy (cryo-EM) and crystal structures and the use of AI all support the identification of candidate molecules.

Despite the opportunities presented by advances in combinatorial chemistry, interest remains in drugs derived from natural products which have evolved over millennia. These exhibit much greater chemical diversity, particularly as regards numbers of chiral centres and drug structure rigidity, both of which are higher in natural products than in conventional combinatorial libraries. The discovery and development of organocatalysis, which has made it much easier to synthesise asymmetric molecules for use as starting blocks, may help to correct this (see, for example, the Nobel lectures from 2021

when the prize in chemistry was awarded for the discovery of organocatalysis – **https://www.youtube.com/watch?v=IW4zgOHhefc**). It has also led to resurgent interest in the search for natural products ('bioprospecting') and in semisynthetic derivatives of natural products.

Advances in the structural biology of different states of drug-bound receptor proteins, including proteins which reside naturally in a membrane environment (see later and **Ch. 3**), are such that it may be possible for mere mortals (lacking the chemical imaginations of Gertrude Elion or James Black) to predict with precision drug structures that will influence receptor structure in a desired manner. The number of potential organic molecules is astronomical and virtual libraries of billions of actual or make-on-demand compounds have been developed, together with 'less is more' strategies as explained later in more detail.

In the special case of RNA drugs, a 'precise prediction' structure-based drug discovery paradigm has already been achieved (see **Ch. 5**). This is thanks both to understanding how RNA codes protein synthesis (such as spike protein antigen for SARS-CoV-2 vaccines, see **Ch. 53**) and to the discovery of RNA silencing by short double-stranded sequences of interfering RNA (siRNA). If a particular protein is critical for the progression of a disease, suppressing its expression needs only a short and predictable sequence of double-stranded RNA to silence its expression. However, to work in vivo such RNA-silencing drugs must be delivered intracellularly to the cytoplasm of the cells where the specific protein target is translated. For example, this has been achieved for siRNA acting in liver hepatocytes by chemically modifying the ribose ring to increase

stability and conjugating the modified RNA with tris-*N*-acetylgalactosamine (GalNAc). GalNAc is recognised by asialoglycoprotein (ASG) receptors in the sinusoidal membranes of hepatocytes, resulting in rapid binding to the ASG receptors and endocytosis of the drug complex into hepatocyte cytoplasm (see **Springer and Dowdy, 2018**, for a review). An example of such a drug in clinical use is **inclisiran** (see **Ch. 22**) which is given by subcutaneous injection twice a year, so is potentially suitable for administration in primary care. Other drugs utilising GalNAc delivery to the hepatocyte cytoplasm have been licensed, e.g. **givosiran** which, given subcutaneously once monthly, reduced the annual frequency of severe attacks of *acute hepatic porphyria* (see **Ch. 12**) by approximately 70%, and which is illustrated on our front cover.

Genomic epidemiology was the source of the idea that PSCK9 suppression would lower low-density lipoprotein (LDL) cholesterol safely, and other novel drugs for a multitude of unmet medical needs (both common and rare diseases) will be enabled if RNA drugs can be distributed into the relevant cell types (see **Springer and Dowdy, 2018**), potentially changing fundamentally the future practice of medicine.

The Stages of a Project

Fig. 60.1 shows in an idealised way the stages of a 'typical' project, aimed at producing a marketable drug that meets a particular medical need (e.g. to alleviate the symptoms of asthma, to retard the progression of cardiac failure or to treat an infection). It is important to note that the drug development process relies on a

substantial body of fundamental research which occurs in both academia and industry and from which the new drug targets emerge and feed into the drug development process. A substantial amount of knowledge is now gained from the use of recombinant protein expression in cell lines. This has enabled high-throughput screens, mutagenesis studies and application of techniques such as cryo-EM to resolve receptor structures within their physiological membrane environment (see below), methods that are revolutionising drug discovery. Animal research plays an important role in both fundamental research and the drug development process but these technologies mean only the best candidates are progressed to in vivo studies. **Fig 60.2** shows how animals are used in different areas of scientific research including the drug development process.

Broadly, the process can be divided into three main components designed to answer multiple specific questions:

1. *Drug discovery*, during which candidate molecules are chosen on the basis of their pharmacological properties.
2. *Preclinical development*, during which a wide range of non-human studies are carried out.
    a. Can pharmaceutical formulation be improved (optimisation may extend into clinical development)?
    b. What organs are most sensitive to its toxicity?
    c. Should specific safety tests (e.g. ophthalmic) be incorporated in future human studies?
    d. What is an appropriate first dose for human studies? Is the candidate effective in animal models of disease?
3. *Clinical development* (usually performed first in healthy – and then in patient – volunteers): Does the drug get to its

site of action? Does it engage with its target? Does it cause the predicted desired biochemical and physiological effects? Is it tolerated (many plant-derived molecules are recognised as foreign and potentially poisonous in the chemoreceptor trigger zone in the brainstem and induce vomiting, see **Ch. 30**)? What dose regimens are appropriate for efficacy trials in patients? Does it work? Is it safe? These are deceptively simple questions that may have uncomfortable answers (e.g. positive inotrope drugs that improve symptoms of heart failure but reduce survival, see **Ch. 20**).

These phases do not necessarily follow in strict succession, as indicated in **Fig. 60.1**, but can overlap. The main factors influencing the timescales for drug development are financial (for a moderately successful drug with sales of $40 million/year, each week's delay in development will cost the company roughly $8 million by reducing the competition-free sales window provided by patent protection) and balancing financial risks and so companies will often wait for each milestone and a risk re-evaluation before progressing to the next stage. As the drug development process progresses, costs increase disproportionately and so therefore does risk. As discussed later in this chapter, deviations from this 'standard' approach are not uncommon. For example, drug repurposing offers an alternative route to clinic. Costs, risk and the commercial interest associated with drug companies are usually necessary factors in the drug development process; however, alternative approaches such as the one set up by Cancer Research UK, the CRUK Centre for Drug Development, have enabled clinical

evaluation of drugs and for indications which may not have progressed under a more typical commercial model.

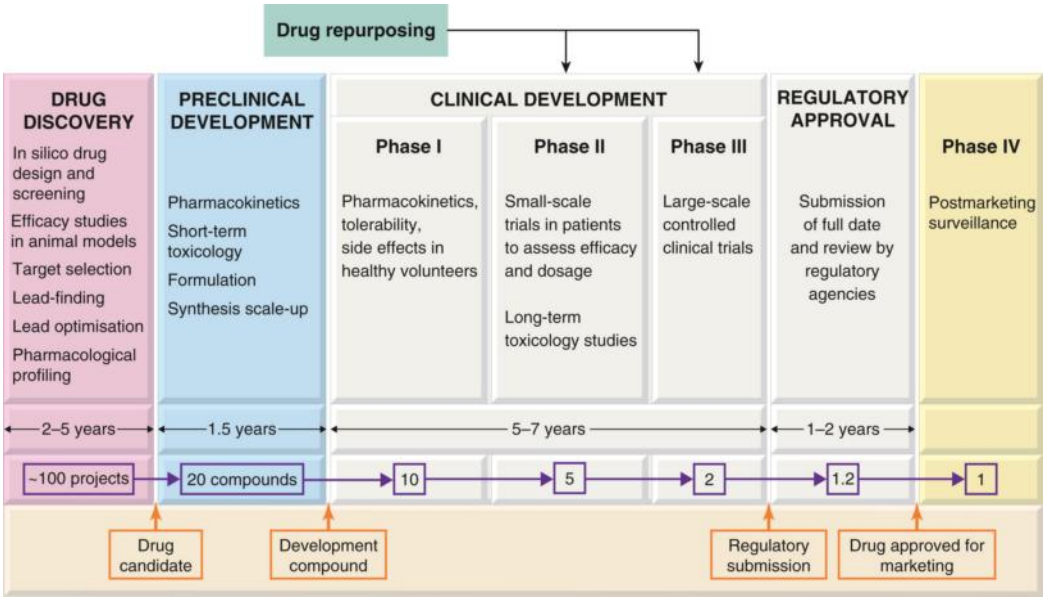

FIG. 60.1 The stages of development of a 'typical' new drug, i.e. a synthetic compound being developed for systemic use.Only the main activities undertaken at each stage are shown, and the details vary greatly according to the kind of drug being developed.

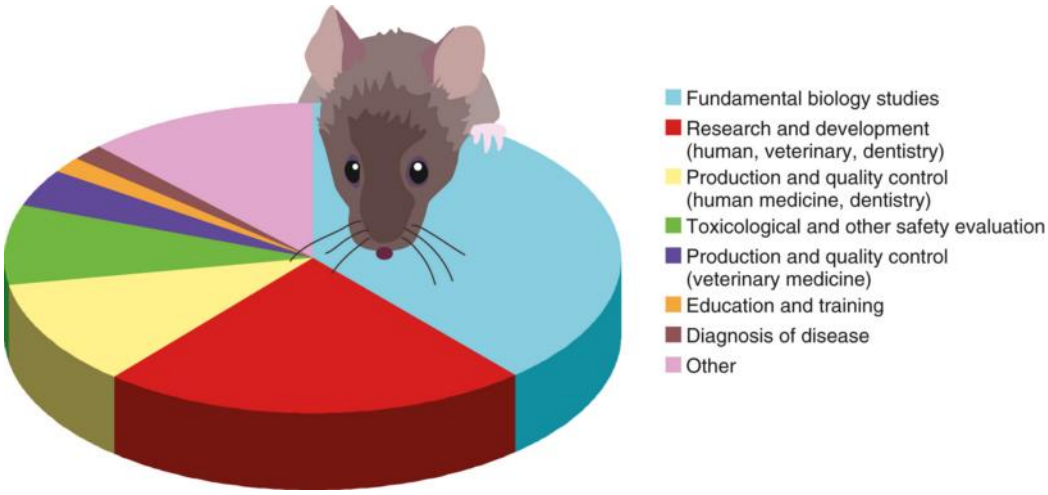

FIG. 60.2 Animal studies in the drug development process.The areas of the pie chart reflect the numbers of animals used annually in the UK in different components of the process from fundamental research supporting the identification of novel drug targets through to pharmacology and toxicology studies. Most of these studies involve rodent models. Adapted from Dolgin, E., 2010. Nat. Med. 16, 1172.

The Drug Discovery Phase

Rational drug design (see earlier) is only feasible where there is strong fundamental biology and a clear hypothesis as seen for diseases such as diabetes mellitus (see **Ch. 31**). For many diseases, particularly those of the central nervous system, knowledge of the underlying pathology and pathophysiology (see **Ch. 40**) remains limited, and this can result in high failure rates. Many new drugs are not entirely novel but 'me-too' versions of drugs already in use. [1] As explained later, developing a new 'first-in-class' drug usually

starts with identifying a new molecular target by following clues from a number of sources including serendipity, genomics and/or fundamental biology research. Conventional biological wisdom, drawing on a rich but incomplete fund of knowledge of disease mechanisms and chemical signalling pathways, coupled with genomic data, is the basis on which novel targets are most often chosen. Disciplines such as genomics, bioinformatics, proteomics and systems analysis are playing an increasing role by revealing new proteins involved in chemical signalling, new genes involved in disease and new models of disease progression.

Target Selection

As discussed in **Chapter 2**, drug targets are, with a few important exceptions, functional proteins (e.g. receptors, enzymes, transport proteins), but an increase in nucleic acid targets is anticipated (see earlier). Although, in the past, drug discovery programmes were often based – successfully – on measuring a complex response in vivo, such as prevention of experimentally induced seizures, lowering of blood sugar or suppression of an inflammatory response, without the need for prior identification of a molecular drug target, nowadays this is less common, and the first step is *target identification*. This most often comes from biological intelligence. It was known, for example, that inhibiting angiotensin-converting enzyme lowers blood pressure by suppressing angiotensin II formation, so it made sense to look for antagonists of the vascular angiotensin II receptor – hence the successful 'sartan' series of antihypertensive drugs (see **Ch. 21**). The success of biopharmaceuticals as treatments for a wide range of disorders from

cancer to immune diseases builds from fundamental biology. However, for many disorders, particularly those involving the central nervous system, knowledge of the causal pathways remains poorly understood which, coupled with the complexity of the brain, has made rational drug design more challenging than in organs where the mechanism is better understood. Serendipity continues to play its part in the discovery of new treatments such as the example of severe infantile haemangioma (**Ch. 15**) which is now treated using propranolol after a baby with this tumour was treated with propranolol for coincident hypertrophic cardiomyopathy (HCM) leading to a large randomised controlled trial (RCT) which confirmed efficacy. A survey of 1194 FDA-approved human medicines (**Santos et al., 2017**) noted that they acted at a total of 893 targets, of which 667 were human proteins (comprising 549 small molecule and 146 biopharmaceutical drug targets) and a further 189 were pathogen protein targets. Based on knowledge derived from the human genome project, there are many thousands more potential drug targets for drug discovery awaiting therapeutic exploitation. Selecting *valid* and 'druggable' targets from this plethora is a major challenge.

Lead Finding

When the biochemical target has been decided and the feasibility of the project has been assessed, the next step is to find *lead compounds*. Here we focus on lead compounds derived from synthetic chemistry – see earlier in the chapter and **Chapter 5** for biopharmaceutical leads from the biotech industry and academia. Commonly, lead finding involves cloning and expression of the

human target protein. An assay system allowing the functional activity of the target protein to be measured is then used for high throughput screening. This could be a cell-free enzyme assay, a membrane-based binding assay or a cellular response assay and is engineered to run automatically, preferably with an optical read-out (e.g. fluorescence or optical absorbance), and in a miniaturised multiwell plate format (96-, 384-, 1536- or 3456-well versions are available) for reasons of speed and economy. Robotically controlled assay facilities capable of testing tens of thousands of compounds per day [2] in several parallel assays are now commonplace in the pharmaceutical industry and have become the standard starting point for most small molecule drug discovery projects. For details on high-throughput screening, see **Ross and Bittker (2016)**.

To keep such hungry monsters running requires very large *compound libraries*. Large companies will typically maintain a growing collection of a million or more synthetic compounds, which will be routinely screened whenever a new assay is set up. Whereas, in the past, compounds were generally synthesised and purified one by one, often taking a week or more for each, the use of combinatorial chemistry allows large families of related compounds to be made simultaneously. By coupling such high-speed synthesis to high-throughput assay systems, the time taken over the initial lead-finding stage of projects has been reduced to a few months or less in most cases, having previously often taken several years.

In structure-based drug discovery use is made of X-ray crystallography and more recently of cryo-EM to provide knowledge of the three-dimensional structure of the target protein. This latter technique which evolved over decades was hailed in the press

release for the 2017 Nobel Prize in chemistry, awarded to Jacques Dubochet, Joachim Frank and Richard Henderson, as having 'moved biochemistry into a new era'. It images vitrified biomolecules with associated water molecules, without the need for crystallisation so enabling study of transmembrane proteins and other difficult-to-crystallise complexes including intermediate and equilibrium states of ligand–protein complexes (**Robertson et al., 2021**). It has been embraced by big pharma and many academic laboratories and has already impacted structure-based drug design for G protein–coupled receptors (GPCRs), ion channels and solute carrier proteins (SLCs), as well as in vaccine development where it enables better antigen design. It is, however, still in its infancy compared with X-ray crystallography which currently provides higher resolution where it is applicable (**Lees at al., 2021**). It thus seems likely that these two technologies will remain complementary for some time at least (**Renaud et al., 2018**).

Computer-based molecular modelling is used to identify possible lead structures within the compound library, in order to reduce the number of compounds to be screened. As mentioned earlier, molecular modelling can also be used to screen huge numbers of hypothetical – not yet synthesised – molecules to provide pointers for the synthesis and screening of new compound families. Refined in this way, screening can identify lead compounds that have the appropriate pharmacological activity and are amenable to further chemical modification. A recent method called V-SYNTH (virtual synthon hierarchical enumeration screening) has been described based on combining much smaller numbers (hundreds of thousands) of compound fragments ('synthons') with reliable

known chemical reactions. This makes the synthesis of potential hits fast (4–6 weeks), reliable (>80% success) and affordable. The virtual library is screened by identifying the best scaffold–synthon combinations to initiate growth then iteratively elaborating such seeds. These can be used to build up molecules via progressive (cycle-by-cycle) additions of synthons to a growing scaffold with improved docking to the target at each cycle, cutting down very substantially on computing resource needed. This worked well in identifying hits for CB1 and CB2 receptors and for a kinase target (**Sadybekov et al., 2022,** and see **Deane and Mokaya, 2022**).

'Hits' detected in the initial screen often turn out to be molecules that have features undesirable in a drug, such as excessive molecular weight or polarity, or possession of groups known to be associated with toxicity. Computational 'prescreening' of compound libraries is often used to eliminate such compounds. Conversely some aspects of molecular structure, such as chirality and rigidity, have been associated with successful drugs, presenting the designer with choosing between screening out candidates that do not conform and potentially missing out on more novel possibilities.

The hits identified from the primary screen are used as the basis for preparing sets of homologues by combinatorial chemistry to establish the critical structural features necessary for binding selectively to the target. Several such iterative cycles of synthesis and screening are usually needed to identify one or more lead compounds for the next stage.

Natural products as lead compounds

Historically, natural products, derived mainly from fungal and plant sources, have proved to be a fruitful source of new therapeutic agents, particularly in the field of anti-infective, anticancer and immunosuppressant drugs. Familiar examples include **penicillin**, **streptomycin** and many other antibiotics; vinca alkaloids; **paclitaxel**; **ciclosporin** and **sirolimus** (**rapamycin**). NMR is often used to determine their complex structures. Recently, there has been renewed interest in psychedelic drugs, many of which are derived from plants and are being investigated as treatments for anxiety and depression and addiction (Chs **48** and **50**). These substances presumably serve a specific protective function, having evolved to recognise, with great precision, vulnerable target molecules in an organism's enemies or competitors. The surface of this resource has barely been scratched, and many companies are actively engaged in generating and testing natural product libraries for lead-finding purposes. Fungi and other microorganisms are particularly suitable for this, because they are ubiquitous, highly diverse and easy to collect and grow in the laboratory. They have also had aeons of evolution to devise an armoury of effective substances fit for specific functions (e.g. antibacterial) which can sometimes be utilised as a starting compound in the search for our desired drug. However, compounds obtained from plants, animals or marine organisms are much more troublesome to produce commercially. Their main disadvantage as lead compounds is that they are often complex molecules that are difficult to synthesise or modify by conventional synthetic chemistry, so that *lead optimisation* may be difficult and commercial production very expensive.

Lead Optimisation

As mentioned earlier, the aim of lead optimisation is to increase the potency of the compound on its target and to optimise it with respect to other characteristics, such as selectivity and pharmacokinetic properties. Whilst this has been a widely adopted approach, in some areas such as psychiatric disorders, highly selective drugs acting at a single target have generally failed in clinical trials despite the predictions from animal models. It is often drugs with multiple sites of action, discovered through more traditional approaches, which have progressed, perhaps reflecting the complexity of brain disorders and our limited understanding of their pathophysiology.

The tests applied during lead optimisation include a broader range of assays than are used during initial screening, including studies to measure the activity and time course of the compounds in vivo (where possible in animal models mimicking aspects of the clinical condition; see **Ch. 8**), and checking for unwanted effects, evidence of genotoxicity and, where appropriate, oral availability. The objective of the lead optimisation phase is to identify one or more *drug candidates* suitable for further development.

As shown in **Fig. 60.1**, only about one project in five succeeds in generating a drug candidate, which can take up to 5 years. The most common problem is that lead optimisation proves to be impossible; despite much ingenious and back-breaking chemistry, the lead compounds, like antisocial teenagers, refuse to give up their bad habits. In other cases, the candidate leads, although they produce the desired effects on the target molecule and have no other obvious defects, fail to produce the expected effects in animal models of the

disease, implying that the target may not be a useful one in humans either. The virtuous minority of drugs proceed to the next phase, preclinical development.

Preclinical Development

The aim of preclinical development is to satisfy all the requirements to enable approval for first-in-man studies. The work falls into four main categories:

1. *Safety pharmacology*. Pharmacological testing to check that the drug does not produce harmful effects, including studies to establish effects on the cardiovascular and respiratory systems and other major organs such as the liver and effects involving the central nervous system such as ataxia (lacking coordinated muscle movement). Many drugs can fail at this early stage due to unwanted pharmacological effects such as QT prolongation (**Ch. 20**) which is an indicator that the drug can have serious cardiac side effects or effects on other major organs such as the liver. Drugs that inhibit hERG channel activity are routinely screened out, as this implies a QT prolongation effect with the potential to predispose to fatal ventricular dysrhythmia. Any drug which penetrates the brain or has targets within the central nervous system is required to undergo assessment for dependence liability. These studies are normally performed in rats and provide essential safety data.
2. *Toxicology*. Toxicological testing to eliminate genotoxicity and to determine the maximum non-toxic dose of the drug, usually when given daily for 28 days, and tested in two

species of which one is a rodent. The more sensitive species is used to determine the 'no observed adverse effect level' (NOAEL), which is used in turn to estimate a 'human equivalent dose' (HED) based usually on scaling to estimated body surface area. The HED is combined with a safety factor determined by individual aspects of the preclinical pharmacology to select a suitable starting dose for the first-in-human study. [3] As well as being checked regularly for weight loss and other gross changes, the animals are examined *postmortem* at the end of the experiment to search for histological and biochemical evidence of tissue damage (see also **Ch. 58**). (Reproductive toxicity, relevant when a drug is likely to be used by women of child-bearing potential, is expensive and studies may overlap early clinical studies in men.)

3. *Pharmacokinetic and pharmacodynamic (PK/PD) testing*, including studies on the absorption, metabolism, distribution and elimination (*ADME studies*) in the species of laboratory animals used for toxicology testing, to link the pharmacological and toxicological effects to plasma concentration and drug exposure.
4. *Chemical and pharmaceutical development* to assess the feasibility of large-scale synthesis and purification, to assess the stability of the compound under various conditions and to develop a formulation suitable for clinical studies.

Much of the work of preclinical development, especially that relating to safety issues, is done under a formal operating code, known as *Good Laboratory Practice* (GLP), which covers such

aspects as record-keeping procedures, data analysis, instrument calibration and staff training. The aim of GLP is to eliminate human error as far as possible and to ensure the reliability of the data submitted to the regulatory authority, and laboratories are regularly monitored for compliance to GLP standards. GLP standards are not usually adopted until projects get beyond the discovery phase.

Roughly half the compounds identified as drug candidates fail during the preclinical development phase; for the rest, a detailed dossier (the 'investigator brochure') is prepared for submission alongside specific study protocols to the responsible regulatory authority, such as the UK Medicines and Healthcare Products Regulatory Agency (MHRA), the European Medicines Agency or the US FDA. These organisations use the results from the preclinical studies to make a decision about whether to grant permission to proceed with studies in humans. This is not lightly given, and the regulatory authority may refuse permission or require further work to be done before giving approval.

Non-clinical development work continues throughout the clinical trials period, when much more data, particularly in relation to long-term and reproductive toxicity in animals, have to be generated. Failure of a compound at this stage is very costly, and considerable efforts are made to eliminate potentially toxic compounds much earlier in the drug discovery process using in vitro, or even in silico, methods.

Clinical Development

Clinical development proceeds through four distinct but overlapping phases of clinical trials (see **Ch. 8**). Just as the regulatory

authorities require GLP studies, clinical trials must be performed under equally strict *Good Clinical Practice* (GCP) conditions. Phase I–III trials are usually all placebo controlled, randomised and double blind – for detailed information, see **Friedman et al. (2015)**.

- *Phase I studies* are performed on a small group (normally 20–80) of volunteers – often healthy young men but sometimes patients. Healthy volunteers are easier to recruit, better able to tolerate adverse effects if these occur and more homogeneous even in the absence of comedication that may be required by patients. Healthy volunteers are not appropriate when even low doses of test drug are expected to cause harm, as with cytotoxic drugs and some other anticancer agents, or when healthy men do not express the target on which the drug acts. Their aim is to check for signs of any potentially *harmful effects*, for example on cardiovascular, [4] respiratory, hepatic or renal function, and *tolerability* (does the drug produce any unpleasant symptoms, for example, headache, nausea, drowsiness?) and to explore its *pharmacokinetic properties* (Is the drug well absorbed? Is absorption affected by food? What is the time course of the plasma concentration in relation to dosing? Is there evidence of accumulation or non-linear kinetics?). These aspects are integrated to establish what dose regimen should be used for phase II studies and when PK sampling and drug effect recording should be undertaken during phase II. Phase I studies may also test for pharmacodynamic effects in volunteers, sometimes

called ‘proof-of-concept’ experimental medicine studies. These sometimes include challenge studies (e.g. does a novel analgesic compound block experimentally induced pain? Does a new anti-inflammatory drug block the effect of a small intravenous challenge dose of lipopolysaccharide endotoxin? How does the desired effect vary with dose?). Various trial designs are used, a common one being to start with single ascending doses in individual cohorts followed by multiple (repeated) ascending doses (so-called ‘SAD/MAD’ studies).

- *Phase II studies* are performed on groups of patients (typically 100–300) and are designed to determine clinically beneficial pharmacodynamic effects in patients, and to establish if the disease process alters the pharmacokinetics of the drug. If pharmacodynamic effect and acceptable pharmacokinetics are confirmed, the aim is to establish the dose regimen to be used in the definitive phase III study. Sometimes, such studies will cover several distinct clinical disorders, e.g. depression, anxiety states and phobias. When new drug targets are being studied, it is not until these phase II trials are completed that the team finds out whether or not its initial hypothesis was correct, and lack of the desired effect is a common reason for failure. Conversely, it is not uncommon for over-optimistic results to emerge from a phase II study that are not confirmed in phase III trials that use more rigorous clinical end-points (such as mortality) rather than just of drug effect on

intermediate biochemical or physiological endpoints (see later).

- *Phase III studies* are the definitive studies almost always required for regulatory approval. They are commonly performed as multicentre trials on thousands of patients, aimed at comparing the new drug with commonly used alternatives or placebos as in studies of standard treatment + placebo versus standard therapy + experimental active. These are extremely costly and difficult to organise and often take years to complete, particularly if the treatment is designed to retard the progression of a chronic disease. It is not uncommon for a drug that seemed highly effective in the limited patient groups tested in phase II to look much less impressive under the more rigorous conditions of phase III trials.

  Increasingly, phase III trials now include a *pharmacoeconomic analysis* (see **Ch. 1**), such that not only the clinical but also economic impact of the new treatment is assessed.

  At the end of phase III, the drug will be submitted to the relevant regulatory authority for licensing. The dossier required for this is a massive and detailed compilation of preclinical and clinical data. Evaluation by the regulatory authority often takes a year or more. Eventually, about two-thirds of submissions gain marketing approval. Estimates vary but approximately 8% of compounds entering phase I are eventually approved. Increasing this proportion by better

compound selection at the laboratory stage is one of the main challenges for the pharmaceutical industry.

- *Phase IV studies* comprise the obligatory postmarketing surveillance designed to detect any rare or long-term adverse effects resulting from the use of the drug in a clinical setting in many thousands of patients. Such events may necessitate limiting the use of the drug to particular patient groups, or even withdrawal of the drug. [5]

Disclosure and publication of trials data

Concern has been expressed that clinical trials showing negative or inconclusive results are less likely to be published than those giving positive results, so creating a more favourable impression of a new drug's clinical efficacy than would be the case if every trial was published. To ensure that all data, good and bad, are published and available to regulatory authorities and researchers, it is now mandatory to register the initiation of any trial in humans and to publish the results in full when the trial is completed. The difficult question of whether to require all past trials of currently registered drugs is under discussion. The accessibility of past data, much of it in the form of paper records in dusty repositories, and the cost of this exercise are serious problems.

Biopharmaceuticals

Biopharmaceuticals are discussed in **Chapter 5**. Such therapeutic agents now comprise about 30% of new products registered each year. The principles underlying the development and testing of biopharmaceuticals are basically the same as for synthetic drugs. In

practice, biopharmaceuticals (often comprised of proteins or nucleic acids which are hydrolysed to their constituent amino acids or bases) generally run into fewer toxicological problems than synthetic drugs, but more problems relating to production, quality control, immunogenicity and drug delivery. Subtle but potentially harmful changes in the product when it is produced by another manufacturer are almost inevitable. This has regulatory consequences when products end their patent life and other companies wish to compete by producing and selling what is apparently the same product. Such competitor products are referred to as 'biosimilars' rather than 'bioequivalents' in acknowledgement of this, and a phase III efficacy trial is required for licensing approval. If this is successful, however, repeat phase III studies are not required for other indications for which the market leader is licensed. **Walsh (2009)** and **Revers and Furczon (2010)** cover this specialised field in more detail. In 2017 the first gene therapy products (for spinal muscular atrophy, see **Ch. 40**) and cell-based therapies for advanced cancer (see **Ch. 57**) were approved – significant milestones.

Commercial Aspects

Fig. 60.1 shows the approximate time taken for such a project and the attrition rate (at each stage and overall) based on recent data from several large pharmaceutical companies. The key messages are (1) that it is a high-risk business, with only about 1 drug discovery project in 50 and 1 development compound in 10 reaching the goal of putting a new drug on the market, (2) that it takes a long time – about 12 years on average and (3) that it costs a lot of money to

develop one drug – estimates vary hugely with the pharmaceutical industry claiming costs of up to $4 billion per drug whilst a more independent analysis in 2019 suggested costs closer to $1 billion (**Wouters et al., 2020**). For any one project, the costs escalate rapidly as development proceeds, phase III trials and long-term toxicology studies being particularly expensive. The time factor is crucial, because the new drug has to be patented, usually at the end of the discovery phase, and the period of exclusivity (20 years in most countries) during which the company is free from competition in the market starts on that date. After 20 years, the patent expires, and other companies, which have not supported the development costs, are free to make and sell the drug much more cheaply, so the revenues for the original company decrease rapidly thereafter. Reducing the development time after patenting is a major concern for all companies, but so far it has remained stubbornly fixed at around 10 years, partly because the regulatory authorities are demanding more clinical data before they will grant a license. In practice, only about one drug in three that goes on the market brings in enough revenue to cover its development costs. Success for the company relies on this one drug generating enough profit to pay for the rest. [6]

Drug Repurposing

An alternative route to bringing forward a new treatment is to test drugs which have already gone through the initial stages of development for one indication but are then trialled for a different, often unrelated disease. Commonly referred to as repurposing or repositioning, this approach has been used for drugs which have

failed due to a lack of efficacy in either phase II or III clinical trials and also drugs which have been licensed for a particular disease but are also found to be useful for a different condition (**Pushpakom et al., 2019**). Risks and costs are reduced because the drug has already passed most of the hurdles in the drug development process and has been found to be 'safe'. Several drugs for psychiatric disorders have been repurposed in this way; for example, certain drugs used to treat epilepsy (see **Ch. 46**) are also now prescribed for anxiety disorders (see **Ch. 45**) whilst others are used as mood stabilisers (see **Ch. 48**); antidepressants are now first-line treatments for generalised anxiety disorder (Chs **45** and **48**) and some antipsychotics are also used for depression and bipolar disorder (Chs **47** and **48**). Repurposing has been critical for the rapid testing and approval of treatments for COVID-19 infections (**Chakraborty et al., 2021**).

Generic Drugs

New drugs brought to the market are protected initially by a patent (see earlier). A generic drug is the same chemical entity as the original, formulated to achieve bioequivalence, which is defined by the regulators such that the generic may safely be substituted for the original licensed product without loss of efficacy (see **Ch. 9** on bioavailability and bioequivalence).

Future Prospects

Since about 1990, the drug discovery process has been in the throes of a substantial and ongoing methodological revolution, following the rapid ascendancy of molecular biology, genomics and

informatics, amid high expectations that this would bring remarkable dividends in terms of speed, cost and success rate. High-throughput screening has emerged as a powerful lead-finding technology, but overall the benefits have not been realised: costs have risen steadily, the success rate has not improved and development times have not decreased.

Fig. 60.3 illustrates the trend in the number of new drugs launched in the major markets worldwide, which had until recently declined steadily despite escalating costs and improved technology, causing serious worries to the industry. There was much speculation as to the causes of the decline, the optimistic view being that fewer but better drugs were being introduced, and that the genomics revolution had yet to make its impact. This optimism may be well founded, for as **Fig. 60.3** shows, the number of approvals has shown an encouraging upturn in recent years.

If the new drugs that are being developed improve the quality of medical care, there is room for optimism. In the latter half of the 20th century, synthetic drugs aimed at new targets (e.g. SSRIs, statins, kinase inhibitors and several monoclonal antibodies) have made major contributions to patient care. The ability of new technologies to make new targets available to the drug discovery machine is beginning to have a real effect on patient care. Creativity remains high, despite the rising costs and declining profits that remain a challenge to the pharmaceutical industry.

The drug development process continues to evolve, with biopharmaceuticals remaining an area of growth for many disorders particularly those involving the immune system and inflammatory disorders and the recent licensing of the first few of an anticipated

wave of RNA drugs. Technologies that enable the drug development process continue to develop with more sophisticated methods for both in silico and high throughput in vitro drug screening. Novel tools include ‘organs on a chip’ and organoids which can recapitulate aspects of biology more complex than cultures of single cell lines. High-throughput methods combined with huge libraries of compounds should have improved the drug development process, but even when a novel drug target is identified, translating this into a new treatment is not as straightforward as it may at first appear. Antibody-based treatments against intra-neuronal amyloid plaques in Alzheimer’s disease are a good example. Despite genetic and pathological evidence suggesting a key role for amyloid in the development of Alzheimer’s disease, the phase III clinical trials produced disappointing clinical results. The idea of using patient genotype to ‘individualise’ treatments remains an important area in pharmacology (see **Ch. 12**) and the recommendations of a recent report by the Royal College of Physicians and British Pharmacological Society is aimed towards this becoming fully integrated into the NHS (**Royal College of Physicians and British Pharmacological Society, 2022**). This approach can improve patient outcomes by avoiding giving drugs to nonresponders or reducing the risk of adverse events through identifying those with genetic risk factors (**Klein et al., 2017**).

FIG. 60.3 Research and development (R&D) spend, sales and new drug registrations, 1980–2017.Registrations refer to new chemical entities (including biopharmaceuticals, excluding new formulations and combinations of existing registered compounds). The decline in registrations up to 2010 has since seen some reversal in more recent years. Data from various sources, including the Centre for Medicines Research, Pharmaceutical Research and Manufacturers Association of America.

A Final Word

The pharmaceutical industry in recent years has attracted much adverse publicity, some of it well deserved, concerning drug pricing and profits, non-disclosure of adverse clinical trials data, reluctance to address major global health problems such as tuberculosis and malaria, aggressive marketing practices [7] and much else (see **Angell, 2004**; **Goldacre, 2012**). These perhaps more commercial aspects of the industry should not detract from the huge advances in fundamental biology and the development of important technologies which have been led by scientist working in the pharmaceutical industry. The pharmaceutical industry has been directly responsible for most of the therapeutic advances of the past half-century and has played a key role in the development of new technologies which underpin scientific advances. Without these new drugs, medical care would effectively have stood still.

Innovation has by no means dried up. In the last decade, drug development has expanded beyond traditional small molecules, and biopharmaceuticals and RNA-based medicines are still in their infancy with many opportunities likely to emerge as we learn more. There has also been a shift in the structure of the industry with the preclinical development and even early clinical trials of new treatments being undertaken by small and medium-sized companies. Even psychiatry research has seen a renewed enthusiasm particularly in relation to the potential for psychedelic-based drugs to treat emotional disorders and addiction (Chs **48** and **50**). Pharmacology remains a fast-moving field. In 2021 the European Medicines Agency approved 54 new active substances, many of which are first-in-class. Of these active substances, 7 related to COVID-19 but other indications were also widely represented: other infections (2), cardiovascular (3), metabolic (2), reproduction (3), gastro-intestinal (1), neurological (5), endocrine (4), skin (3), eyes (2), rheumatology (3), haematology (5), cancer (12) and vaccines other than those directed against SARS-CoV2 (2).

QUESTIONS

QUESTION 60.1

Drug discovery is a highly focused and managed process which has moved from the domain of inventive doctors to that of scientists.

Which of the following statements about drug discovery is correct?

OPTIONS:

A. Most drugs are now developed using rational drug design rather than ‘discovered’ through serendipity.

B. Molecules synthesised in combinatorial libraries exhibit much greater chemical diversity than can be found in natural products.

C. Structure-based drug discovery is focused on the identification of a biochemical target.

D. For many psychiatric disorders, the development of highly selective drugs acting at a single target has been most successful.

E. Drugs which activate hERG (human ether-à-go-go-related gene) channels have the potential to caused dysrhythmias.

QUESTION 60.2

Clinical development proceeds through four distinct but overlapping phases of clinical trials.

Which of the following statements about clinical trials is incorrect?

OPTIONS:

A. Phase II trials are usually all placebo controlled, randomised and double blind.

B. Healthy volunteers are recruited in phase I trials to test the tolerability of cytotoxic drugs.

C. In phase II, a lack of the desired effect is a common reason for failure.

D. In phase III, new entities are often given in addition to standard therapy.

E. Less than 10% of drugs entering phase I are finally approved.

QUESTION 60.3

Biopharmaceuticals, often comprised of proteins or nucleic acids, now comprise about 30% of new products registered each year.

Which is least likely to be an issue with the development of biopharmaceutics?

OPTIONS:

A. Toxicity

B. Production

C. Quality control

D. Immunogenicity

E. Drug delivery

ANSWERS

ANSWER 60.1

RATIONALE:

A. Currently both approaches remain highly productive.

B. Natural products exhibit much greater chemical diversity, particularly as regards numbers of chiral centres and drug structure rigidity, than conventional combinatorial libraries. However, the discovery and development of organocatalysis, which has made it much easier to synthesise asymmetric molecules for use as starting blocks, may help to correct this.

C.

D. In some areas such as psychiatric disorders, highly selective drugs acting at a single target have generally failed in clinical trials despite the predictions from animal models.

E. Drugs that inhibit hERG channel activity are routinely screened out, as this implies a QT prolongation effect with the potential to predispose to fatal ventricular dysrhythmia.

CORRECT ANSWER WITH EXPLANATION:

C. Structure-based drug discovery is dependent on the identification of a biochemical target.

Although, in the past, drug discovery programmes were often based on measuring a complex response in vivo, without the need for prior identification of a molecular drug target, nowadays this is less common, and the first step is *target identification*. George Hitchings and Gertrude Elion were among the first to design drugs directed at specific biochemical targets which can be regarded as the forefather of structure-based drug discovery.

ANSWER 60.2

RATIONALE:

A. Phase I–III trials are usually all placebo controlled, randomised and double blind.

B.

C. It is not until phase II trials are completed that the initial hypothesis can be confirmed or rejected, and lack of the desired effect is a common reason for failure.

D. Phase III trials are aimed at comparing the new drug with commonly used alternatives or placebos and often involve

studies of standard treatment + placebo versus standard treatment + experimental active.

E. *Estimates vary but approximately 8% of compounds entering phase I are eventually approved*.

CORRECT ANSWER WITH EXPLANATION:

B. Healthy volunteers are recruited in phase I trials to test the tolerability of cytotoxic drugs.

Healthy volunteers are not appropriate when even low doses of test drug are expected to cause harm as with cytotoxic drugs and some other anticancer agents.

ANSWER 60.3

RATIONALE:

A.

B. Subtle but potentially harmful changes in the product when it is produced by another manufacturer are almost inevitable.

C. Quality control is paramount as different batches of biopharmaceuticals can vary considerably in efficacy and carry risks of contamination.

D. Due to the biological nature of the drugs, they are more likely to induce an immunogenic response.

E. The 'biological' nature of the drug means that oral delivery is not usually a viable option and alternative delivery mechanisms must be utilised.

CORRECT ANSWER WITH EXPLANATION:

A. Toxicity

Biopharmaceuticals generally run into fewer toxicological problems than synthetic drugs.

[1] Many commercially successful drugs have in the past emerged from exactly such 'me-too' projects; examples are the many ß-adrenoceptor-blocking drugs developed in the wake of propranolol, the 'triptans' that followed the introduction of sumatriptan to treat migraine and selective serotonin reuptake inhibitors (SSRIs) for anxiety and depression. Quite small improvements (e.g. in pharmacokinetics or side effects), coupled with marketing, have often proved enough, but the barriers to registration are getting higher, so the emphasis has shifted towards developing innovative (first in class) drugs aimed at novel molecular targets.

[2] Testing up to 100,000 compounds per day is possible, and is known as ultra-high-throughput screening.

[3] A different approach is generally used for biopharmaceuticals, where a "minimum anticipated biologically effective level" (MABEL) is estimated from available relevant data such as effects on human (or humanized) cells or tissues. This was introduced after serious on-target toxicity from a monoclonal antibody biopharmaceutical TGN 1412 in healthy volunteers admitted to Northwick Park hospital in 2006 – see Ch. 5 and below.

[4] QT prolongation, a sign of potentially dangerous cardiac arrhythmias (see Ch. 22), is a common cause of failure in early development, and regulators demand extensive – and expensive – studies to test for this risk. Today, such studies are usually performed on cells expressing the hERG (human Ether-à-go-go-Related Gene – no, seriously!) that produces the $K_v11.1$ potassium channel. Drugs that inhibit hERG channel activity are routinely

screened out, as this implies a QT prolongation effect with the potential to predispose to fatal ventricular dysrhythmia.

[5] Recent high-profile cases include the withdrawal of rofecoxib (a cyclo-oxygenase-2 inhibitor; see Ch. 25) when it was found (in a phase III trial for a new indication) to increase the frequency of heart attacks, and of cerivastatin (Ch. 22), a cholesterol-lowering drug found to cause severe muscle damage in a few patients.

[6] But note that companies spend at least as much on marketing and administration as on research and development.

[7] The aggressive marketing of the opioid drug OxyContin (oxycodone) in the United States has been a major factor in the current opioid crisis. For those interested see Patrick Radden Keefe's 'Empire of Pain: The Secret History of the Sackler Dynasty'.

allergic response to, **792**

in blood pressure regulation, **525** , **525b**

for depression, **642t**

3,4-Methylenedioxymethamphetamine (MDMA), **530–531** , **532b** , **664t** , **667–668** , **668b** , **684**

lifestyle use of, **795t**

pharmacological effects of, **668** , **668f**

potential therapeutic use of, **668**

structure of, **665f**

Methylephedrine, in sports, **800**

Methylmalonyl-coenzyme A (CoA), isomerisation of, to succinyl-CoA, **343**

Methylnaltrexone, for gastrointestinal motility, **425–426**

Methylnaltrexone bromide, **585** , **590**
blood-brain barrier and, **135**
α-Methylnoradrenaline, **221**
Methylone, **664t**
Methylphenidate, **222** , **664t** , **665f** , **666** , **666b** , **673**
lifestyle use of, **795t** , **796**
Methylprednisolone, **460t**
α–Methyltryptamine (α–MT), **675**
α-Methyltyrosine, **208** , **221**
for depression, **642t**
Methylxanthines, **664t** , **668–669** , **669b**
for asthma, **395–396**
clinical uses of, **669**
mechanism of action of, **395**
pharmacokinetic aspects of, **395–396**
pharmacological effects of, **669**
unwanted effects of, **395** , **669**
Methysergide, **229–230** , **230b** , **530** , **572**
clinical use of, **572**
unwanted effects of, **572**
Meticillin, **698** , **704** , **708**

Metoclopramide, **229b** , **230** , **423b** , **424** , **568b**

for gastrointestinal motility, **425**

unwanted effects of, **573**

in vomiting, **529**

Metolazone, **411**

Metoprolol, **213t** , **285–286** , **286b** , **309** , **309b** , **573–574**

for systemic hypertension, **307t**

Metreleptin, for obesity, **450**

Metronidazole, **145–146** , **329** , **680** , **716** , **752b** , **753–755**

for *Helicobacter pylori* infection, **420–421**

Metyrapone, **460**

Mexiletine, **592**

Mianserin, **645** , **655–656** , **656b**

characteristics of, **646t–649t**

Mibefradil, **292**

Miconazole, **739**

Micro-RNA, **79**

Microangiopathy, in diabetes mellitus, **435**

Microfilaments, **697**

Microfilariae, **758**

Microglial cells, **502–504**

MicroRNAs (miRNAs), **94**

Microsomal enzymes, **140**

induction of, **143**

Microsomal triglyceride transport protein (MTP), **314–315**

inhibitors of, **320**

Microspheres, gene delivery vectors, **83–84**

Microsporum spp., **736** , **737t**

Microtubules, **697** , **697b**

Midazolam, **561t** , **562** , **567** , **605t** , **610b**

clinical use of, **608** , **622** , **624b**

$GABA_A$-receptor α-subunit selectivity of, **608t**

Midodrine, action of, **212t**

Mifepristone, **481** , **481b**

Migraine, **568–570**

chronic, **569**

clinical symptoms of, **569**

drugs used for, **568b**

episodic, **569**

pain, mechanism of, **570f**

pathophysiology of, **569–570** , **570f**

prophylaxis, treatment of, **624**

Milk, excretion via, **140**

Milrinone, **35–36** , **289** , **301**

Miltefosine, **754**

Minamata disease, **790–791**

Mineralocorticoid receptor, **46** , **48t** , **466**

Mineralocorticoids, **459** , **465b** , **466**

antagonists of, **466**

biosynthesis of, **461f**

clinical use of, **466**

regulation of aldosterone synthesis and release and, **456f** , **466**

Minimal alveolar concentration (MAC), **558**

Minocycline, **715b**

Minoxidil, **142** , **296b** , **300** , **307** , **380**

lifestyle use of, **795t**

Mipomersen, **78f** , **320**

Mirabegron, **414**

action of, **212t**

Mirtazapine, **571** , **573** , **610** , **645** , **652** , **655–656** , **656b**

characteristics of, **646t–649t**

Misfolding, protein, **539** , **540f**

Misoprostol, **244** , **244b–245b** , **354** , **418** , **487** , **488b**

gastric acid mucosa protection and, **421**

Mitobronitol, **773**

Mitochondria, **691**

excitotoxicity and, **541**

pathway, in apoptosis, **93**

role of, **58**

Mitochondrial uncoupling proteins (UCP), **446–447**

Mitogen-activated protein kinase (MAP-kinase), **35** , **37–39** , **39f** , **41f** , **433**

activation of, **39f**

Mitomycin, **775** , **775b**

Mitosis, **88**

Mitotane, **460**

Mitoxantrone, **774**

Mivacurium, **165** , **194**

characteristics of, **195t**

pharmacokinetics of, **196**

unwanted effect of, **196**

Mizolastine, **368t**

MLCK, *See* **Myosin light-chain kinase**

Moclobemide, **645** , **645b** , **656** , **658b**

characteristics of, **646t–649t**
Modafinil, **664t** , **666** , **666b**
clinical use of
attention deficit/hyperactivity disorder, **666**
narcolepsy, **666**
lifestyle use of, **795t** , **796**
in sports, **800**
Modipafant, **248**
Modulators, **524–538.e2** , **537b**
acetylcholine as, **531–533**
dopamine as, **526–529**
histamine as, **534**
5-hydroxytryptamine as, **529–531**
noradrenaline as, **524–526**
purines as, **533–534**
Mole, **377**
Molecular biology revolution, **81**
Molnupiravir, for COVID-19, **732**
Mometasone, for asthma, **397**
Monoamine oxidase (MAO), **141–142** , **210** , **225** , **524**
Monoamine oxidase A (MAO-A), **627**

Monoamine oxidase B (MAO-B) inhibitors, for Parkinson disease, **552**

Monoamine oxidase inhibitors (MAOIs), **507** , **645** , **655t** , **656–657** , **658b**

characteristics of, **646t–649t**

chemical aspects of, **656–657**

clinical use, for anxiety, **603–605**

for depression, **642t**

drug interactions with, **163**

interaction with other drugs and foods, **657**

pharmacological effects of, **656**

Monoamine receptor antagonists, **656b**

characteristics of, **646t–649t**

Monoamine theory, of depression

neuroendocrine mechanisms, **642**

neuropsychological hypothesis, **643** , **644f**

neurotrophic effects and neuroplasticity, **642–643**

Monoamine uptake inhibitors, **643–645** , **652–655**

characteristics of, **646t–649t**

other, **655b**

selective 5-hydroxytryptamine uptake inhibitors, **652–653** , **652f**

serotonin and noradrenaline uptake inhibitors, **654–655**
tricyclic antidepressants, **653–654** , **654f** , **654b**
acute toxicity of, **653–654**
characteristics of, **646t–649t**
drug interactions with, **653**
mechanism of action of, **653** , **655t**
pharmacokinetic aspects of, **654**
unwanted effects of, **653**
Monobactams, **700** , **710**
Monoclonal antibodies, **75t** , **769t–771t** , **777–778** , **779f** , **779b**
bevacizumab, **778**
catumaxomab, **778**
chimeric, **74** , **74f**
gemtuzumab, **778**
HER2, **777–778**
humanised, **74** , **74f**
ipilimumab, **778**
nivolumab, **778**
rituximab, **777–778**
Monocyte, in innate immune response, **103**
Monocyte chemoattractant protein-1 (MCP-1), **103**

Monoiodotyrosine (MIT), **469**

Montelukast, **247** , **393** , **395b** , **396**

Mood

5-hydroxytryptamine in, **531**

noradrenaline in, **525–526**

Mood-stabilising drugs, clinical uses of, **661b**

Morphine, **238** , **426** , **563–564** , **567** , **581** , **582f** , **587t–588t** , **593b** , **683** , **802**

actions of, **585b**

bioassay of, **115f**

for cough, **400**

effect of age on, **161–162**

enterohepatic circulation in, **146**

excretion of, **408**

partitioning into fat/tissues, **130**

pharmacokinetic aspects of, **586–588**

physical dependence on, **586**

purification of, **2**

in sensory transmission, **531**

in sports, **799t**

tolerance, **586**

Mosquirix, **751**

Motility, gastrointestinal, **424–427** , **425b**

effect of muscarinic antagonists on, **191**

effect on drug absorption, **132**

Raloxifene, **480** , **480b** , **497–498** , **777**

Raltegravir, **732** , **728b** , **731t** , **732b**

Raltitrexed, **773**

Ramelteon, **535** , **611**

Ramipril, **304b** , **309b** , **310**

RAMPs, *See* **Receptor activity-modifying proteins**

Randomised controlled clinical trial, **118**

Ranibizumab, **388**

intravitreal injection of, **134**

Ranitidine, **419**

Ranolazine, **289**

Rapamycin, as lead compounds, **806**

Rapid-acting antidepressants (RAADs), **640–641** , **645** , **657–658**

impact of, **651**

neuropsychological effects of, **651–652**

Rapid depolarisation, in cardiac action potential, **275**

Ras/Raf pathway, **44**

Ras signalling complex, **433**

Rasagiline, **550** , **552**

Rasburicase, **366b** , **367**

Rational drug design, **802** , **804–805**

Raynaud's disease, vasoactive drugs for, **310**

Rb protein, **89**

Re-entry, **277** , **278f**

Reactive depression, **640**

Reactive oxygen species (ROS), **541** , **785**

Rebound hyperglycaemia, **436**

Receptors, **24** , **25f**

activation of, **8–9** , **8f**

constitutive, **14–16**

antagonists, *See* **Antagonists**

binding of drugs to, **9–10** , **22b**

change in, **19**

classification of, **8**

control of expression of, **51**

death, **93f**

desensitisation of, **19f**

disease and, **51–52**

drug, **6–7**

drug interactions with, **8–11**

quantitative aspects of, **20–22**

heterogeneity of, **27–28**

kinase-linked, *See* **Kinase-linked receptors**

molecular structure of, **29f** , **31–32** , **33f**

orphan, **24** , **45**

in physiological systems, **7**

proteins, **26–47**

spare, **10–11**

subtypes of, **27–28**

translocation of, **19–20**

two-state model of, **16** , **16f**

types of, **26** , **27t**

Receptor activator of nuclear factor kappa B (NF-κB), **493**

Receptor activity-modifying proteins (RAMPs), **42**

Receptor blocking antidepressants, **645** , **655–656**

Receptor-effector linkage, types of, **27f**

Receptor ligands, **769t–771t**

Receptor occupancy, **12–13**

‘Receptor-operated channels,’, **56**

Receptor-response linkage, block of, **17–19**

Receptor serine/threonine kinases, **43**

Receptor tyrosine kinases (RTKs), **43** , **99**

Recombinant protein, **73**

Recreational drug use, term, **684t**

Rectal administration, **133**

Rectangular hyperbola, **20–21** , **21f**

Red blood cells, **337**

Reetine, **655**

characteristics of, **646t–649t**

Refractoriness, of drug, **19**

Regadenoson, **234** , **287** , **289–290**

Regeneration, **94b** , **95**

Regulated on activation normal T cell expressed and secreted (RANTES) receptor, **103**

Regulators of G protein signalling (RGS) proteins, **34**

Relapse, **686–687**

Relapse-remitting, multiple sclerosis, **554**

Relative potency, **114**

Reldesemtiv, **554**

Remdesivir, for COVID-19, **732**

Remifentanil, **560** , **567** , **586** , **587t–588t** , **589**

Remimazolam, **562**

Renal clearance, **146**

Renal failure, drugs used in, **414**

Renal tubular function, **408b**

Renal tubule, diffusion across, **147–148** , **148f** , **148t**

Renin, **403–404**

release and formation of, control of, **297f**

Renin inhibitors, **302** , **302t**

Renin-angiotensin-aldosterone system (RAAS)

drugs inhibiting, **302t**

heart failure and, **308–309**

Renin-angiotensin system, **297f** , **298–299**

Repaglinide, for insulin secretion, **439–440**

Repair, **94** , **94b**

Repolarisation, in cardiac action potential, **276**

Reproductive system, **476–490.e2**

drugs affecting, **478–484**

endocrine control of, **476–478**

female, neurohormonal control of, **476–478** , **477f** , **478b**

male, neurohormonal control of, **478** , **479f**

Reserpine, **208** , **214t** , **221–222** , **306** , **643b**

action of, **627–628**

Resins, bile acid-binding, **319** , **320b**

Resistance arteries, **172**

Reslizumab, for asthma, **397**

Resolvins, **247–248**

Respiration

afferent pathways and, **390–391**

control of, **390**

efferent pathways and, **390**

physiology of, **390–391**

regulation of musculature, blood vessels and glands of airways in, **390–391** , **391b**

sensory receptors and, **390–391**

Respiratory depression, due to opioids, **584**

Respiratory distress syndrome, **400**

Respiratory syncytial virus, **730**

Respiratory system, **390–401.e2**

effect of muscarinic antagonists on, **192b**

general anaesthetic agents on, **559–560**

leukotriene in, **246–247**

‘Resting’ cell, **59**

ionic balance of, **59f**

Reteplase, **335** , **336b**

Reticular layer, **373**

Retina, **384**

Retinal blood vessels, **384**

Retinal endothelial junctions, **384**

Retinoblastoma (Rb) gene, **89f**

Retinoblastoma (Rb) protein, **89**

Retinoic acid, **380** , **769t–771t**

Retinoic acid receptor, **48t**

Retinoid X receptor (RXR), **45** , **48t**

Retinoid X receptor modulators, **769t–771t**

Retinoids, **380–381** , **381f**

adverse effects of, **789t** , **790**

Retinol, **380**

Retroviral integrase, **83**

Retroviruses, **83** , **695–696** , **723**

Reverse transcriptase, **695–696**

Reverse transcriptase enzyme, **722–723**

Reverse transcriptase inhibitors, **728b** , **730–731**

Reward pathways, **685**

Reye's syndrome, **357**

Rezafungin, **740**

RGS, *See* **Regulators of G protein signalling**

endothelin, **297–298**
renin-angiotensin system and, **297f** , **298–299**
smooth muscle, **296b**
endothelium in, **298b**
tone of, **295–299**
structure and function of, **294–295**
vasoactive drugs and, **299–304** , **299t**
clinical uses of, **305–311** , **305b**
for heart failure, **307–309** , **308f**
for peripheral vascular disease, **310**
for pulmonary hypertension, **310–311** , **311f** , **311b**
for Raynaud’s disease, **310**

for systemic hypertension, **305–307**

for vasodilatory shock and hypotensive states, **309–310** , **310f**

Vasoactive drugs, **299–304** , **299t**

clinical uses of, **305–311**

for heart failure, **307–309** , **308f**

for peripheral vascular disease, **310**

for pulmonary hypertension, **310–311** , **311f** , **311b**

for Raynaud's disease, **310**

for systemic hypertension, **305–307** , **306f**

for vasodilatory shock and hypotensive states, **309–310** , **310f**

Vasoactive intestinal peptide (VIP), **390**

as NANC transmitters, **179t**

Vasoconstriction, as effect of adrenaline, **205**

Vasoconstrictor drugs, **299–300** , **299t** , **300b**

Vasodilatation

as effect of adrenaline, **205**

as effects of local anaesthetics, **598**

non-steroidal anti-inflammatory drugs and, **353**

Vasodilator drugs, **299t** , **300–304** , **301b**

direct-acting, **300–301**

indirectly acting, **301–304** , **302t**

angiotensin-converting enzyme inhibitors, **302–304** , **303f** , **303b**

angiotensin II receptor antagonists, **304** , **304f**

renin inhibitors, **302**

types of, **304b**

with uncertain mechanism of action, **301**

Vasodilatory shock, vasoactive drugs for, **309–310**

Vasopressin, **299** , **310** , **407** , **458**

actions of, **458**

non-renal, **458**

renal, **458**

clinical uses of, **459b**

mutated, **51–52**

pharmacokinetic aspects of, **458**

physiological role of, **458**

secretion of, regulation of, **458**

unwanted effects of, **458**

Vasopressin receptors, **458**

Vaughan Williams classification, of antidysrhythmic drugs, **284** , **284t**

Vazegepant, **572**

clinical use of, **573**

Vecuronium, **126–127** , **193t** , **194** , **567**

characteristics of, **195t**

effect of disease on, **163**

excretion of, **146**

Vedolizumab, for diarrhoea, **428**

VEGF, *See* **Vascular endothelial growth factor**

Vemurafenib, **778**

Venlafaxine, **571** , **573** , **592** , **603–605** , **654** , **655b** , **666**

characteristics of, **646t–649t**

Venous thrombus, **322**

Ventral tegmental area (VTA), **685**

Ventricular arrhythmias,drug-induced, **278**

Ventricular fibrillation, **277**
